U.S. Environmental Protection Agency (EPA). (2011) Exposure Factors Handbook: 2011 Edition. National Center for Environmental Assessment, Washington, DC; EPA/600/R-09/052F. Available from the National Technical Information Service, Springfield, VA, and online at <http://www.epa.gov/ncea/efh>.

FOREWORD

The U.S. Environmental Protection Agency (U.S. EPA), Office of Research and Development (ORD), National Center for Environmental Assessment's (NCEA) mission is to provide guidance and risk assessments aimed at protecting human health and the environment. To accomplish this mission, NCEA works to develop and improve the models, databases, tools, assumptions, and extrapolations used in risk assessments. NCEA established the Exposure Factors Program to develop tools and databases that improve the scientific basis of exposure and risk assessment by (1) identifying exposure factors needs in consultation with clients, and exploring ways for filling data gaps; (2) compiling existing data on exposure factors needed for assessing exposures/risks; and (3) assisting clients in the use of exposure factors data. The *Exposure Factors Handbook* and the *Child-Specific Exposure Factors Handbook*, as well as other companion documents such as *Example Exposure Scenarios*, are products of the Exposure Factors Program.

The *Exposure Factors Handbook* provides information on various physiological and behavioral factors commonly used in assessing exposure to environmental chemicals. The handbook was first published in 1989 and was updated in 1997. Since then, new data have become available. This updated edition incorporates data available since 1997 up to July 2011. It also reflects the revisions made to the *Child-Specific Exposure Factors Handbook*, which was updated and published in 2008. This edition of the handbook supersedes the information presented in the 2008 *Child-Specific Exposure Factors Handbook*. Each chapter in the 2011 edition of the *Exposure Factors Handbook* presents recommended values for the exposure factors covered in the chapter as well as a discussion of the underlying data used in developing the recommendations. These recommended values are based solely on NCEA's interpretations of the available data. In many situations, different values may be appropriate to use in consideration of policy, precedent, or other factors.

David Bussard
Director, Washington Division
National Center for Environmental Assessment

AUTHORS, CONTRIBUTORS, AND REVIEWERS

The National Center for Environmental Assessment (NCEA), Office of Research and Development was responsible for the preparation of this handbook. Jacqueline Moya served as the Work Assignment Manager for the current updated edition, providing overall direction and technical assistance, and is a contributing author. The current draft was prepared by Westat Inc. under contract with the U.S. EPA (contract number GS-23F-8144H). Earlier drafts of this report were prepared by Versar, Inc.

AUTHORS, CONTRIBUTORS, AND REVIEWERS (continued)**REVIEWERS**

The following U.S. EPA individuals reviewed earlier drafts of this document and provided valuable comments:

Ted Berner, NCEA	John Langstaff, OAQPS
Heidi Bethel, OW	Sarah Levinson, Region 1
Margot Brown, OCHP	Matthew Lorber, NCEA
Lisa Conner, OAQPS	Tom McCurdy, NERL
Mark Corrales, OPEI	Robert McGaughy, NCEA (retired)
Dave Crawford, OSWER	Marian Olsen, Region 2
Becky Cuthbertson, OSW	David Riley, Region 6
Lynn Delpire, OPPTS	Rita Schoeny, OW
Cathy Fehrenbacher, OPPTS	Marc Stifelman, Region 10
Gary Foureman, NCEA (retired)	Zachary Pekar, OAQPS
Ann Johnson, OPEI	Aaron Yeow, OSWER
Henry Kahn, NCEA	Linda Watson, Region 3
Youngmoo Kim, Region 6	Valerie Zartarian, NERL
Lon Kissinger, Region 10	

AUTHORS, CONTRIBUTORS, AND REVIEWERS (continued)

This document was reviewed by an external panel of experts. The panel was composed of the following individuals:

- Henry Anderson, MD, Wisconsin Division of Public Health, Madison
- Paloma Beamer, PhD, Environmental Health Sciences, University of Arizona
- Deborah H. Bennett, PhD, Department of Public Health Sciences, University of California, Davis
- Robert J. Blaisdell, PhD, Office of Environmental Health Hazard Assessment, California Environmental Protection Agency
- Alesia Ferguson, PhD, College of Public Health, University of Arkansas Medical Services
- Brent L. Finley, PhD, ChemRisk
- David W. Gaylor, PhD, Gaylor and Associates, LLC
- Panos G. Georgopoulos, PhD, Robert Wood Johnson Medical School, University of Medicine and Dentistry of New Jersey
- Annette Guiseppi-Ellie, PhD, Dupont Engineering, Corporate Remediation Group
- Michael D. Lebowitz, PhD, University of Arizona, Tucson, AZ
- Agnes B. Lobscheid, PhD, Environmental Energy Technologies Division, Indoor Air Department, Lawrence Berkeley National Laboratory
- P. Barry Ryan, PhD, Rollins School of Public Health, Emory University
- Alan H. Stern, PhD, Independent Consultant
- Nga L. Tran, PhD, Health Sciences Center for Chemical Regulation and Food Safety, Exponent, Washington, DC
- Rosemary T. Zaleski, PhD, Occupational and Public Health Division, ExxonMobil Biomedical Sciences, Inc.

AUTHORS, CONTRIBUTORS, AND REVIEWERS (continued)**ACKNOWLEDGMENTS**

The authors wish to acknowledge the important contributions of the following U.S. EPA individuals who conducted additional analyses for the revisions of this handbook:

- David Hrdy, Office of Pesticide Programs
- Henry Kahn, National Center for Environmental Assessment
- David Miller, Office of Pesticide Programs
- James Nguyen, Office of Pesticide Programs
- Aaron Niman, Office of Pesticide Programs
- Allison Nowotarski, Office of Pesticide Programs
- Sheila Piper, Office of Pesticide Programs
- Kristin Rury, Office of Pesticide Programs
- Bernard Schneider, Office of Pesticide Programs
- Nicolle Tulse, National Exposure Research Laboratory
- Julie Van Alstine, Office of Pesticide Programs
- Philip Villanueva, Office of Pesticide Programs

In addition, the U.S. EPA, ORD, National Exposure Research Laboratory (NERL) made an important contribution to this handbook by conducting additional analyses of the National Human Activity Pattern Survey (NHAPS) data. U.S. EPA input to the NHAPS data analysis came from Karen A. Hammerstrom and Jacqueline Moya from NCEA-Washington Division, William C. Nelson from NERL-Research Triangle Park, and Stephen C. Hern, Joseph V. Behar (retired), and William H. Englemann from NERL-Las Vegas.

The U.S. EPA Office of Water and Office of Pesticide Programs made important contributions by conducting an analysis of the U.S. Department of Agriculture (USDA) Continuing Survey of Food Intakes by Individual (CSFII) data in previous versions of the handbook. More recently, the Office of Pesticide Programs conducted an analysis of the National Health and Nutrition Examination Survey (NHANES) 2003–2006 to update the Food Commodity Intake Database (FCID) and food consumption chapters of this edition of the handbook.

The authors also want to acknowledge the following individuals in NCEA: Terri Konoza for managing the document production activities and copy editing, Vicki Soto for copy editing, and Maureen Johnson for developing and managing the Web page.

EXECUTIVE SUMMARY

Some of the steps for performing an exposure assessment are (1) identifying the source of the environmental contamination and the media that transports the contaminant; (2) determining the contaminant concentration; (3) determining the exposure scenarios, and pathways and routes of exposure; (4) determining the exposure factors related to human behaviors that define time, frequency, and duration of exposure; and (5) identifying the exposed population. Exposure factors are factors related to human behavior and characteristics that help determine an individual's exposure to an agent. This *Exposure Factors Handbook* has been prepared to provide information and recommendations on various factors used in assessing exposure to both adults and children. The purpose of the *Exposure Factors Handbook* is to (1) summarize data on human behaviors and characteristics that affect exposure to environmental contaminants, and (2) recommend values to use for these factors. This handbook provides nonchemical-specific data on the following exposure factors:

- Ingestion of water and other selected liquids (see Chapter 3),
- Non-dietary ingestion factors (see Chapter 4),
- Ingestion of soil and dust (see Chapter 5),
- Inhalation rates (see Chapter 6),
- Dermal factors (see Chapter 7),
- Body weight (see Chapter 8),
- Intake of fruits and vegetables (see Chapter 9),
- Intake of fish and shellfish (see Chapter 10),
- Intake of meat, dairy products, and fats (see Chapter 11),
- Intake of grain products (see Chapter 12),
- Intake of home-produced food (see Chapter 13),
- Total food intake (see Chapter 14),
- Human milk intake (see Chapter 15),
- Activity factors (see Chapter 16),
- Consumer products (see Chapter 17),
- Lifetime (see Chapter 18), and
- Building characteristics (see Chapter 19).

The handbook was first published in 1989 and was revised in 1997 (U.S. EPA, 1989, 1997). Recognizing that exposures among infants, toddlers, adolescents, and teenagers can vary significantly, the U.S. EPA published the *Child-Specific Exposure Factors Handbook* in 2002 (U.S. EPA, 2002) and its revision in 2008 (U.S. EPA, 2008). The 2008 revision of the *Child-Specific Exposure Factors Handbook* as well as this 2011 edition of the

Front Matter

Exposure Factors Handbook reflect the age categories recommended in the U.S. EPA *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). This 2011 edition of the *Exposure Factors Handbook* also incorporates new factors and data provided in the 2008 *Child-Specific Exposure Factors Handbook* (and other relevant information published through July 2011). The information presented in this 2011 edition of the *Exposure Factors Handbook* supersedes the 2008 *Child-Specific Exposure Factors Handbook*.

The data presented in this handbook have been compiled from various sources, including government reports and information presented in the scientific literature. The data presented are the result of analyses by the individual study authors. However, in some cases, the U.S. EPA conducted additional analysis of published primary data to present results in a way that will be useful to exposure assessors and/or in a manner that is consistent with the recommended age groups. Studies presented in this handbook were chosen because they were seen as useful and appropriate for estimating exposure factors based on the following considerations: (1) soundness (adequacy of approach and minimal or defined bias); (2) applicability and utility (focus on the exposure factor of interest, representativeness of the population, currency of the information, and adequacy of the data collection period); (3) clarity and completeness (accessibility, reproducibility, and quality assurance); (4) variability and uncertainty (variability in the population and uncertainty in the results); and (5) evaluation and review (level of peer review and number and agreement of studies). Generally, studies were designated as “key” or “relevant” studies. Key studies were considered the most up-to-date and scientifically sound for deriving recommendations; while relevant studies provided applicable or pertinent data, but not necessarily the most important for a variety of reasons (e.g., data were outdated, limitations in study design). The recommended values for exposure factors are based on the results of key studies. The U.S. EPA also assigned confidence ratings of *low*, *medium*, or *high* to each recommended value based on the evaluation elements described above. These ratings are not intended to represent uncertainty analyses; rather, they represent the U.S. EPA’s judgment on the quality of the underlying data used to derive the recommendations.

Key recommendations from the handbook are summarized in Table ES-1. Additional recommendations and detailed supporting information for these recommendations can be found in the individual chapters of this handbook. In providing recommendations for the various exposure factors, an attempt was made to present percentile values that are consistent with the exposure estimators defined in the *Guidelines for Exposure Assessment* (U.S. EPA, 1992) (i.e., mean and upper percentile). However, this was not always possible because the data available were limited for some factors, or the authors of the study did not provide such information. As used throughout this handbook, the term “upper percentile” is intended to represent values in the upper tail (i.e., between 90th and 99.9th percentile) of the distribution of values for a particular exposure factor. The 95th percentile was used throughout the handbook to represent the upper tail because it is the middle of the range between 90th and 99th percentile. Other percentiles are presented, where available, in the tables at the end of each chapter. It should be noted that users of the handbook may use the exposure metric that is most appropriate for their particular situation.

The recommendations provided in this handbook are not legally binding on any U.S. EPA program and should be interpreted as suggestions that program offices or individual exposure/risk assessors can consider and modify as needed based on their own evaluation of a given risk assessment situation. In certain cases, different

values may be appropriate in consideration of policy, precedent, strategy, or other factors (e.g., more up-to-date data of better quality or more representative of the population of concern).

a	Based on weighted average of geometric mean soil loadings for 2 groups of children (ages 3 to 13 years; <i>N</i> = 10) playing indoors.					
b	Based on weighted average of geometric mean soil loadings for 4 groups of daycare children (ages 1 to 6.5 years; <i>N</i> = 21) playing both indoors and outdoors.					
c	Based on geometric mean soil loadings of 8 children (ages 13 to 15 years) playing soccer.					
d	Based on geometric mean soil loadings of 6 children (ages ≥8 years) and 1 adult engaging in Tae Kwon Do.					
e	Based on weighted average of geometric mean soil loadings for gardeners and archeologists (ages 16 to 35 years).					
f	Based on weighted average of geometric mean soil loadings of 2 groups of children (age 9 to 14 years; <i>N</i> = 12) playing in mud.					
g	Based on geometric mean soil loadings of 9 children (ages 7 to 12 years) playing in tidal flats.					
h	Based on weighted average of geometric mean soil loadings of 3 groups of adults(ages 23 to 33 years) playing rugby and 2 groups of adults (ages 24 to 34) playing soccer.					
i	Based on weighted average of geometric mean soil loadings for 69 gardeners, farmers, groundskeepers, landscapers, and archeologists (ages 16 to 64 years) for faces, arms and hands; 65 gardeners, farmers, groundskeepers, and archeologists (ages 16 to 64 years) for legs; and 36 gardeners, groundskeepers, and archeologists (ages 16 to 62) for feet.					
j	Based on weighted average of geometric mean soil loadings for 27 construction workers, utility workers and equipment operators (ages 21 to 54) for faces, arms, and hands; and based on geometric mean soil loadings for 8 construction workers (ages 21 to 30 years) for legs.					
k	Based on geometric mean soil loadings of 18 adults (ages 33 to 63 years) clamming in tidal flats.

Chapter 1—Introduction

1. INTRODUCTION**1.1. BACKGROUND AND PURPOSE**

Some of the steps for performing an exposure assessment are (1) identifying the source of the environmental contamination and the media that transports the contaminant; (2) determining the contaminant concentration; (3) determining the exposure scenarios, and pathways and routes of exposure; (4) determining the exposure factors related to human behaviors that define time, frequency, and duration of exposure; and (5) identifying the exposed population. Exposure factors are factors related to human behavior and characteristics that help

determine an individual's exposure to an agent. The National Academy of Sciences (NAS) report on *Risk Assessment in the Federal Government:*

Managing the Process and subsequent publication of the U.S. Environmental Protection Agency's (EPA) exposure guidelines in 1986 identified the need for summarizing exposure factors data necessary for characterizing some of the steps outlined above (U.S. EPA, 1987a; NRC, 1983). Around the same time, the U.S. EPA published a report entitled *Development of Statistical Distributions or Ranges of Standard Factors Used in Exposure Assessment* to support the 1986 exposure guidelines and to promote consistency in U.S. EPA's exposure assessment activities (U.S. EPA, 1985). The exposure assessment field continued to evolve and so did the need for more comprehensive data on exposure factors. The *Exposure Factors Handbook* was first published in 1989 and updated in 1997 in response to this need (U.S. EPA, 1997a, 1989a). This current edition is the update of the 1997 handbook (U.S. EPA, 1997a), and it incorporates data from the *Child-Specific Exposure Factors Handbook* (U.S. EPA, 2008a) that was published in September 2008. The information presented in this handbook supersedes the *Child-Specific Exposure Factors Handbook* published in 2008 (U.S. EPA, 2008a).

The purpose of the *Exposure Factors Handbook* is to (1) summarize data on human behavioral and physiological characteristics that affect exposure to environmental contaminants, and (2) provide exposure/risk assessors with recommended values for

Exposure factors are factors related to human behavior and characteristics that help determine an individual's exposure to an agent.

Purpose:

- (1) summarize data on human behavioral and physiological characteristics
- (2) provide exposure/risk assessors with recommended values for these factors

these factors that can be used to assess exposure among both adults and children.

1.2. INTENDED AUDIENCE

The *Exposure Factors Handbook* is intended for use by exposure and risk assessors both within and outside the U.S. EPA as a reference tool and primary source of exposure factor information. It may be used by scientists, economists, and other interested parties as a source of data and/or U.S. EPA recommendations on numeric estimates for behavioral and physiological characteristics needed to estimate exposure to environmental agents.

1.3. SCOPE

This handbook incorporates the changes in risk assessment practices that were first presented in the U.S. EPA's Cancer Guidelines, regarding the need to

consider life stages rather than subpopulations (U.S. EPA, 2005c, e). A life stage "refers to a distinguishable time frame in an individual's life characterized by unique and relatively stable behavioral and/or physiological characteristics that are associated with development and growth" (U.S. EPA, 2005b). The handbook emphasizes a major recommendation in U.S. EPA's *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* (U.S. EPA, 2005e) to sum exposures and risks across life stages rather than relying on the use of a lifetime average adult exposure to calculate risk. This handbook also uses updated information to incorporate any new exposure factors data/research that have become available since it was last revised in 1997 and is consistent with the U.S. EPA's new set of standardized childhood age groups (U.S. EPA, 2005b), which are recommended for use in exposure assessments. Available data through July 2011 are included in the handbook.

The recommendations presented in this handbook are not legally binding on any U.S. EPA program and should be interpreted as suggestions that program offices or individual exposure assessors can consider and modify as needed. The recommendations provided in this handbook do not supersede standards or guidance established by U.S. EPA program offices, states, or other risk assessment organizations outside the Agency (e.g.,

World Health Organization, National Research Council). Many of these factors are best quantified on a site- or situation-specific basis. The decision as to whether to use site-specific or national values for an assessment may depend on the quality of the competing data sets as well as on the purpose of the specific assessment. The handbook has strived to include full discussions of the issues that assessors should consider in deciding how to use these data and recommendations.

This document does not include chemical-specific data or information on physiological parameters that may be needed for exposure assessments involving physiologically based pharmacokinetic (PBPK) modeling. Information on the application of PBPK models and supporting data are found in U.S. EPA (2006a) and Lipscomb (2006).

1.4. UPDATES TO PREVIOUS VERSIONS OF THE HANDBOOK

All chapters have been revised to include published literature up to July 2011. Some of the main revisions are highlighted below:

- Added food and water intake data obtained from the National Health and Nutrition Examination Survey (NHANES) 2003–2006;
- Added fat intake data and total food intake data;
- Added new chapter on non-dietary factors;
- Updated soil ingestion rates for children and adults;
- Updated data on dermal exposure and added information on other factors such as film thickness of liquids to skin, transfer of residue, and skin thickness;
- Updated fish intake rates for the general population using data obtained from NHANES 2003–2006;
- Updated body-weight data with National Health and Nutrition Examination Survey 1999–2006;
- Added body-weight data for pregnant/lactating women and fetal weight;
- Updated children's factors with new recommended age groupings (U.S. EPA, 2005b);
- Updated life expectancy data with U.S. Census Bureau data 2006;
- Updated data on human milk ingestion and prevalence of breast-feeding; and

- Expanded residential characteristics chapter to include data from commercial buildings.

1.5. SELECTION OF STUDIES FOR THE HANDBOOK AND DATA PRESENTATION

Many scientific studies were reviewed for possible inclusion in this handbook. Although systematic literature searches were initially conducted for every chapter, much of the literature was identified through supplementary targeted searches and from personal communications with researchers in the various fields. Information in this handbook has been summarized from studies documented in the scientific literature and other publicly available sources. As such, this handbook is a compilation of data from a variety of different sources. Most of the data presented in this handbook are derived from studies that target (1) the general population (e.g., Center for Disease Control and Prevention [CDC] NHANES) or (2) a sample population from a specific area or group (e.g., fish consumption among Native American children). With very few exceptions, the data presented are the analyses of the individual study authors. Since the studies included in this handbook varied in terms of their objectives, design, scope, presentation of results, etc., the level of detail, statistics, and terminology may vary from study to study and from factor to factor. For example, some authors used geometric means to present their results, while others used arithmetic means or distributions. Authors have sometimes used different terms to describe the same racial/ethnic populations. Within the constraint of presenting the original material as accurately as possible, the U.S. EPA has made an effort to present discussions and results in a consistent manner and using consistent terminology. The strengths and limitations of each study are discussed to provide the reader with a better understanding of the uncertainties associated with the values derived from the study.

If it is necessary to characterize a population that is not directly covered by the data in this handbook, the risk or exposure assessor may need to evaluate whether these data may be used as suitable substitutes for the population of interest or whether there is a need to seek additional population-specific data. If information is needed for identifying and enumerating populations who may be at risk for greater contaminant exposures or who exhibit a heightened sensitivity to particular chemicals, refer to *Socio-demographic Data Used for Identifying Potentially Highly Exposed Populations* (U.S. EPA, 1999).

Chapter 1—Introduction

Studies were chosen that were seen as useful and appropriate for estimating exposure factors for both adults and children. In conjunction with the *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005b), this handbook adopted the age group notation “X to <Y” (e.g., the age group 3 to <6 years is meant to span a 3-year time interval from a child’s 3rd birthday up until the day before his or her 6th birthday). Every attempt was made to present the data for the recommended age groups. In cases where age group categories from the study authors did not match exactly with the U.S. EPA recommended age groups, the recommendations were matched as closely as possible. In some cases, data were limited, and age groups were lumped into bigger age categories to obtain adequate sample size. It is also recognized that dose-response data may not be available for many of the recommended age groupings. However, a standard set of age groups can assist in data collection efforts and provide focus for future research to better assess all significant variations in life stage (U.S. EPA, 2005b). To this date, no specific guidance is available with regard to age groupings for presenting adult data. Therefore, adult data (i.e., >21 years old) are presented using the age groups defined by the authors of the individual studies. No attempt was made to reanalyze the data using a consistent set of age groups. Therefore, in cases where data were analyzed by the U.S. EPA, age categories were defined as finely as possible based on adequacy of sample size. It is recognized that adults’ activity patterns will vary with many factors including age, especially in the older adult population.

Certain studies described in this handbook are designated as “key,” that is, the most up-to-date and scientifically sound for deriving recommendations for exposure factors. The recommended values for all exposure factors are based on the results of the key studies (see Section 1.6). Other studies are designated “relevant,” meaning applicable or pertinent, but not necessarily the most important. As new data or analyses are published, “key” studies may be moved to the “relevant” category in future revisions because they are replaced by more up-to-date data or an analysis of improved quality. Studies may be classified as “relevant” for one or more of the following reasons: (1) they provide supporting data (e.g., older studies on food intake that may be useful for trend analysis); (2) they provide information related to the factor of interest (e.g., data on prevalence of breast-feeding); (3) the study design or approach makes the data less applicable to the

population of interest (e.g., studies with small sample size, studies not conducted in the United States).

It is important to note that studies were evaluated based on their ability to represent the population for which the study was designed. The users of the handbook will need to evaluate the studies’ applicability to their population of interest.

1.5.1. General Assessment Factors

The Agency recognizes the need to evaluate the quality and relevance of scientific and technical information used in support of Agency actions (U.S. EPA, 2006c, 2003d, 2002). When evaluating scientific and technical information, the U.S. EPA’s Science Policy Council recommends using five General Assessment Factors (GAFs): (1) soundness, (2) applicability and utility, (3) clarity and completeness, (4) uncertainty and variability, and (5) evaluation and review (U.S. EPA, 2003d). These GAFs were adapted and expanded to include specific considerations deemed to be important during evaluation of exposure factors data and were used to judge the quality of the underlying data used to derive recommendations.

1.5.2. Selection Criteria

The confidence ratings for the various exposure factor recommendations, and selection of the key studies that form the basis for these recommendations, were based on specific criteria within each of the five GAFs, as follows:

- 1) **Soundness:** *Scientific and technical procedures, measures, methods, or models employed to generate the information are reasonable for, and consistent with, the intended application.* The soundness of the experimental procedures or approaches in the study designs of the available studies was evaluated according to the following:
 - a) **Adequacy of the Study Approach Used:**
In general, more confidence was placed on experimental procedures or approaches that more likely or closely captured the desired measurement. Direct exposure data collection techniques, such as direct observation, personal monitoring devices, or other known methods were preferred where available. If studies utilizing direct measurement were not available, studies were selected that relied on validated indirect measurement methods such as surrogate measures (such as heart rate for

inhalation rate), and use of questionnaires. If questionnaires or surveys were used, proper design and procedures include an adequate sample size for the population under consideration, a response rate large enough to avoid biases, and avoidance of bias in the design of the instrument and interpretation of the results. More confidence was placed in exposure factors that relied on studies that gave appropriate consideration to these study design issues. Studies were also deemed preferable if based on primary data, but studies based on secondary sources were also included where they offered an original analysis. In general, higher confidence was placed on exposure factors based on primary data.

- b) **Minimal (or Defined) Bias in Study Design:** Studies were sought that were designed with minimal bias, or at least if biases were suspected to be present, the direction of the bias (i.e., an overestimate or underestimate of the parameter) was either stated or apparent from the study design. More confidence was placed on exposure factors based on studies that minimized bias.
- 2) ***Applicability and Utility:*** *The information is relevant for the Agency's intended use. The applicability and utility of the available studies were evaluated based on the following criteria:*
 - a) **Focus on Exposure Factor of Interest:** Studies were preferred that directly addressed the exposure factor of interest or addressed related factors that have significance for the factor under consideration. As an example of the latter case, a selected study contained useful ancillary information concerning fat content in fish, although it did not directly address fish consumption.
 - b) **Representativeness of the Population:** More confidence was placed in studies that addressed the U.S. population. Data from populations outside the United States were sometimes included if behavioral patterns or other characteristics of exposure were similar. Studies seeking to characterize a particular region or demographic characteristic were selected, if appropriately representative of that population. In cases where data were limited, studies with limitations in this area were included, and limitations were

noted in the handbook. Higher confidence ratings were given to exposure factors where the available data were representative of the population of interest. The risk or exposure assessor may need to evaluate whether these data may be used as suitable substitutes for their population of interest or whether there is a need to seek additional population-specific data.

- c) **Currency of Information:** More confidence was placed in studies that were sufficiently recent to represent current exposure conditions. This is an important consideration for those factors that change with time. Older data were evaluated and considered in instances where the variability of the exposure factor over time was determined to be insignificant or unimportant. In some cases, recent data were very limited. Therefore, the data provided in these instances were the only available data. Limitations on the age of the data were noted. Recent studies are more likely to use state-of-the-art methodologies that reflect advances in the exposure assessment field. Consequently, exposure factor recommendations based on current data were given higher confidence ratings than those based on older data, except in cases where the age of the data would not affect the recommended values.
- d) **Adequacy of Data Collection Period:** Because most users of the handbook are primarily addressing chronic exposures, studies were sought that utilized the most appropriate techniques for collecting data to characterize long-term behavior. Higher confidence ratings were given to exposure factor recommendations that were based on an adequate data collection period.
- 3) ***Clarity and Completeness:*** *The degree of clarity and completeness with which the data, assumptions, methods, quality assurance, sponsoring organizations and analyses employed to generate the information is documented.* Clarity and completeness were evaluated based on the following criteria:
 - a) **Accessibility:** Studies that the user could access in their entirety, if needed, were preferred.
 - b) **Reproducibility:** Studies that contained sufficient information so that methods could be reproduced, or could be

Chapter 1—Introduction

evaluated, based on the details of the author's work, were preferred.

- c) **Quality Assurance:** Studies with documented quality assurance/quality control measures were preferred. Higher confidence ratings were given to exposure factors that were based on studies where appropriate quality assurance/quality control measures were used.
- 4) **Variability and Uncertainty:** *The variability and uncertainty (quantitative and qualitative) in the information or the procedures, measures, methods, or models are evaluated and characterized.* Variability arises from true heterogeneity across people, places, or time and can affect the precision of exposure estimates and the degree to which they can be generalized. The types of variability include spatial, temporal, and inter-individual. Uncertainty represents a lack of knowledge about factors affecting exposure or risk and can lead to inaccurate or biased estimates of exposure. Increasingly probabilistic methods are being utilized to analyze variability and uncertainty independently as well as simultaneously. It is sometimes challenging to distinguish between variability and parameter uncertainty in this context as both can involve the distributions of a random variable. The types of uncertainty include scenario, parameter, and model. More information on variability and uncertainty is provided in Chapter 2 of this handbook. The uncertainty and variability associated with the studies were evaluated based on the following criteria:
 - a) **Variability in the Population:** Studies were sought that characterized any variability within populations. The variability associated with the recommended exposure factors is described in Section 1.6. Higher confidence ratings were given to exposure factors that were based on studies where variability was well characterized.
 - b) **Uncertainty:** Studies were sought with minimal uncertainty in the data, which was judged by evaluating all the considerations listed above. Studies were preferred that identified uncertainties, such as those due to possible measurement error. Higher confidence ratings were given to exposure factors based on studies where uncertainty had been minimized.

- 5) **Evaluation and Review:** *The information or the procedures, measures, methods, or models are independently verified, validated, and peer reviewed.* Relevant factors that were considered included:

- a) **Peer Review:** Studies selected were those from the peer-reviewed literature and final government reports. Unpublished and internal or interim reports were avoided, where possible, but were used in some cases to supplement information in published literature or government reports.
- b) **Number and Agreement of Studies:** Higher confidence was placed on recommendations where data were available from more than one key study, and there was good agreement between studies.

1.6. APPROACH USED TO DEVELOP RECOMMENDATIONS FOR EXPOSURE FACTORS

As discussed above, the U.S. EPA first reviewed the literature pertaining to a factor and determined key studies. These key studies were used to derive recommendations for the values of each factor. The recommended values were derived solely from the U.S. EPA's interpretation of the available data. Different values may be appropriate for the user in consideration of policy, precedent, strategy, or other factors such as site-specific information. The U.S. EPA's procedure for developing recommendations was as follows:

- 1) **Study Review and Evaluation:** Key studies were evaluated in terms of both quality and relevance to specific populations (general U.S. population, age groups, sex, etc.). Section 1.5 describes the criteria for assessing the quality of studies.
- 2) **Selection of One versus Multiple Key Studies:** If only one study was classified as key for a particular factor, the mean value from that study was selected as the recommended central value for that population. If multiple key studies with reasonably equal quality, relevance, and study design information were available, a weighted mean (if appropriate, considering sample size and other statistical factors) of the studies was chosen as the recommended

mean value. Recommendations for upper percentiles, when multiple studies were available, were calculated as the mid-point of the range of upper percentile values of the studies for each age group where data were available. It is recognized that the mid-point of the range of upper percentiles may not provide the best estimate, but in the absence of raw data, more sophisticated analysis could not be performed.

- 3) **Assessing Variability:** The variability of the factor across the population is discussed. For recommended values, as well as for each of the studies on which the recommendations are based, variability was characterized in one or more of three ways: (1) as a table with various percentiles or ranges of values; (2) as analytical distributions with specified parameters; and/or (3) as a qualitative discussion. Analyses to fit standard or parametric distributions (e.g., normal, lognormal) to the exposure data have not been performed by the authors of this handbook, but have been reproduced as they were found in the literature. Recommendations on the use of these distributions were made where appropriate based on the adequacy of the supporting data. Table 1-1 presents the list of exposure factors and the way in which variability in the population has been characterized throughout this handbook (i.e., average, median, upper percentiles, multiple percentiles).

In providing recommendations for the various exposure factors, an attempt was made to present percentile values that are consistent with the exposure estimators defined in *Guidelines for Exposure Assessment* (U.S. EPA, 1992c) (i.e., mean, 50th, 90th, 95th, 98th, and 99.9th percentiles). However, this was not always possible, because the data available were limited for some factors, or the authors of the study did not provide such information. It is important to note, however, that these percentiles were discussed in the guidelines within the context of risk descriptors and not individual exposure factors. For example, the guidelines state that the assessor may derive a high-end estimate of exposure by using maximum or near maximum values for one or more sensitive exposure factors, leaving others at their mean value. The term “upper percentile” is used throughout this handbook, and it is intended to represent values in the

upper tail (i.e., between 90th and 99.9th percentiles) of the distribution of values for a particular exposure factor. Tables providing summaries of recommendations at the beginning of each chapter generally present a mean and an upper percentile value. The 95th percentile was used as the upper percentile in these tables, if available, because it is the middle of the range between the 90th and 99.9th percentiles. Other percentiles are presented, where available, in the tables at the end of the chapters. Users of the handbook should employ the exposure metric that is most appropriate for their particular situation.

- 4) **Assessing Uncertainty:** Uncertainties are discussed in terms of data limitations, the range of circumstances over which the estimates were (or were not) applicable, possible biases in the values themselves, a statement about parameter uncertainties (measurement error, sampling error), and model or scenario uncertainties if models or scenarios were used to derive the recommended value. A more detailed discussion of variability and uncertainty for exposure factors is presented in Chapter 2 of this handbook.
- 5) **Assigning Confidence Ratings:** Finally, the U.S. EPA assigned a confidence rating of *low*, *medium*, or *high* to each recommended value in each chapter. This qualitative rating is not intended to represent an uncertainty analysis; rather, it represents the U.S. EPA's judgment on the quality of the underlying data used to derive the recommendation. This judgment was made using the GAFs described in Section 1.5. Table 1-2 provides an adaptation of the GAFs, as they pertain to the confidence ratings for the exposure factor recommendations. Clearly, there is a continuum from *low* to *high*, and judgment was used to assign a rating to each factor. It is important to note that these confidence ratings are based on the strengths and limitations of the underlying data and not on how these data may be used in a particular exposure assessment.

The study elements listed in Table 1-2 do not have the same weight when arriving at the overall confidence rating for the various exposure factors. The relative weight of each of these elements for the various factors was subjective and based on the professional judgment of the authors of this handbook.

Chapter 1—Introduction

Also, the relative weights depend on the exposure factor of interest. For example, the adequacy of the data collection period may be more important when determining usual intake of foods in a population, but it is not as important for factors where long-term variability may be small, such as tap water intake. In the case of tap water intake, the currency of the data was a critical element in determining the final rating. In general, most studies ranked high with regard to “level of peer review,” “accessibility,” “focus on the factor of interest,” and “data pertinent to the United States” because the U.S. EPA specifically sought studies for the handbook that met these criteria.

The confidence rating is also a reflection of the ease at which the exposure factor of interest could be measured. This is taken into consideration under the *soundness* criterion. For example, soil ingestion by children can be estimated by measuring, in feces, the levels of certain elements found in soil. Body weight, however, can be measured directly, and it is, therefore, a more reliable measurement than estimation of soil ingestion. The fact that soil ingestion is more difficult to measure than body weight is reflected in the overall confidence rating given to both of these factors. In general, the better the methodology used to measure the exposure factor, the higher the confidence in the value.

Some exposure factors recommendations may have different confidence ratings depending on the population of interest. For example a lower confidence rating may be noted for some age groups for which sample sizes are small. As another example, a lower confidence rating was assigned to the recommendations as they would apply to long-term chronic exposures versus acute exposures because of the short-term nature of the data collection period. To the extent possible, these caveats were noted in the confidence rating tables.

- 6) **Recommendation Tables:** The U.S. EPA developed a table at the beginning of each chapter that summarizes the recommended values for the relevant factor. Table ES-1 of the Executive Summary of this handbook summarizes the principal exposure factors addressed in this handbook and provides the confidence ratings for each exposure factor.

1.7. SUGGESTED REFERENCES FOR USE IN CONJUNCTION WITH THIS HANDBOOK

Many of the issues related to characterizing exposure from selected exposure pathways have been addressed in a number of existing U.S. EPA documents. Some of these provide guidance while others demonstrate various aspects of the exposure process. These include, but are not limited to, the following references listed in chronological order:

- *Methods for Assessing Exposure to Chemical Substances, Volumes 1–13* (U.S. EPA, 1983-1989);
- *Standard Scenarios for Estimating Exposure to Chemical Substances During Use of Consumer Products* (U.S. EPA, 1986b, c);
- *Selection Criteria for Mathematical Models Used in Exposure Assessments: Surface Water Models* (U.S. EPA, 1987b);
- *Selection Criteria for Mathematical Models Used in Exposure Assessments: Groundwater Models* (U.S. EPA, 1988);
- *Risk Assessment Guidance for Superfund, Volume I, Part A, Human Health Evaluation Manual* (U.S. EPA, 1989b);
- *Methodology for Assessing Health Risks Associated with Indirect Exposure to Combustor Emissions* (U.S. EPA, 1990);
- *Risk Assessment Guidance for Superfund, Volume I, Part B, Development of Preliminary Remediation Goals* (U.S. EPA, 1991a);
- *Risk Assessment Guidance for Superfund, Volume I, Part C, Risk Evaluation of Remedial Alternatives* (U.S. EPA, 1991b);
- *Guidelines for Exposure Assessment* (U.S. EPA, 1992c);
- *Dermal Exposure Assessment: Principles and Applications* (U.S. EPA, 1992a);
- *Soil Screening Guidance* (U.S. EPA, 1996b);
- *Series 875 Occupational and Residential Exposure Test Guidelines—Final Guidelines—Group A—Application Exposure Monitoring Test Guidelines* (U.S. EPA, 1996a);
- *Series 875 Occupational and Residential Exposure Test Guidelines—Group B—Post Application Exposure Monitoring Test Guidelines* (U.S. EPA, 1998);
- *Policy for Use of Probabilistic Analysis in Risk Assessment at the U.S. Environmental Protection Agency* (U.S. EPA, 1997c);

Chapter 1—Introduction

- *Guiding Principles for Monte Carlo Analysis* (U.S. EPA, 1997b);
- *Sociodemographic Data for Identifying Potentially Highly Exposed Populations* (U.S. EPA, 1999);
- *Options for Development of Parametric Probability Distributions for Exposure Factors* (U.S. EPA, 2000a);
- *Risk Assessment Guidance for Superfund, Volume I, Part D, Standardized Planning, Reporting, and Review of Superfund Risk Assessments* (U.S. EPA, 2001b);
- *Risk Assessment Guidance for Superfund Volume III, Part A, Process for Conducting Probabilistic Risk Assessments* (U.S. EPA, 2001c)
- *Framework for Cumulative Risk Assessment* (U.S. EPA, 2003b);
- *Example Exposure Scenarios* (U.S. EPA, 2004a);
- *Exposure and Human Health Reassessment of 2,3,7,8-Tetrachlorodibenzo-p-Dioxin (TCDD) and Related Compounds National Academy Sciences Review Draft* (U.S. EPA, 2003a);
- *Risk Assessment Guidance for Superfund, Volume I, Part E, Supplemental Guidance for Dermal Risk Assessment* (U.S. EPA, 2004b);
- *Cancer Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005c);
- *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* (U.S. EPA, 2005e);
- *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005b);
- *Human Health Risk Assessment Protocol for Hazardous Waste Combustion Facilities* (U.S. EPA, 2005d);
- *Aging and Toxic Response: Issues Relevant to Risk Assessment* (U.S. EPA, 2005a);
- *A Framework for Assessing Health Risk of Environmental Exposures to Children* (U.S. EPA, 2006b);
- *Dermal Exposure Assessment: A Summary of EPA Approaches* (U.S. EPA, 2007b);
- *Child-Specific Exposure Factors Handbook* (U.S. EPA, 2008a);
- *Concepts, Methods, and Data Sources For Cumulative Health Risk Assessment of Multiple Chemicals, Exposures and Effects: A Resource Document* (U.S. EPA, 2007a);
- *Physiological Parameters Database for Older Adults (Beta 1.1)* (U.S. EPA, 2008b);
- *Risk Assessment Guidance for Superfund Volume I: Human Health Evaluation Manual Part F, Supplemental Guidance for Inhalation Risk Assessment* (U.S. EPA, 2009b);
- *Draft Technical Guidelines Standard Operating Procedures for Residential Pesticide Exposure Assessment* (U.S. EPA, 2009a);
- *Stochastic Human Exposure and Dose Simulation (SHEDS)-Multimedia. Details of SHEDS-Multimedia Version 3: ORD/NERL's Model to Estimate Aggregate and Cumulative Exposures to Chemicals* (U.S. EPA, 2010); and
- *Recommended Use of Body Weight^{3/4} (BW^{3/4}) as the Default Method in Derivation of the Oral Reference Dose (RfD)* (U.S. EPA, 2011).

These documents may serve as valuable information resources to assist in the assessment of exposure. Refer to them for more detailed discussion.

1.8. THE USE OF AGE GROUPINGS WHEN ASSESSING EXPOSURE

When this handbook was published in 1997, no specific guidance existed with regard to which age groupings should be used when assessing children's exposure. Age groupings varied from case to case and among Program Offices within the U.S. EPA. They depended on availability of data and were often based on professional judgment. More recently, the U.S. EPA has established a consistent set of age groupings and published guidance on this topic (U.S. EPA, 2005b). This revision of the handbook attempts to present data in a manner consistent with the U.S. EPA's recommended set of age groupings for children. The presentation of data for these fine age categories does not necessarily mean that every age category needs to be the subject of a particular assessment. It will depend on the objectives of the assessment and communications with toxicologists to identify the critical windows of susceptibility.

The development of standardized age bins for children was the subject of discussion in a 2000 workshop sponsored by the U.S. EPA Risk Assessment Forum. The workshop was titled *Issues Associated with Considering Developmental Changes in Behavior and Anatomy When Assessing Exposure to Children* (U.S. EPA, 2000b). The purpose of this

Chapter 1—Introduction

workshop was to gain insight and input into factors that need to be considered when developing standardized age bins and to identify future research necessary to accomplish these goals.

Based upon consideration of the findings of the technical workshop, as well as analysis of available data, U.S. EPA developed guidance that established a set of recommended age groups for development of exposure factors for children entitled *Guidance for Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005b). This revision of the handbook for individuals <21 years of age presents exposure factors data in a manner consistent with U.S. EPA's recommended set of childhood age groupings. The recommended age groups (U.S. EPA, 2005b) are as follows:

Birth to <1 month
1 to <3 months
3 to <6 months
6 to <12 months
1 to <2 years
2 to <3 years
3 to <6 years
6 to <11 years
11 to <16 years
16 to <21 years

1.9. CONSIDERING LIFE STAGE WHEN CALCULATING EXPOSURE AND RISK

In recent years, there has been an increased concern regarding the potential impact of environmental exposures to children and other susceptible populations such as older adults and pregnant/lactating women. As a result, the U.S. EPA and others have developed policy and guidance and undertaken research to better incorporate life stage data into human health risk assessment (Brown et al., 2008). The *Child-Specific Exposure Factors Handbook* was published in 2008 to address the need to characterize children's exposures at various life stages (U.S. EPA, 2008a). Children are of special concern because (1) they consume more of certain foods and water per unit of body weight than adults; (2) they have a higher ratio of body surface area to volume than adults; and (3) they experience important, rapid changes in behavior and physiology that may lead to differences in exposure (Moya et al., 2004). Many studies have shown that young children can be exposed to various contaminants, including

pesticides, during normal oral exploration of their environment (i.e., hand-to-mouth behavior) and by touching floors, surfaces, and objects such as toys (Garry, 2004; Eskenazi et al., 1999; Lewis et al., 1999; Nishioka et al., 1999; Gurunathan et al., 1998). Dust and tracked-in soil accumulate in carpets, where young children spend a significant amount of time (Lewis et al., 1999). Children living in agricultural areas may experience higher exposures to pesticides than do other children (Curwin et al., 2007). They may play in nearby fields or be exposed via consumption of contaminated human milk from their farmworker mothers (Eskenazi et al., 1999).

In terms of risk, children may also differ from adults in their vulnerability to environmental pollutants because of toxicodynamic differences (e.g., when exposures occur during periods of enhanced susceptibility) and/or toxicokinetic differences (i.e., differences in absorption, metabolism, and excretion) (U.S. EPA, 2000b). The immaturity of metabolic enzyme systems and clearance mechanisms in young children can result in longer half-lives of environmental contaminants (Clewett et al., 2004; Ginsberg et al., 2002). The cellular immaturity of children and the ongoing growth processes account for elevated risk (American Academy of Pediatrics, 1997). Toxic chemicals in the environment can cause neurodevelopmental disabilities, and the developing brain can be particularly sensitive to environmental contaminants. For example, elevated blood lead levels and prenatal exposures to even relatively low levels of lead can result in behavior disorders and reductions of intellectual function in children (Landrigan et al., 2005). Exposure to high levels of methylmercury can result in developmental disabilities (e.g., intellectual deficiency, speech disorders, and sensory disturbances) among children (Myers and Davidson, 2000). Other authors have described the importance of exposure timing (i.e., pre-conceptional, prenatal, and postnatal) and how it affects the outcomes observed (Selevan et al., 2000). Exposures during these critical windows of development and age-specific behaviors and physiological factors can lead to differences in response (Makri et al., 2004). Fetal exposures can occur from the mobilization of chemicals of maternal body burden and transfer of those chemicals across the placenta (Makri et al., 2004). Absorption through the gastrointestinal tract is more efficient in neonates and infants, making ingestion exposures a significant route of exposure during the first year of age (Makri et al., 2004).

It has also been suggested that higher levels of exposure to indoor air pollution and allergens among inner-city children compared to non-inner-city

children may explain the difference in asthma levels between these two groups (Breysse et al., 2005). With respect to contaminants that are carcinogenic via a mutagenic mode of action (MOA), the U.S. EPA has found that childhood is a particularly sensitive period of development in which cancer potencies per year of exposure can be an order of magnitude higher than during adulthood (U.S. EPA, 2005e).

A framework for considering life stages in human health risk assessments was developed by the U.S. EPA in the report entitled *A Framework for Assessing Health Risks of Environmental Exposures to Children* (U.S. EPA, 2006b). Life stages are defined as “temporal stages (or intervals) of life that have distinct anatomical, physiological, behavioral, and/or functional characteristics that contribute to potential differences in environmental exposures” (Brown et al., 2008). One way to understand the differential exposures among life stages is to study the data using age binning or age groups as it is the recommendation for childhood exposures. Although the framework discusses the importance of incorporating life stages in the evaluation of risks to children, the approach can also be applied to other life stages that may have their own unique susceptibilities. For example, older individuals may experience differential exposures and risks to environmental contaminants due to biological changes that occur during aging, disease status, drug interactions, different exposure patterns, and activities. More information on the toxicokinetic and toxicodynamic impact of environmental agents in older adults can be found in U.S. EPA’s document entitled *Aging and Toxic Response: Issues Relevant to Risk Assessment* (U.S. EPA, 2005a). The need to better characterize differential exposures of the older adult population to environmental agents was recognized at the U.S. EPA’s workshop on the development of exposure factors for the aging (U.S. EPA, 2007c). A panel of experts in the fields of gerontology, physiology, exposure assessment, risk assessment, and behavioral science discussed existing data, data gaps, and current relevant research on the behavior and physiology of older adults, as well as practical considerations of the utility of developing an exposure factors handbook for the aging (U.S. EPA, 2007c). Pregnant and lactating women may also be a life stage of concern due to physiological changes during pregnancy and lactation. For example, lead is mobilized from the maternal skeleton during pregnancy and the postpartum period, increasing the chances for fetal lead exposure (Gulson et al., 1999).

The U.S. EPA encourages the consideration of all life stages and endpoints to ensure that vulnerabilities

during specific time periods are taken into account (Brown et al., 2008). Although the importance of assessing risks from environmental exposures to all susceptible populations is recognized, most of the guidance developed thus far relates to children. Furthermore, it is recognized that there is a lack of dose-response data to evaluate differential responses at various life stages (e.g., age groups, pregnant/lactating mothers, older populations). A key component of U.S. EPA’s *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005b) involves the need to sum age-specific exposures across time when assessing long-term exposure, as well as integrating these age-specific exposures with age-specific differences in toxic potency in those cases where information exists to describe such differences: an example is carcinogens that act via a mutagenic mode of action [*Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* – (U.S. EPA, 2005e)]. When assessing chronic risks (i.e., exposures greater than 10% of human lifespan), rather than assuming a constant level of exposure for 70 years (usually consistent with an adult level of exposure), the Agency is now recommending that assessors calculate chronic exposures by summing time-weighted exposures that occur at each life stage; this handbook provides data arrayed by childhood age in order to follow this new guidance (U.S. EPA, 2005e). This approach is expected to increase the accuracy of risk assessments, because it will take into account life stage differences in exposure. Depending on whether body-weight-adjusted childhood exposures are either smaller or larger compared to those for adults, calculated risks could either decrease or increase when compared with the historical approach of assuming a lifetime of a constant adult level of exposure.

The *Supplemental Guidance* report also recommended that in those cases where age-related differences in toxicity were also found to occur, differences in both toxicity and exposure would need to be integrated across all relevant age intervals (U.S. EPA, 2005e). This guidance describes such a case for carcinogens that act via a mutagenic mode of action, where age dependent adjustments factors (ADAFs) of 10× and 3× are recommended for children ages birth to <2 years, and 2 to <16 years, respectively, when there is exposure during those years, and available data are insufficient to derive chemical-specific adjustment factors.

Table 1-3, along with Chapter 6 of the *Supplemental Guidance* (U.S. EPA, 2005e) report, have been developed to help the reader understand

Chapter 1—Introduction

how to use the new sets of exposure and potency age groupings when calculating risk through the integration of life stage specific changes in exposure and potency for mutagenic carcinogens.

Thus, Table 1-3 presents Lifetime Cancer Risk (for a population with average life expectancy of 70 years) = $\sum (\text{Exposure} \times \text{Duration}/70 \text{ years} \times \text{Potency} \times \text{ADAF})$ summed across all the age groups. This is a departure from the way cancer risks have historically been calculated based upon the premise that risk is proportional to the daily average of the long-term adult dose.

1.10. FUNDAMENTAL PRINCIPLES OF EXPOSURE ASSESSMENT

An exposure assessment is the “process of estimating or measuring the magnitude, frequency, and duration of exposure to an agent, along with the number and characteristics of the population exposed” (Zartarian et al., 2007). The definition of exposure as used by the International Program on Chemical Safety (WHO, 2001) is the “contact of an organism with a chemical or physical agent, quantified as the amount of chemical available at the exchange boundaries of the organism and available for absorption.” The term “agent” refers to a chemical, biological, or physical entity that contacts a target. The “target” refers to any physical, biological, or ecological object exposed to an agent. In the case of human exposures, the contact occurs with the visible exterior of a person (i.e., target) such as the skin, and openings such as the mouth, nostrils, and lesions. The process by which an agent crosses an outer exposure surface of a target without passing an absorption barrier (i.e., through ingestion or inhalation) is called an intake. The resulting dose is the intake dose. The intake dose is sometimes referred to in the literature as the administered dose or potential dose.

The terms “exposure” and “dose” are very closely related and, therefore, are often confused (Zartarian et al., 2007). Dose is the amount of agent that enters a target in a specified period of time after crossing a contact boundary. An exposure does not necessarily leads to a dose. However, there can be no dose without a corresponding exposure (Zartarian et al., 2007). Figure 1-1 illustrates the relationship between exposure and dose.

Figure 1-1. Conceptual Drawing of Exposure and Dose Relationship (Zartarian et al., 2007).

In other words, the process of an agent entering the body can be described in two steps: contact (exposure) followed by entry (crossing the boundary). In the context of environmental risk assessment, risk to an individual or population can be represented as a continuum from the source through exposure to dose to effect as shown in Figure 1-2 (Ott, 2007; WHO, 2006; U.S. EPA, 2003c). The process begins with a chemical or agent released from a source into the environment. Once in the environment, the agent can be transformed and transported through the environment via air, water, soil, dust, and diet (i.e., exposure pathway). Fate and transport mechanisms result in various chemical concentrations with which individuals may come in contact. Individuals encounter the agent either through inhalation, ingestion, or skin/eye contact (i.e., exposure route). The individual’s activity patterns as well as the concentration of the agent will determine the magnitude, frequency, and duration of the exposure. The exposure becomes an absorbed dose when the agent crosses an absorption barrier (e.g., skin, lungs, gut). Other terms used in the literature to refer to absorbed dose include internal dose, bioavailable dose, delivered dose, applied dose, active dose, and biologically effective dose (Zartarian et al., 2007). When an agent or its metabolites interact with a target tissue, it becomes a target tissue dose, which may lead to an adverse health outcome. The text under the boxes in Figure 1-2 indicates the specific information that may be needed to characterize each box.

This approach has been used historically in exposure assessments and exposure modeling. It is usually referred to as source-to-dose approach. In recent years, person-oriented approaches and models have gained popularity. This approach is aimed at accounting for cumulative and aggregate exposures to individuals (Georgopoulos, 2008; Price et al.,

2003a). The person-oriented approach can also take advantage of information about the individual's susceptibility to environmental factors (e.g., genetic differences) (Georgopoulos, 2008).

There are three approaches to calculate exposures: (1) the point-of-contact approach, (2) the scenario evaluation approach, and (3) the dose reconstruction approach (U.S. EPA, 1992c). The data presented in this handbook are generally useful for evaluating exposures using the scenario approach. There are advantages and disadvantages associated with each approach. Although it is not the purpose of this handbook to provide guidance on how to conduct an exposure assessment, a brief description of the approaches is provided below.

The point-of-contact approach, or direct approach, involves measurements of chemical concentrations at the point where exposure occurs (i.e., at the interface between the person and the environment). This chemical concentration is coupled with information on the length of contact with each chemical to calculate exposure. The scenario evaluation approach, or the indirect approach, utilizes data on chemical concentration, frequency, and duration of exposure as well as information on the behaviors and characteristics of the exposed life stage. The third approach, dose reconstruction, allows exposure to be estimated from dose, which can be reconstructed through the measurement of biomarkers of exposure. A biomarker of exposure is a chemical, its metabolite, or the product of an interaction between a chemical and some target molecule or cell that is measured in a compartment in an organism (NRC, 2006). Biomonitoring is becoming a tool for identifying, controlling, and preventing human exposures to environmental chemicals (NRC, 2006). For example, blood lead concentrations and the associated health effects were used by the U.S. EPA in its efforts to reduce exposure to lead in gasoline. The Centers for Disease Control and Prevention conducts biomonitoring studies to help identify chemicals that are both present in the environment and in human tissues (NRC, 2006). Biomonitoring studies also assist public health officials in studying distributions of exposure in a population and how they change overtime. Biomonitoring data can be converted to exposure using pharmacokinetic modeling (NRC, 2006). Although biomonitoring can be a powerful tool, interpretation of the data is difficult. Unlike the other two approaches, biomonitoring provides information on internal doses integrated across environmental pathways and media. Interpretation of these data requires knowledge and understanding of how the chemicals are absorbed, excreted, and metabolized in

the biological system, as well as the properties of the chemicals and their metabolites (NRC, 2006). The interpretation of biomarker data can be further improved by the development of other cellular and molecular approaches to include advances in genomics, proteomics, and other approaches that make use of molecular-environmental interactions (Lioy et al., 2005). Physiological parameters can also vary with life stage, age, sex, and other demographic information (Price et al., 2003b). Physiologic and metabolic factors and how they vary with life stage have been the subject of recent research. Pharmacokinetic models are frequently developed from data obtained from young adults. Therapeutic drugs have been used as surrogates to study pharmacokinetic differences in fetuses, children, and adults (Ginsberg et al., 2004). Specific considerations of susceptibilities for other populations (e.g., children, older adults) require knowledge of the physiological parameters that most influence the disposition of the chemicals in the body (Thompson et al., 2009). Physiological parameters include alveolar ventilation, cardiac output, organ and tissue weights and volumes, blood flows to organs and tissues, clearance parameters, and body composition (Thompson et al., 2009). Price et al. (2003b) developed a tool for capturing the correlation between organs and tissue and compartment volumes, blood flows, body weight, sex, and other demographic information. A database that records key, age-specific pharmacokinetic model inputs for healthy older adults and for older adults with conditions such as diabetes, chronic obstructive pulmonary disease, obesity, heart disease, and renal disease has been developed by the U.S. EPA (Thompson et al., 2009; U.S. EPA, 2008b).

Computational exposure models can play an important role in estimating exposures to environmental chemicals (Sheldon and Cohen Hubal, 2009). In general, these models combine measurements of the concentration of the chemical agent in the environment (e.g., air, water, soil, food) with information about the individual's activity patterns to estimate exposure (WHO, 2005). Several models have been developed and may be used to support risk management decisions. For example, the U.S. EPA SHEDS model is a probabilistic model that simulates daily activities to predict distributions of daily exposures in a population (U.S. EPA, 2010). Other models such as the Modeling Environment for Total Risk Studies incorporates and expands the approach used by SHEDS and considers multiple routes of exposure (Georgopoulos and Lioy, 2006).

Chapter 1—Introduction

1.10.1. Exposure and Dose Equations

Exposure can be quantified by multiplying the concentration of an agent times the duration of the contact. Exposure can be instantaneous when the contact between an agent and a target occurs at a single point in time and space (Zartarian et al., 2007). The summation of instantaneous exposures over the exposure duration is called the time-integrated exposure (Zartarian et al., 2007). Equation 1-1 shows the time-integrated exposure.

$$E = \int_{t_1}^{t_2} C(t)dt \quad (\text{Eqn. 1-1})$$

where:

E = Time-integrated exposure (mass/volume),
 $t_2 - t_1$ = Exposure duration (ED) (time), and
 C = Exposure concentration as a function of time (mass/volume).

Dividing the time-integrated exposure by the exposure duration, results in the time-averaged exposure (Zartarian et al., 2007).

Dose can be classified as an intake dose or an absorbed dose (U.S. EPA, 1992c). Starting with a general integral equation for exposure, several dose equations can be derived depending upon boundary assumptions. One of the more useful of these derived equations is the average daily dose (ADD). The ADD, which is used for many non-cancer effects, averages exposures or doses over the period of time exposure occurred. The ADD can be calculated by averaging the intake dose over body weight and an averaging time as shown in Equations 1-2 and 1-3.

$$ADD = \frac{\text{Intake Dose}}{\text{Body Weight} \times \text{Averaging Time}} \quad (\text{Eqn. 1-2})$$

The exposure can be expressed as follows:

$$\text{Intake Dose} = C \times IR \times ED \quad (\text{Eqn. 1-3})$$

where:

C = Concentration of the Agent (mass/volume),
 IR = Intake Rate (mass/time), and

ED = Exposure Duration (time).

Concentration of the agent is the mass of the agent in the medium (air, food, soil, etc.) per unit volume contacting the body and has units of mass/volume or mass/mass.

The intake rate refers to the rates of inhalation, ingestion, and dermal contact, depending on the route of exposure. For ingestion, the intake rate is simply the amount of contaminated food ingested by an individual during some specific time period (units of mass/time). Much of this handbook is devoted to rates of ingestion for some broad classes of food. For inhalation, the intake rate is that at which contaminated air is inhaled. Factors presented in this handbook that affect dermal exposure are skin surface area and estimates of the amount of solids that adheres to the skin, film thickness of liquids to skin, transfer of residues, and skin thickness. It is important to note that there are other key factors in the calculation of dermal exposures that are not covered in this handbook (e.g., chemical-specific absorption factors).

The exposure duration is the length of time of contact with an agent. For example, the length of time a person lives in an area, frequency of bathing, time spent indoors versus outdoors, and in various microenvironments, all affect the exposure duration. Chapter 16, Activity Factors, gives some examples of population behavior and macro and micro activities that may be useful for estimating exposure durations.

When the above parameter values IR and ED remain constant over time, they are substituted directly into the dose equation. When they change with time, a summation approach is needed to calculate dose. In either case, the exposure duration is the length of time exposure occurs at the concentration and the intake rate specified by the other parameters in the equation.

Note that the advent of childhood age groupings means that separate ADDs should be calculated for each age group considered. Chronic exposures can then be calculated by summing across each life stage-specific ADD.

Cancer risks have traditionally been calculated in those cases where a linear non-threshold model is assumed, in terms of lifetime probabilities by utilizing dose values presented in terms of lifetime ADDs (LADDs). The LADD takes the form of Equation 1-2, with lifetime replacing averaging time. While the use of LADDs may be appropriate when developing screening-level estimates of cancer risk, the U.S. EPA recommends that risks should be calculated by integrating exposures or risks throughout all life stages (U.S. EPA, 1992c).

For some types of analyses, dose can be expressed as a total amount (with units of mass, e.g., mg) or as a dose rate in terms of mass/time (e.g., mg/day), or as a rate normalized to body mass (e.g., with units of mg of chemical per kg of body weight per day [mg/kg-day]). The LADD is usually expressed in terms of mg/kg-day or other mass/mass-time units.

In most cases (inhalation and ingestion exposures), the dose-response parameters for carcinogenic risks have been adjusted for the difference in absorption across body barriers between humans and the experimental animals used to derive such parameters. Therefore, the exposure assessment in these cases is based on the intake dose, with no explicit correction for the fraction absorbed. However, the exposure assessor needs to make such an adjustment when calculating dermal exposure and in other specific cases when current information indicates that the human absorption factor used in the derivation of the dose-response factor is inappropriate.

For carcinogens, the duration of a lifetime has traditionally been assigned the nominal value of 70 years as a reasonable approximation. For dose estimates to be used for assessments other than carcinogenic risk, various averaging periods have been used. For acute exposures, the doses are usually averaged over a day or a single event. For non-chronic non-cancer effects, the time period used is the actual period of exposure (exposure duration). The objective in selecting the exposure averaging time is to express the dose in a way that can be combined with the dose-response relationship to calculate risk.

The body weight to be used in Equation 1-2 depends on the units of the exposure data presented in this handbook. For example, for food ingestion, the body weights of the surveyed populations were known in the USDA and NHANES surveys, and they were explicitly factored into the food intake data in order to calculate the intake as g/kg body weight-day. In this case, the body weight has already been included in the “intake rate” term in Equation 1-3, and the exposure assessor does not need to explicitly include body weight.

The units of intake in this handbook for the incidental ingestion of soil and dust are not normalized to body weight. In this case, the exposure assessor will need to use (in Equation 1-2) the average weight of the exposed population during the time when the exposure actually occurs. When making body-weight assumptions, care must be taken that the values used for the population parameters in the dose-response analysis are consistent with the

population parameters used in the exposure analysis. Intraspecies adjustments based on life stage can be made using a correction factor (CF) (U.S. EPA, 2011, 2006b). Appendix 1A of this chapter discusses these adjustments in more detail. Some of the parameters (primarily concentrations) used in estimating exposure are exclusively site specific, and, therefore, default recommendations should not be used. It should be noted that body weight is correlated with food consumption rates, body surface area, and inhalation rates (for more information, see Chapters 6, 7, 9, 10, 11, 12, 13, and 14).

The link between the intake rate value and the exposure duration value is a common source of confusion in defining exposure scenarios. It is important to define the duration estimate so that it is consistent with the intake rate:

- The intake rate can be based on an individual event (e.g., serving size per event). The duration should be based on the number of events or, in this case, meals.
- The intake rate also can be based on a long-term average, such as 10 g/day. In this case, the duration should be based on the total time interval over which the exposure occurs.

The objective is to define the terms so that, when multiplied, they give the appropriate estimate of mass of agent contacted. This can be accomplished by basing the intake rate on either a long-term average (chronic exposure) or an event (acute exposure) basis, as long as the duration value is selected appropriately.

Inhalation dosimetry is employed to derive the human equivalent exposure concentrations on which inhalation unit risks (IURs), and reference concentrations (RfCs), are based (U.S. EPA, 1994). U.S. EPA has traditionally approximated children’s respiratory exposure by using adult values, although a recent review (Ginsberg et al., 2005) concluded that there may be some cases where young children’s greater inhalation rate per body weight or pulmonary surface area as compared to adults can result in greater exposures than adults. The implications of this difference for inhalation dosimetry and children’s risk assessment were discussed at a peer involvement workshop hosted by the U.S. EPA in 2006 (Foos et al., 2008).

Consideration of life stage-particular physiological characteristics in the dosimetry analysis may result in a refinement to the human equivalent

Chapter 1—Introduction

concentration (HEC) to ensure relevance in risk assessment across life stages, or might conceivably conclude with multiple HECs, and corresponding IUR values (e.g., separate for childhood and adulthood) (U.S. EPA, 2005e). The RfC methodology, which is described in *Methods for Derivation of Inhalation Reference Concentrations and Applications of Inhalation Dosimetry* (U.S. EPA, 1994), allows the user to incorporate population-specific assumptions into the models. Refer to U.S. EPA guidance (U.S. EPA, 1994) on how to make these adjustments.

There are no specific exposure factor assumptions in the derivation of RfDs for susceptible populations. With regard to childhood exposures for a susceptible population, for example, the assessment of the potential for adverse health effects in infants and children is part of the overall hazard and dose-response assessment for a chemical. Available data pertinent to children's health risks are evaluated along with data on adults and the no-observed-adverse-effect level (NOAEL) or benchmark dose (BMD) for the most sensitive critical effect(s), based on consideration of all health effects. By doing this, protection of the health of children will be considered along with that of other sensitive populations. In some cases, it is appropriate to evaluate the potential hazard to a susceptible population (e.g., children) separately from the assessment for the general population or other population groups. For more information regarding life stage-specific considerations for assessing children exposures, refer to the U.S. EPA report entitled *Framework for Assessing Health Risk of Environmental Exposures to Children* (U.S. EPA, 2006b).

1.10.2. Use of Exposure Factors Data in Probabilistic Analyses

Probabilistic risk assessment provides a range and likelihood estimate of risk rather than a single point estimate. It is a tool that can provide additional information to risk managers to improve decision making. Although this handbook is not intended to provide complete guidance on the use of Monte Carlo and other probabilistic analyses, some of the data in this handbook may be appropriate for use in probabilistic assessments. More detailed information on treating variability and uncertainty is discussed in Chapter 2 of this handbook. The use of Monte Carlo or other probabilistic analysis requires characterization of the variability of exposure factors and requires the selection of distributions or histograms for the input parameters of the dose equations presented in Section 1.10.1. The following

suggestions are provided for consideration when using such techniques:

- The exposure assessor should only consider using probabilistic analysis when there are credible distribution data (or ranges) for the factor under consideration. Even if these distributions are known, it may not be necessary to apply this technique. For example, if only average exposure values are needed, these can often be computed accurately by using average values for each of the input parameters unless a non-linear model is used. Generally, exposure assessments follow a tiered approach to ensure the efficient use of resources. They may start with very simple techniques and move to more sophisticated models. The level of assessment needed can be determined initially during the problem formulation. There is also a tradeoff between the level of sophistication and the need to make timely decisions (NRC, 2009). Probabilistic analysis may not be necessary when conducting assessments for the first tier, which is typically done for screening purposes, i.e., to determine if unimportant pathways can be eliminated. In this case, bounding estimates can be calculated using maximum or near maximum values for each of the input parameters. Alternatively, the assessor may use the maximum values for those parameters that have the greatest variance.
- The selection of distributions can be highly site-specific and dependent on the purpose of the assessment. In some cases, the selection of distributions is driven by specific legislation. It will always involve some degree of judgment. Distributions derived from national data may not represent local conditions. Also, distributions may be representative of some age groups, but not representative when finer age categories are used. The assessor should evaluate the distributional data to ensure that it is representative of the population that needs to be characterized. In cases where site-specific data are available, the assessor may need to evaluate their quality and applicability. The assessor may decide to use distributional data drawn from the national or other surrogate population. In this case, it is important that the assessor address the extent to which local conditions may differ from the surrogate data.
- It is also important to consider the independence/dependence of variables and data used in a simulation. For example, it may

be reasonable to assume that ingestion rate and contaminant concentration in foods are independent variables, but ingestion rate and body weight may or may not be independent.

In addition to a qualitative statement of uncertainty, the representativeness assumption should be appropriately addressed as part of a sensitivity analysis. Distribution functions used in probabilistic analysis may be derived by fitting an appropriate function to empirical data. In doing this, it should be recognized that in the lower and upper tails of the distribution, the data are scarce, so that several functions, with radically different shapes in the extreme tails, may be consistent with the data. To avoid introducing errors into the analysis by the arbitrary choice of an inappropriate function, several techniques can be used. One technique is to avoid the problem by using the empirical data themselves rather than an analytic function. Another is to do separate analyses with several functions that have adequate fit but form upper and lower bounds to the empirical data. A third way is to use truncated analytical distributions. Judgment must be used in choosing the appropriate goodness-of-fit test.

Information on the theoretical basis for fitting distributions can be found in a standard statistics text, [e.g., Gilbert (1987), among others]. Off-the-shelf computer software can be used to statistically determine the distributions that fit the data. Other software tools are available to identify outliers and for conducting Monte Carlo simulations.

If only a range of values is known for an exposure factor, the assessor has several options. These options include:

- keep that variable constant at its central value;
- assume several values within the range of values for the exposure factor;
- calculate a point estimate(s) instead of using probabilistic analysis; and
- assume a distribution. (The rationale for the selection of a distribution should be discussed at length.) The effects of selecting a different, but equally probable distribution should be discussed. There are, however, cases where assuming a distribution may introduce considerable amount of uncertainty. These include:
 - data are missing or very limited for a key parameter;
 - data were collected over a short time period and may not represent long-term

trends (the respondent's usual behavior)—examples include food consumption surveys; activity pattern data;

- data are not representative of the population of interest because sample size was small or the population studied was selected from a local area and was, therefore, not representative of the area of interest; for example, soil ingestion by children; and
- ranges for a key variable are uncertain due to experimental error or other limitations in the study design or methodology; for example, soil ingestion by children.

1.11. AGGREGATE AND CUMULATIVE EXPOSURES

The U.S. EPA recognizes that individuals may be exposed to mixtures of chemicals both indoors and outdoors through more than one pathway. New directions in risk assessments in the U.S. EPA put more emphasis on total exposures via multiple pathways (U.S. EPA, 2007a, 2003c). Assessments that evaluate a single agent or stressor across multiple routes are not considered cumulative risk assessments. These are defined by the Food Quality Protection Act as aggregate risk assessments and can provide useful information to cumulative assessments (U.S. EPA, 2003c). Concepts and considerations to conduct aggregate risk assessments are provided in the U.S. EPA document entitled *General Principles for Performing Aggregate Exposure and Risk Assessments* (U.S. EPA, 2001a).

Cumulative exposure is defined as the exposure to multiple agents or stressors via multiple routes. In the context of risk assessment, it means that risks from multiple routes and agents need to be combined, not necessarily added (U.S. EPA, 2003b). Analysis needs to be conducted on how the various agents and stressors interact (U.S. EPA, 2003b).

In order to achieve effective risk assessment and risk management decisions, all media and routes of exposure should be assessed (NRC, 2009, 1991). Over the last several years, the U.S. EPA has developed a methodology for assessing risk from multiple chemicals (U.S. EPA, 2000c, 1986a). For more information, refer to the U.S. EPA's Framework for Cumulative Risk Assessment (U.S. EPA, 2003b). The recent report by the NAS also recommends the development of approaches to incorporate the interactions between chemical and non-chemical stressors (NRC, 2009).

Chapter 1—Introduction

1.12. ORGANIZATION OF THE HANDBOOK

All the chapters of this handbook have been organized in a similar fashion. An introduction is provided that discusses some general background information about the exposure factor. This discussion is followed by the recommendations for that exposure factor including summary tables of the recommendations and confidence ratings. The goal of the summary tables is to present the data in a simplified fashion by providing mean and upper percentile estimates and referring the reader to more detailed tables with more percentile estimates or other demographic information (e.g., sex) at the end of the chapter. Because of the large number of tables in this handbook, tables that include information other than the recommendations and confidence ratings are presented at the end of each chapter, before the appendices, if any. Following the recommendations, the key studies are summarized. Relevant data on the exposure factor are also provided. These data are presented to provide the reader with added perspective on the current state-of-knowledge pertaining to the exposure factor of interest. Summaries of the key and relevant studies include discussions about their strengths and limitations. Note that because the studies often were performed for reasons unrelated to developing the factor of interest, the attributes that were characterized as limitations might not be limitations when viewed in the context of the study's original purpose.

The handbook is organized as follows:

Chapter 1	Introduction—includes discussions about general concepts in exposure assessments as well as the purpose, scope, and contents of the handbook.
Chapter 2	Variability and Uncertainty—provides a brief overview of the concepts of variability and uncertainty and directs the reader to other references for more in-depth information.
Chapter 3	Ingestion of Water and Other Select Liquids—provides information on drinking water consumption and data on intake of select liquids for the general population and various demographic groups; also provides data on intake of water while swimming.

Chapter 4	Non-dietary Ingestion—presents data on mouthing behavior necessary to estimate non-dietary exposures.
Chapter 5	Soil and Dust Ingestion—provides information on soil and dust ingestion for both adults and children.
Chapter 6	Inhalation Rates—presents data on average daily inhalation rates and activity-specific inhalation rates for the general population and various demographic groups.
Chapter 7	Dermal Exposure Factors—presents information on body surface area and solids adherence to the skin, as well as data on other non-chemical-specific factors that may affect dermal exposure.
Chapter 8	Body Weight—provides data on body weight for the general population and various demographic groups.
Chapter 9	Intake of Fruits and Vegetables—provides information on total fruit and vegetable consumption as well as intake of individual fruits and vegetables for the general population and various demographic groups.
Chapter 10	Intake of Fish and Shellfish—provides information on fish consumption for the general population, recreational freshwater and marine populations, and various demographic groups.
Chapter 11	Intake of Meats, Dairy Products, and Fats—provides information on meat, dairy products, and fats consumption for the general population and various demographic groups.
Chapter 12	Intake of Grain Products—provides information on grain consumption for the general population and various demographic groups.
Chapter 13	Intake of Home-produced Foods—provides information on home-produced food consumption for the general population and various demographic groups.
Chapter 14	Total Food Intake—provides information on total food consumption for the general population and various demographic groups; information on the composition of the diet is also provided.

Chapter 15	Human Milk Intake—presents data on human milk consumption for infants at various life stages.
Chapter 16	Activity Factors—presents data on activity patterns for the general population and various demographic groups.
Chapter 17	Consumer Products—provides information on frequency, duration, and amounts of consumer products used.
Chapter 18	Life Expectancy—presents data on the projected length of a lifetime, based on age and demographic factors.
Chapter 19	Building Characteristics—presents information on both residential and commercial building characteristics necessary to assess exposure to indoor air pollutants.

Figure 1-3 provides a schematic diagram that shows the linkages of a select number of exposure pathways with the exposure factors presented in this handbook and the corresponding exposure routes. Figure 1-4 provides a roadmap to assist users of this handbook in locating recommended values and confidence ratings for the various exposure factors presented in these chapters.

Chapter 1—Introduction

Table 1-2. Criteria Used to Rate Confidence in Recommended Values

General Assessment Factors	Elements Increasing Confidence	Elements Decreasing Confidence
Soundness <i>Adequacy of Approach</i> <i>Minimal (or defined) Bias</i>	<p>The studies used the best available methodology and capture the measurement of interest.</p> <p>As the sample size relative to that of the target population increases, there is greater assurance that the results are reflective of the target population.</p> <p>The response rate is greater than 80% for in-person interviews and telephone surveys, or greater than 70% for mail surveys.</p> <p>The studies analyzed primary data.</p> <p>The study design minimizes measurement errors.</p>	<p>There are serious limitations with the approach used; study design does not accurately capture the measurement of interest.</p> <p>Sample size too small to represent the population of interest.</p> <p>The response rate is less than 40%.</p> <p>The studies are based on secondary sources.</p> <p>Uncertainties with the data exist due to measurement error.</p>
Applicability and Utility <i>Exposure Factor of Interest</i> <i>Representativeness</i> <i>Currency</i> <i>Data Collection Period</i>	<p>The studies focused on the exposure factor of interest.</p> <p>The studies focused on the U.S. population.</p> <p>The studies represent current exposure conditions.</p> <p>The data collection period is sufficient to estimate long-term behaviors.</p>	<p>The purpose of the studies was to characterize a related factor.</p> <p>Studies are not representative of the U.S. population.</p> <p>Studies may not be representative of current exposure conditions.</p> <p>Shorter data collection periods may not represent long-term exposures.</p>
Clarity and Completeness <i>Accessibility</i> <i>Reproducibility</i> <i>Quality Assurance</i>	<p>The study data are publicly available.</p> <p>The results can be reproduced, or methodology can be followed and evaluated.</p> <p>The studies applied and documented quality assurance/quality control measures.</p>	<p>Access to the primary data set was limited.</p> <p>The results cannot be reproduced, the methodology is hard to follow, and the author(s) cannot be located.</p> <p>Information on quality assurance/control was limited or absent.</p>

Table 1-2. Criteria Used to Rate Confidence in Recommended Values (continued)

General Assessment Factors	Increasing Confidence	Decreasing Confidence
Variability and Uncertainty <i>Variability in Population</i>	The studies characterize variability in the population studied.	The characterization of variability is limited.
<i>Uncertainty</i>	The uncertainties are minimal and can be identified. Potential bias in the studies are stated or can be determined from the study design.	Estimates are highly uncertain and cannot be characterized. The study design introduces biases in the results.
Evaluation and Review <i>Peer Review</i>	The studies received a high level of peer review (e.g., they are published in peer-reviewed journals).	The studies received limited peer review.
<i>Number and Agreement of Studies</i>	The number of studies is greater than three. The results of studies from different researchers are in agreement.	The number of studies is one. The results of studies from different researchers are in disagreement.

Table 1-3. Age-Dependent Potency Adjustment Factor by Age Group for Mutagenic Carcinogens

Exposure Age Group ^a	Exposure Duration (year)	Age-Dependent Potency Adjustment Factor
Birth to <1 month	0.083	10×
1 <3 months	0.167	10×
3 <6 months	0.25	10×
6 <12 months	0.5	10×
1 to <2 years	1	10×
2 to <3 years	1	3×
3 to <6 years	3	3×
6 to <11 years	5	3×
11 to <16 years	5	3×
16 to <21 years	5	1×
≥21 years (21 to <70 years)	49	1×
^a U.S. EPA's recommended childhood age groups (excluding ages >21 years).		

Chapter 1—Introduction

Figure 1-2. Exposure-Dose-Effect Continuum.

Source: Redrawn from U.S. EPA (2003c); WHO (2006); Ott (2007).

The exposure-dose-effect continuum depicts the trajectory of an agent from its source to an effect. The agent can be transformed and transported through the environment via air, water, soil, dust, and diet. Individuals can become in contact with the agent through inhalation, ingestion, or skin/eye contact. The individual's physiology, behavior, and activity patterns as well as the concentration of the agent will determine the magnitude, frequency, and duration of the exposure. The exposure becomes an absorbed dose once the agent crosses the absorption barrier (i.e., skin, lungs, eyes, gastrointestinal tract, placenta). Interactions of the chemical or its metabolites with a target tissue may lead to an adverse health outcome. The text under the boxes indicates the specific information that may be needed to characterize each step in the exposure-dose-effect continuum.

APPENDIX 1A

**RISK CALCULATIONS USING EXPOSURE FACTORS HANDBOOK DATA AND DOSE-RESPONSE
INFORMATION FROM THE INTEGRATED RISK INFORMATION SYSTEM (IRIS)**

**APPENDIX 1A—RISK CALCULATIONS
USING EXPOSURE FACTORS HANDBOOK
DATA AND DOSE-RESPONSE INFORMATION
FROM THE INTEGRATED RISK
INFORMATION SYSTEM (IRIS)****1A-1. INTRODUCTION**

When estimating risk to a specific population from chemical exposure, whether it is the entire national population or some smaller population of interest, exposure data (either from this handbook or from other sources) must be combined with dose-response information. The dose-response information typically comes from the Integrated Risk Information System (IRIS) database, which maintains a list of toxicity (i.e., dose-response) values for a number of chemical agents (www.epa.gov/iris). Care must be taken to ensure that population parameters from the dose-response assessment are consistent with the population parameters used in the exposure analysis. This appendix discusses procedures for ensuring this consistency.

The U.S. EPA's approach to estimating risks associated with toxicity from non-cancer effects is fundamentally different from its approach to estimating risks associated with toxicity from carcinogenic effects. One difference is that different assumptions are made regarding the mode of action that is involved in the generation of these two types of effects. For non-cancer effects, the Agency assumes that these effects are produced through a non-linear (e.g., "threshold") mode of action (i.e., there exists a dose below which effects do not occur) (U.S. EPA, 1993). For carcinogenic effects, deemed to operate through a mutagenic mode of action or for which the mode of action is unknown, the Agency assumes there is the absence of a "threshold" (i.e., there exists no level of exposure that does not pose a small, but finite, probability of generating a carcinogenic response).

For carcinogens, quantitative estimates of risks for the oral route of exposure are generated using cancer slope factors. The cancer slope factor is an upper bound estimate of the increase in cancer risk per unit of dose and is typically expressed in units of $(\text{mg/kg-day})^{-1}$. Because dose-response assessment typically involves extrapolating from laboratory animals to humans, a human equivalent dose (HED) is calculated from the animal data in order to derive a cancer slope factor that is appropriately expressed in human equivalents. The Agency endorses a hierarchy of approaches to derive human equivalent oral exposures from data in laboratory animal species, with the preferred approach being physiologically based toxicokinetic (PBTK) modeling. In the absence

of PBTK modeling, U.S. EPA advocates using body weight to the $3/4$ power ($\text{BW}^{3/4}$) as the default scaling factor for extrapolating toxicologically equivalent doses of orally administered agents from animals to humans (U.S. EPA, 2011).

Application of the $\text{BW}^{3/4}$ scaling factor is based on adult animal and human body weights to adjust for dosimetric differences (predominantly toxicokinetic) between adult animals and humans (U.S. EPA, 2011). The internal dosimetry of other life stages (e.g., children, pregnant or lactating mothers) may be different from that of an adult (U.S. EPA, 2011). In some cases where data are available on effects in infants or children, adult PBTK models (if available) could be parameterized in order to predict the dose metric in children, as described in U.S. EPA's report, *A Framework for Assessing Health Risk of Environmental Exposures to Children* (U.S. EPA, 2011, 2006b). However, more research is needed to develop models for children's dosimetric adjustments across life stages and experimental animal species (U.S. EPA, 2006b).

In Summary:

- *No correction factors are applied to RfDs and RfCs when combined with exposure information from specific populations of interest.*
- *ADAFs are applied to oral slope factors, drinking water unit risks, and inhalation unit risks for chemicals with a mutagenic mode of action as in Table 1A-1.*
- *Correction factors are applied to water unit risks for both body weight and water intake rate for specific populations of interest.*

For cancer data from chronic animal studies, no explicit lifetime adjustment is necessary when extrapolating to humans because the assumption is that events occurring in a lifetime animal bioassay will occur with equal probability in a human lifetime. For cancer data from human studies (either occupational or general population), the Agency typically makes no explicit assumptions regarding body weight or human lifetime. For both of these parameters, there is an implicit assumption that the exposed population of interest has the same characteristics as the population analyzed by the Agency in deriving its dose-response information. In the rare situation where this assumption is known to be violated, the Agency has made appropriate

Chapter 1—Introduction

corrections so that the dose-response parameters are representative of the national average population.

For carcinogens acting through a mutagenic MOA, where chemical-specific data concerning early life susceptibility are lacking, early life susceptibility should be assumed, and the following ADAFs should be applied to the oral cancer slope factor, drinking water unit risks, and inhalation unit risks as described in the *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* (U.S. EPA, 2005e) and summarized in Section 1.9 of this handbook:

- 10-fold for exposures occurring before 2 years of age;
- 3-fold for exposures occurring between the ages of 2 and 16 years of age; and
- no adjustment for exposures occurring after 16 years of age.

In addition to cancer slope factors, dose-response measures for carcinogens are also expressed as increased cancer risk per unit concentration for estimating risks from exposure to substances found in air or water (U.S. EPA, 1992b). For exposure via inhalation, this dose-response value is referred to as an IUR and is typically expressed in units of $(\mu\text{g}/\text{m}^3)^{-1}$. For exposure via drinking water, this dose-response value is termed the drinking water unit risk (U.S. EPA, 1992b). These unit risk estimates implicitly assume standard adult intake rates (i.e., 2 L/day of drinking water; 20-m³/day inhalation rate). It is generally not appropriate to adjust the inhalation unit risk for different body weights or inhalation rates because the amount of chemical that reaches the target site is not a simple function of two parameters (U.S. EPA, 2009b). For drinking water unit risks, however, it would be appropriate for risk assessors to replace the standard intake rates with values representative of the exposed population of interest, as described in Section 1A-2 and Table 1A-1 below (U.S. EPA, 2005e).

As indicated above, for non-cancer effects, dose-response assessment is based on a threshold hypothesis, which holds that there is a dose above which effects (or their precursors) begin to occur. The U.S. EPA defines the RfD as “an estimate of a daily oral exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. It is derived from a benchmark dose lower confidence limit (BMDL), a no-observed-adverse-effect level, a

lowest-observed-adverse-effect level, or another suitable point of departure, with uncertainty/variability factors applied to reflect limitations of the data used.” The point of departure on which the RfD is based can come directly from animal dosing experiments or occasionally from human studies followed by application of uncertainty factors to reflect uncertainties such as extrapolating from subchronic to chronic exposure, extrapolating from animals to humans, and deficiencies in the toxicity database. Consistent with the derivation of oral cancer slope factors noted above, the U.S. EPA prefers the use of PBTK modeling to derive HEDs to extrapolate from data in laboratory animal species, but in the absence of a PBTK model, endorses the use of BW^{3/4} as the appropriate default scaling factor for use in calculating HEDs for use in derivation of the oral RfD (U.S. EPA, 2011). Body-weight scaling using children’s body weight may not be appropriate in the derivation of the RfD because RfDs are already intended to be protective of the entire population including susceptible populations such as children and other life stages (U.S. EPA, 2011). Uncertainty factors are used to account for intraspecies variation in susceptibility (U.S. EPA, 2011). As indicated above, body-weight scaling is meant to predominantly address toxicokinetic differences between animals and humans and can be viewed as a dosimetric adjustment factor (DAF). Data on toxicodynamic processes needed to assess the appropriateness of body-weight scaling for early life stages are not currently available (U.S. EPA, 2011).

The procedure for deriving dose-response values for non-cancer effects resulting from the inhalation route of exposure (i.e., RfCs) differs from the procedure used for deriving dose-response values for non-cancer effects resulting from the oral route of exposure (i.e., RfDs). The difference lies primarily in the source of the DAFs that are employed. As with the RfD, the U.S. EPA prefers the application of PBTK modeling in order to extrapolate laboratory animal exposure concentrations to HECs for the derivation of an RfC. In the absence of a PBTK model, the U.S. EPA advocates the use of a default procedure for deriving HECs that involve application of DAFs. This procedure uses species-specific physiologic and anatomic factors relevant to the physical form of the pollutant (i.e., particulate or gas) and categorizes the pollutant with regard to whether it elicits a response either locally (i.e., within the respiratory tract) or remotely (i.e., extrarrespiratory). These factors are combined in determining an appropriate DAF. The default dosimetric adjustments and physiological parameters used in RfC derivations assume an adult male with an air intake rate of 20

m³/day and a body weight of 70 kg (U.S. EPA, 1994). Assumptions for extrathoracic, tracheobronchial, and pulmonary surface areas are also made based on an adult male (U.S. EPA, 1994). For gases, the parameters needed for deriving a DAF include species-to-species ratios of blood:gas partition coefficients. For particulates, the DAF is termed the regional deposition dose ratio and is derived from parameters that include region-specific surface areas, the ratio of animal-to-human minute volumes, and the ratio of animal-to-human regional fractional deposition. If DAFs are not available, simple ventilation rate adjustments can be made in generating HECs for use in derivation of the RfC (U.S. EPA, 2006b). Toxicity values (RfCs) derived using the default approach from the inhalation dosimetry methodology described in U.S. EPA (1994) are developed for the human population as a whole, including sensitive groups. Therefore, no quantitative adjustments of these toxicity values are needed to account for different ventilation rates or body weights of specific age groups (U.S. EPA, 2009b).

1A-2. CORRECTIONS FOR DOSE-RESPONSE PARAMETERS

The correction factors for the dose-response values tabulated in the IRIS database for non-cancer and carcinogenic effects are summarized in Table 1A-1. Use of these correction factors is necessary to avoid introducing errors into the risk analysis. This table is applicable in most cases that will be encountered, but it is not applicable when (a) the effective dose has been derived with a PBTK model, and (b) the dose-response data have been derived from human data. In the former case, the population parameters need to be incorporated into the model. In the latter case, the correction factor for the dose-response parameter must be evaluated on a case-by case basis by examining the specific data and assumptions employed in the derivation of the parameter.

It is important to note that the 2 L/day per capita water intake assumption is closer to a 90th percentile intake value than an average value. If an average measure of exposure in adults is of interest, the drinking water unit risk can be adjusted by multiplying it by 1.0/2 or 0.5, where 1.0 L/day is the average per capita water intake for adults ≥21 years old (see Chapter 3 of this handbook). If the population of interest is children, rather than adults, then a body-weight adjustment is also necessary. For example, the average water intake for children 3 to <6 years of age is 0.33 L/day (see Chapter 3 of this handbook), and the average body weight in this age

group is 18.6 kg (see Chapter 8 of this handbook). The water unit risk then needs to be adjusted by multiplying it by an adjustment factor derived from these age-group-specific values and calculated using the formula from Table 1A-1 as follows:

Water unit risk correction factor =

$$\left[\frac{0.33(L/day)}{2(L/day)} \right] \times \left[\frac{70(kg)}{18.6(kg)} \right] = 0.6 \quad (\text{Eqn. 1A-1})$$

Chapter 2—Variability and Uncertainty

2. VARIABILITY AND UNCERTAINTY

Accounting for variability and uncertainty is fundamental to exposure assessment and risk analysis. While more will be said about the distinction between variability and uncertainty in Section 2.1, it is useful at this point to motivate the treatment of variability and uncertainty in exposure assessment. Given that exposure and susceptibility to exposure is usually not uniform across a population, accounting for variability is the means by which a risk assessor properly accounts for risk to the population as a whole. However, a risk assessment usually involves uncertainties about the precision of a risk estimate. A heuristic distinction between variability and uncertainty is to consider uncertainty as a lack of knowledge about factors affecting exposure or risk, whereas variability arises from heterogeneity across people, places, or time.

Properly addressing variability and uncertainty will increase the likelihood that results of an assessment or analysis will be used in an appropriate manner. Characterizing and communicating variability and uncertainty should be done throughout all the components of the risk assessment process (NRC, 1994). Thus, careful consideration of the variability and uncertainty associated with the exposure factors information used in an exposure assessment is of utmost importance. Proper characterization of variability and uncertainty will also support effective communication of risk estimates to risk managers and the public.

This chapter provides an overview of variability and uncertainty in the context of exposure analysis and is not intended to present specific methodological guidance. It is intended to acquaint the exposure assessor with some of the fundamental concepts of variability and uncertainty as they relate to exposure assessment and the exposure factors presented in this handbook. It also provides summary descriptions of methods and considerations for evaluating and presenting the uncertainty associated with exposure estimates and a bibliography of references on a wide range of methodologies concerned with the application of variability and uncertainty analysis in exposure assessment. Subsequent sections in this chapter are devoted to the following topics:

- 2.1 Variability versus uncertainty;
- 2.2 Types of variability;
- 2.3 Addressing variability;
- 2.4 Types of uncertainty;
- 2.5 Reducing uncertainty;
- 2.6 Analyzing variability and uncertainty;

- 2.7 Literature review of variability and uncertainty analysis;
- 2.8 Presenting results of variability and uncertainty analyses; and
- 2.9 References.

There are numerous ongoing efforts in the U.S. Environmental Protection Agency (EPA) and elsewhere to further improve the characterization of variability and uncertainty. The U.S. EPA's Risk Assessment Forum has established guidelines for the use of probabilistic techniques (e.g., Monte Carlo analysis) to better assess and communicate risk (U.S. EPA, 1997a, b). The U.S. EPA's Science Policy Council is developing white papers on the use of expert elicitation for characterizing uncertainty in risk assessments. Expert judgment has been used in the past by some regulatory agencies when limited data or knowledge results in large uncertainties (NRC, 2009). The International Program on Chemical Safety (IPCS) has developed guidance on characterizing and communicating uncertainty in exposure assessment (WHO, 2008). Suggestions for further reading on variability and uncertainty include Babendreier and Castleton (2005), U.S. EPA (2008), Saltelli and Annoni (2010), Bogen et al. (2009), and Refsgaard et al. (2007).

2.1. VARIABILITY VERSUS UNCERTAINTY

While some authors have treated variability as a specific type or component of uncertainty, the U.S. EPA (1995), following the NRC (1994) recommendation, has advised the risk assessor to distinguish between variability and uncertainty. Variability is a quantitative description of the range or spread of a set of values. Common measures include variance, standard deviation, and interquartile range. Variability arises from heterogeneity across individuals, places, or time. Uncertainty can be defined as a lack of precise knowledge, either qualitative or quantitative. In the context of exposure assessment, data uncertainty refers to the lack of knowledge about factors affecting exposure.

The key difference between uncertainty and variability is that variability cannot be reduced, only better characterized (NRC, 2009).

We will describe a brief example of human water consumption in relation to lead poisoning to help distinguish between variability and parameter uncertainty (a particular type of uncertainty). We might characterize the variability of water consumption across individuals by sampling from a population and measuring water consumption. From

Chapter 2—Variability and Uncertainty

this sample, we obtain useful statistics on the variability of water consumption, which we assume here represents the population of interest. There may be similar statistics on the variability in the concentration of lead in the water consumed. A risk model may include a factor (i.e., dose response, representing the absorption of lead from ingested water to blood). The dose response may be represented by a constant in a risk model. However, knowledge about the dose response may be uncertain, motivating an uncertainty analysis. Dose response values are often relatively uncertain compared to exposure parameters. Therefore, in the above example, a high uncertainty surrounds the absorption of lead, whereas there is less uncertainty associated with the parameters of water consumption (i.e., population mean and standard deviation). One challenge in modeling dose-response uncertainty is the lack of consensus on its treatment.

Most of the data presented in this handbook concern variability. Factors contributing to variability in risk include variability in exposure potential (e.g., differing behavioral patterns, location), variability in susceptibility due to endogenous factors (e.g., age, sex, genetics, pre-existing disease), variability in susceptibility due to exogenous factors (e.g., exposures to other agents) (NRC, 2009).

2.2. TYPES OF VARIABILITY

Variability in exposure is dependent on contaminant concentrations as well as variability in human exposure factors. Human exposure factors may vary because of an individual's location, specific exposure time, or behavior. However, even if all of those factors were constant across a set of individuals, there could still be variability in risk because of variability in susceptibilities. Variations in contaminant concentrations and human exposure factors are not necessarily independent. For example, contaminant concentrations and behavior might be correlated.

A useful way to think about sources of variability is to consider these four broad categories:

- 1) Spatial variability: variability across locations;
- 2) Temporal variability: variability over time;
- 3) Intra-individual variability: variability within an individual; and
- 4) Inter-individual variability: variability across individuals.

Spatial variability refers to differences that may occur because of location. For example, outdoor pollutant levels can be affected at the regional level by industrial activities and at the local level by activities of individuals. In general, higher exposures tend to be associated with closer proximity to a pollutant source, whether it is an industrial plant or related to a personal activity such as showering or gardening. Susceptibilities may vary across locations, for example, some areas have particularly high concentrations of a younger or older population.

Temporal variability refers to variations over time, whether long- or short-term. Different seasons may cause varied exposure to pesticides, bacteria, or indoor air pollution, each of which might be considered an example of long-term variability. Examples of short-term variability are differences in industrial or personal activities on weekdays versus weekends or at different times of the day.

Intra-individual variability is a function of fluctuations in an individual's physiologic (e.g., body weight), or behavioral characteristics (e.g., ingestion rates or activity patterns). For example, patterns of food intake change from day to day and may do so significantly over a lifetime. Intra-individual variability may be associated with spatial or temporal variability. For example, because an individual's dietary intake may reflect local food sources, intake patterns may change if place of residence changes. Also, physical activity may vary depending upon the season, life stage, or other factors associated with temporal variability.

Inter-individual variability refers to variation across individuals. Three broad categories include the following:

- 1) individual characteristics such as sex, age, race, height, or body weight (including any obesity), phenotypic genetic expression, and pathophysiological conditions;
- 2) individual behaviors such as activity patterns, and ingestion rates; and
- 3) susceptibilities due to such things as life stage or genetic predispositions.

Inter-individual variability may also be related to spatial and temporal factors.

2.3. ADDRESSING VARIABILITY

In this handbook, variability is addressed by presenting data on the exposure factors in one of the following three ways: (1) as tables with percentiles or ranges of values for various age groups or other

Chapter 2—Variability and Uncertainty

populations, (2) as probability distributions with specified parameter estimates and related confidence intervals, or (3) as a qualitative discussion. One approach to exposure assessment is to assume a single value for a given exposure level, often the mean or median, in order to calculate a single point estimate of risk. Often however, individuals vary in their exposure, and an exposure assessment would be remiss to exclude other possible exposure levels. Thus, an exposure assessment often involves a quantification of the exposure at high levels of the exposure factor, i.e., 90th, 95th, and 99th percentiles, and not only the mean or median exposure. Where possible, confidence limits for estimated percentiles should be provided. The U.S. EPA's approach to variability assessment is described in *Risk Assessment Principles and Practices: Staff Paper* (U.S. EPA, 2004b). Accounting for variability in an exposure assessment may be limited to a deterministic model in which high-end values are used or may involve a probabilistic approach, e.g., Monte Carlo Analysis (U.S. EPA, 1997a).

Populations are by nature heterogeneous. Characterizing the variability in the population can assist in focusing analysis on segments of the population that may be at higher risk from environmental exposure. Although population variability cannot be reduced, data variability can be lessened by disaggregating the population into segments with similar characteristics.

Although much of this handbook is concerned with variability in exposure, it is critical to note that there are also important variations among individuals in a population with respect to susceptibility. As noted in NRC (2009), people differ in susceptibility to the toxic effects of a given chemical exposure because of such factors as genetics, lifestyle, predisposition to diseases and other medical conditions, and other chemical exposures that influence underlying toxic processes. Susceptibility is also a function of life stages, e.g., children may be at risk of high exposure relative to adults. Susceptibility factors are broadly considered to include any factor that increases (or decreases) the response of an individual to a dose relative to a typical individual in the population. The distribution of disease in a population can result not only from differences in susceptibility, but from differing exposures of individuals and target groups in a population. Taken together, variations in disease susceptibility and exposure potential give rise to potentially important variations in vulnerability to the effects of environmental chemicals (NRC, 2009).

2.4. TYPES OF UNCERTAINTY

Uncertainty in exposure analysis is related to the lack of knowledge concerning one or more components of the assessment process. The U.S. EPA (1992) has classified uncertainty in exposure assessment into three broad categories: (1) scenario uncertainty, (2) parameter uncertainty, and (3) model uncertainty.

Scenario uncertainty

Scenario uncertainty arises from descriptive errors, aggregation errors, errors in professional judgment, and incomplete analysis. Descriptive errors are errors in information that translate into errors in the development of exposure pathways, scenarios, exposed population, and exposure estimates. Aggregation errors occur as a result of lumping approximations. These include, for example, assuming a homogeneous population, and spatial and temporal assumptions. Uncertainty can also arise from errors in professional judgment. These errors affect how an exposure scenario is defined, the selection of exposure parameters, exposure routes and pathways, populations of concern, chemicals of concern, and the selection of appropriate models. An incomplete analysis can also be a source of uncertainty because important exposure scenarios and susceptible populations may be overlooked.

Parameter uncertainty

Risk assessments depict reality interpreted through mathematical representations that describe major processes and relationships. Process or mechanistic models use equations to describe the processes that an environmental agent undergoes in the environment in traveling from the source to the target organism. Mechanistic models have also been developed to represent the toxicokinetic and toxicodynamic processes that take place inside the organism, leading to the toxic endpoint. The specific parameters of the equations found in these models are factors that influence the release, transport, and transformation of the environmental agent, the exposure of the target organism to the agent, transport and metabolism of the agent in the body, and interactions on the cellular and molecular levels. Empirical models are also used to define relationships between two values, such as the dose and the response. Uncertainty in parameter estimates stem from a variety of sources, including the following:

Chapter 2—Variability and Uncertainty

- a. Measurement errors:
 - 1. Random errors in analytical devices (e.g., imprecision of continuous monitors that measure stack emissions).
 - 2. Systemic bias (e.g., estimating inhalation from indoor ambient air without considering the effect of volatilization of contaminants from hot water during showers).
- b. Use of surrogate data for a parameter instead of direct analysis of it (e.g., use of standard emission factors for industrialized processes).
- c. Misclassification (e.g., incorrect assignment of exposures of subjects in historical epidemiologic studies due to faulty or ambiguous information).
- d. Random sampling error (e.g., variation in estimates due to who was randomly selected).
- e. Non-representativeness with regard to specified criteria (e.g., developing emission factors for dry cleaners based on a sample of “dirty” plants that do not represent the overall population of plants).
- f. Extent of (dis)aggregation used in the model (e.g., whether to break up the fat compartment into subcutaneous and abdominal fat in a physiologically based pharmacokinetic, or PBPK, model).

Although difficult to quantify, model uncertainty is inherent in risk assessment that seeks to capture the complex processes impacting release, environmental fate and transport, exposure, and exposure response.

2.5. REDUCING UNCERTAINTY

Identification of the sources of uncertainty in an exposure assessment is the first step in determining how to reduce uncertainty. Because uncertainty in exposure assessments is fundamentally tied to a lack of knowledge concerning important exposure factors, strategies for reducing uncertainty often involve the application of more resources to gather either more or targeted data. Example strategies to reduce uncertainty include (1) collecting new data, (2) implementing an unbiased sample design, (3) identifying a more direct measurement method or a more appropriate target population, (4) using models to estimate missing values, (5) using surrogate data, (6) using default assumptions, (7) narrowing the scope of the assessment, and (8) obtaining expert elicitation. The best strategy likely depends on a combination of resource availability, time constraints, and the degree of confidence necessary in the results.

2.6. ANALYZING VARIABILITY AND UNCERTAINTY

There are different strategies available for addressing variability and uncertainty that vary in their level of sophistication. The level of effort required to conduct the analysis needs to be balanced against the need for transparency and timeliness.

Exposure assessments are often developed in a tiered approach. The initial tier usually screens out the exposure scenarios or pathways that are not expected to pose much risk, to eliminate them from more detailed, resource-intensive review. Screening-level assessments typically examine exposures on the high end of the expected exposure distribution. Because screening-level analyses usually are included in the final exposure assessment, it may contain scenarios that differ in sophistication, data quality, and amenability to quantitative expressions of variability or uncertainty. Several approaches can be used to analyze uncertainty in parameter values. When uncertainty is high, for example, an assessor

Model uncertainty

Model uncertainties arise because of gaps in the scientific theory that is required to make predictions on the basis of causal inferences. Common types of model uncertainties in various risk assessment-related activities include the following:

- a. Relationship errors (e.g., incorrectly inferring the basis of correlations between chemical structure and biological activity).
- b. Oversimplified representations of reality (e.g., representing a three-dimensional aquifer with a two-dimensional mathematical model).
- c. Incompleteness, i.e., exclusion of one or more relevant variables (e.g., relating asbestos to lung cancer without considering the effect of smoking on both those exposed to asbestos and those unexposed).
- d. Use of surrogate variables for ones that cannot be measured (e.g., using wind speed at the nearest airport as a proxy for wind speed at the facility site).
- e. Failure to account for correlations that cause seemingly unrelated events to occur more frequently than expected by chance (e.g., two separate components of a nuclear plant are both missing a particular washer because the same newly hired assembler put them together).

Chapter 2—Variability and Uncertainty

may set order-of-magnitude bounding estimates of parameter ranges (e.g., from 0.1 to 10 liters for daily water intake). Another method may involve setting a range for each parameter as well as point estimates for certain parameters determined by available data or professional judgment.

A sensitivity analysis can be used to determine which parameters and exposures have the most impact on an exposure assessment. General concepts in sensitivity analysis are described in Saltelli et al. (2008). The International Program on Chemical Safety proposes a four-tier approach for addressing uncertainty and variability (WHO, 2006). The four tiers are similar to those proposed in U.S. EPA (1992) and include the use of default assumptions; a qualitative, systematic identification and characterization of uncertainty; a qualitative evaluation of uncertainty using bounding estimates, interval analysis, and sensitivity analysis; and a more sophisticated one- or two-stage probabilistic analysis (WHO, 2006).

Practical considerations regarding an uncertainty analysis include whether uncertainty would affect the results in a non-trivial way; an issue might be addressed by an initial sensitivity analysis in which a range of values are explored. An initial analysis of this sort might be facilitated by use of Microsoft Excel. Probabilistic risk analysis techniques are becoming more widely applied and are increasing in the level of sophistication. Bedford and Cooke (2001) describe in more detail the main tools and modeling techniques available for probabilistic risk analysis (Bedford and Cooke, 2001). If a probabilistic approach is pursued, another consideration is the choice of a software package. Popular software packages for Monte Carlo analysis range from the more general: Fortran, Mathematica, R, and SAS to the more specific: Crystal Ball, @Risk (Palisade Corporation), RISKMAN (PLG Inc.), and SimLab (Saltelli et al., 2004).

Increasingly, probabilistic methods are being utilized to analyze variability and uncertainty independently as well as simultaneously. It is sometimes challenging to distinguish between variability and parameter uncertainty in this context as both can involve the distributions of a random variable. For instance, parameter uncertainty can be estimated by the standard error of a random variable (itself a function of variability). Note that in this case, increasing the sample size necessarily reduces the parameter uncertainty (i.e., standard error).

More sophisticated techniques that attempt to simultaneously model both variability and uncertainty by sampling from their respective probability distributions are known as two-stage

probabilistic analysis, or two-stage Monte Carlo analysis, which is discussed in great detail in Bogen and Spear (1987), Bogen (1990), Chapter 11 and Appendix I-3 of NRC (1994), and U.S. EPA (2001). These methods assume a probabilistic distribution for certain specified parameters. Random samples are drawn from each probabilistic distribution in a simulation and are used as input into a deterministic model. Analysis of the results from the simulations characterizes either the variability or uncertainty (or both) of the exposure assessment.

Through the implementation of computationally efficient Markov Chain Monte Carlo algorithms like Metropolis-Hastings, Bayesian methods offer an alternative approach to uncertainty analysis that is attractive in part because of increasing usability of software. For more on Bayesian methods, see Gelman et al. (2003), Gilks et al. (1995), Robert and Casella (2004).

The U.S. EPA has made significant efforts to use probabilistic techniques to characterize uncertainty. These efforts have resulted in documents such as the March 1997 *Guiding Principles for Monte Carlo Analysis* (U.S. EPA, 1997a), the May 1997 Policy Statement (U.S. EPA, 1997b), and the December 2001 Superfund document *Risk Assessment Guidance for Superfund: Volume III—Part A, Process for Conducting Probabilistic Risk Assessment* (U.S. EPA, 2001).

2.7. LITERATURE REVIEW OF VARIABILITY AND UNCERTAINTY ANALYSIS

There has been a great deal of recent scholarly research in the area of uncertainty with the widespread use of computer simulation. Some of this research also incorporates issues related to variability. The purpose of the literature review below is to give a brief description of notable developments. Section 2.9 provides references for further research.

Cox (1999) argues that, based on information theory, models with greater complexity lead to more certain risk estimates. This may only be true if there is some degree of certainty in the assumptions used by the model. Uncertainties associated with the model need to be evaluated (NRC, 2009). These methods were discussed in Bogen and Spear (1987), Cox and Baybutt (1981), Rish and Marnicio (1988), and U.S. EPA (1985). Seiler (1987) discussed the analysis of error propagation with respect to general mathematical formulations typically found in risk assessment, such as linear combinations, powers of one variable, and multiplicative normally distributed variables. Even for large and uncertain errors, the

Chapter 2—Variability and Uncertainty

formulations in Seiler (1987) are demonstrated to have practical value. Iman and Helton (1988) compared three methodologies for uncertainty and sensitivity analysis: (1) response surface analysis, (2) Latin hypercube sampling (with and without regression analysis), and (3) differential analysis. They found that Latin hypercube sampling with regression analysis had the best performance in terms of flexibility, estimate-ability, and ease of use. Saltelli (2002) and Frey (2002) offer views on the role of sensitivity analysis in risk assessment, and Frey and Patil (2002) compare methods for sensitivity analysis and recommend that two or more different sensitivity assessment methods should be used in order to obtain robust results. A Bayesian perspective on sensitivity analysis is described in Greenland (2001), who recommends that sensitivity analysis and Monte Carlo risk analysis should begin with specification of prior distributions, as in Bayesian analysis. Bayesian approaches to uncertainty analysis are described in Nayak and Kundu (2001).

Price et al. (1999) review the history of the inter-individual variability factor, as well as the relative merits of the sensitive population conceptual model versus the finite sample size model in determining the magnitude of the variability factor. They found that both models represent different sources of uncertainty and that both should be considered when developing inter-individual uncertainty factors. Uncertainties related to inter-individual and inter-species variability are treated in Hattis (1997) and Meek (2001), respectively. And Renwick (1999) demonstrates how inter-species and inter-individual uncertainty factors can be decomposed into kinetic and dynamic defaults by taking into account toxicodynamic and toxicokinetic differences. Burin and Saunders (1999) evaluate the robustness of the intra-species uncertainty factor and recommend intra-species uncertainty factoring in the range of 1-10.

Based on Monte Carlo analysis, Shlyakhter (1994) recommends inflation of estimated uncertainties by default safety factors in order to account for unsuspected uncertainties.

Jayjock (1997) defines uncertainty as either natural variability or lack of knowledge and also provides a demonstration of uncertainty and sensitivity analysis utilizing computer simulation. Additional approaches for coping with uncertainties in exposure modeling and monitoring are addressed by Nicas and Jayjock (2002).

Distributional risk assessment should be employed when data are available that support its use. Fayerweather et al. (1999) describe distributional risk assessment, as well as its strengths and

weaknesses. Exposure metrics for distributional risk assessment using log-normal distributions of time spent showering (Burmester, 1998a), water intake (Burmester, 1998c), and body weight (Burmester, 1998b; Burmester and Crouch, 1997) have been developed. The lognormal distribution provides a succinct mathematical form that facilitates exposure and risk analyses. The fitted lognormal distribution is an approximation that should be carefully evaluated. One approach is to compare the lognormal distribution with other distributions (e.g., Weibull, Gamma). This is the approach used by Jacobs et al. (1998) and U.S. EPA (2002) in developing estimates of fish consumption and U.S. EPA (2004a) and Kahn and Stralka (2009) for estimates of water ingestion. These estimates were derived from the Continuing Survey of Food Intake by Individuals (CSFII), which was a Nationwide statistical survey of the population of the United States conducted by the U.S. Department of Agriculture. The CSFII collected extensive information on food and beverage intake from a sample that represented the population of the United States, and the sample weights provided with the data supported the estimation of empirical distributions of intakes for the entire population and various target populations such as intake distributions by various age categories. Kahn and Stralka (2008) used the CSFII data to estimate empirical distributions of water ingestion by pregnant and lactating women and compared the results to those presented by Burmester (1998c). The comparison highlights the differences between the older data used by Burmester and the CSFII and the differences between fitted approximate lognormal distributions and empirical distributions. The CSFII also collected data on body weight self-reported by respondents that supported the estimation of body-weight distributions by age categories, which are presented in Kahn and Stralka (2009). Detailed summary tables of results based on the CSFII data used by Kahn and Stralka (2009) are presented in Kahn (2008) personal communication (Kahn, 2008).

When sensitivity analysis or uncertainty propagation analysis indicates that a parameter profoundly influences exposure estimates, the assessor should, if possible, develop a probabilistic description of its range. It is also possible to use estimates derived from a large-scale survey such as the CSFII as a basis for alternative parameter values that may be used in a sensitivity analysis. The CSFII provides the basis for an objective point of reference for food and beverage intake variables, which are critical components of many risk and exposure assessments. For example, an assumed value for a mean or upper percentile could be compared to a

Chapter 2—Variability and Uncertainty

suitable value from the CSFII to assess sensitivity. Deterministic and probabilistic approaches to risk assessment are reviewed for non-carcinogenic health effects in Kalbelah et al. (2003), with attention to quantifying sources of uncertainty. Kelly and Campbell (2000) review guidance for conducting Monte Carlo analysis and clarify the distinction between variability and uncertainty. This distinction is represented by two-stage Monte Carlo simulation, where a probability distribution represents variability in a population, while a separate distribution for uncertainty defines the degree of variation in the parameters of the population variability distribution. Another example of two-stage Monte Carlo simulation is given in Xue et al. (2006). Price et al. (1997) utilize a Monte Carlo approach to characterize uncertainties for a method aimed at estimating the probability of adverse, non-cancer health effects for exposures exceeding the reference dose. Their method relies on general toxicologic information for a compound, such as the no-observed-adverse-effect-level dose (NOAEL). Semple et al. (2003) examine uncertainty arising in reconstructed exposure estimates using Monte Carlo methods. Uncertainty in PBPK models is discussed in Simon (1997) and Bois (2010). Slob and Pieters (1998) propose replacing uncertainty factors with probabilistic uncertainty distributions and discuss how uncertainties may be quantified for animal NOAELs and extrapolation factors. Zheng and Frey (2005) demonstrate the use of Monte Carlo methods for characterizing uncertainty and emphasize that uncertainty estimates will be biased if contributions from sampling error and measurement error are not accounted for separately.

Distributional biometric data for probabilistic risk assessment are available for some exposure factors. Empirical distributions are provided in this handbook when available. If the data are unavailable or otherwise inadequate, expert judgment can be used to generate a subjective probabilistic representation. Such judgments should be developed in a consistent, well-documented manner. Morgan et al. (1990) and Rish (1988) describe techniques to solicit expert judgment, while Weiss (2001) demonstrates use of a Web-based survey.

Standard statistical methods may be less cumbersome than a probabilistic approach and may be preferred, if there are enough data to justify their use and they are sufficient to support the environmental decision needed. Epidemiologic analyses may, for example, be used to estimate variability in human populations, as in Peretz et al. (1997), who describe variation in exposure time. Sources of variation and uncertainty may also be

explored and quantified using a linear regression modeling framework, as in Robinson and Hurst (1997). A general framework for statistical assessment of uncertainty and variance is given for additive and multiplicative models in Rai et al. (1996) and Rai and Krewski (1998), respectively. Wallace and Williams (2005) describe a robust method for estimating long-term exposures based on short-term measurements.

In addition to the use of defaults and quantitative analysis, exposure and risk assessors often rely on expert judgment when information is insufficient to establish uncertainty bounds (NRC, 2009). There are, however, some biases introduced during expert elicitation. Some of these include availability, anchoring and adjustment, representativeness, disqualification, belief in “law of small numbers,” and overconfidence (NRC, 2009). Availability refers to the tendency to assign greater probability to commonly encountered or frequently mentioned events (NRC, 2009). Anchoring and adjustment is the tendency to be over-influenced by the first information seen or provided (NRC, 2009). Representativeness is the tendency to judge an event by reference to another (NRC, 2009). Disqualification is the tendency to ignore data or evidence that contradicts strongly held convictions (NRC, 2009). The belief in the “law of small numbers” is to believe that small samples from a population are more representative than is justified (NRC, 2009). Overconfidence is the tendency of experts to believe that their answers are correct (NRC, 2009).

2.8. PRESENTING RESULTS OF VARIABILITY AND UNCERTAINTY ANALYSES

The risk assessor is advised to distinguish between variability of exposure and associated uncertainties. A risk assessment should include three components involving elements of variability and uncertainty: (1) the estimated risk itself (X), (2) the level of confidence (Y) that the risk is no higher than X, and (3) the percent of the population (Z) that X is intended to apply to in a variable population (NRC, 1994). This information will provide risk managers with a better understanding of how exposures are distributed over the population and of the certainty of the exposure assessment.

Sometimes analyzing all exposure scenarios is unfeasible. At minimum, the assessor should describe the rationale for excluding reasonable exposure scenarios; characterize the uncertainty in these decisions as high, medium, or low; and state whether

Chapter 2—Variability and Uncertainty

they were based on data, analogy, or professional judgment. Where uncertainty is high, a sensitivity analysis can be used to estimate upper limits on exposure by way of a series of “what if” questions.

Although assessors have historically used descriptors (e.g., high-end, worst case, average) to communicate risk variability, the 1992 *Guidelines for Exposure Assessment* (U.S. EPA, 1992) established quantitative definitions for these risk descriptors. The data presented in this handbook are one of the tools available to exposure assessors to construct the various risk descriptors. A thorough risk assessment should include particular assumptions about human behavior and biology that are a result of variability. A useful example is given in NRC (1994):

“...a poor risk characterization for a hazardous air pollutant might say ‘The risk number R is a plausible upper bound.’” A better characterization would say, “The risk number R applies to a person of reasonably high-end behavior living at the fenceline 8 hours a day for 35 years.”

In addition to presenting variability in exposure, frequently, exposure assessments include an uncertainty analysis. An exposure assessment will include assumptions about the contaminant, contaminant exposure routes and pathways, location, time, population characteristics, and susceptibilities. Each of these assumptions may be associated with uncertainties. Uncertainties may be presented using a variety of techniques, depending on the requirements of the assessment, the amount of data available, and the audience. Simple techniques include risk designations, i.e., high, medium, or low (un)certainities. Sophisticated techniques may include quantitative descriptions of the uncertainty analysis or graphical representations.

The exposure assessor may need to make many decisions regarding the use of existing information in constructing scenarios and setting up the exposure equations. In presenting the scenario results, the assessor should strive for a balanced and impartial treatment of the evidence bearing on the conclusions with the key assumptions highlighted. For these key assumptions, one should cite data sources and explain any adjustments of the data.

The exposure assessor should describe the rationale for any conceptual or mathematical models. This discussion should address their verification and validation status, how well they represent the situation being assessed (e.g., average versus

high-end estimates), and any plausible alternatives in terms of their acceptance by the scientific community.

To the extent possible, this handbook provides information that can be used in a risk assessment to characterize variability, and to some extent, uncertainty. In general, variability is addressed by providing probability distributions, where available, or qualitative discussions of the data sets used. Uncertainty is addressed by applying confidence ratings to the recommendations provided for the various factors, along with detailed discussions of any limitations of the data presented.

DISCLAIMER

This document has been reviewed in accordance with U.S. Environmental Protection Agency policy and approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

TABLE OF CONTENTS

LIST OF TABLES.....	3-vi
LIST OF FIGURES.....	3-ix
 3. INGESTION OF WATER AND OTHER SELECT LIQUIDS	3-1
3.1. INTRODUCTION	3-1
3.2. RECOMMENDATIONS	3-2
3.2.1. Water Ingestion from Consumption of Water as a Beverage and from Food and Drink.....	3-2
3.2.2. Pregnant and Lactating Women	3-2
3.2.3. Formula-Fed Infants	3-3
3.2.4. Water Ingestion While Swimming or Diving.....	3-3
3.3. DRINKING WATER INGESTION STUDIES	3-13
3.3.1. Key Drinking Water Ingestion Study for the General Population	3-13
3.3.1.1. U.S. EPA Analysis of NHANES 2005–2010 Data	3-13
3.3.2. Relevant Drinking Water Ingestion Studies for the General Population	3-14
3.3.2.1. Wolf (1958)—Body Water Content	3-14
3.3.2.2. National Research Council (1977)—Drinking Water and Health	3-14
3.3.2.3. Pennington (1983)—Revision of the Total Diet Study Food List and Diets	3-15
3.3.2.4. U.S. EPA (1984)—An Estimation of the Daily Average Food Intake by Age and Sex for Use in Assessing the Radionuclide Intake of the General Population	3-15
3.3.2.5. Cantor et al. (1987)—Bladder Cancer, Drinking Water Source, and Tap Water Consumption.....	3-15
3.3.2.6. Ershow and Cantor (1989)—Total Water and Tap Water Intake in the United States: Population-Based Estimates of Quantities and Sources.....	3-16
3.3.2.7. Roseberry and Burmaster (1992)—Lognormal Distributions for Water Intake	3-16
3.3.2.8. Levy et al. (1995)—Infant Fluoride Intake from Drinking Water Added to Formula, Beverages, and Food.....	3-17
3.3.2.9. USDA (1995)—Food and Nutrient Intakes by Individuals in the United States, 1 Day, 1989–1991.....	3-17
3.3.2.10. U.S. EPA (1996)—Descriptive Statistics from a Detailed Analysis of the National Human Activity Pattern Survey (NHAPS) Responses.....	3-18
3.3.2.11. Heller et al. (2000)—Water Consumption and Nursing Characteristics of Infants by Race and Ethnicity	3-18
3.3.2.12. Marshall et al. (2003a)—Patterns of Beverage Consumption during the Transition Stage of Infant Nutrition	3-19
3.3.2.13. Marshall et al. (2003b)—Relative Validation of a Beverage Frequency Questionnaire in Children Aged 6 Months through 5 Years Using 3-Day Food and Beverage Diaries.....	3-20
3.3.2.14. Skinner et al. (2004)—Transition in Infants’ and Toddlers’ Beverage Patterns.....	3-20
3.3.2.15. Barraj et al. (2009)—Within-Day Drinking Water Consumption Patterns: Results from a Drinking Water Consumption Study	3-20
3.3.2.16. Zizza et al. (2009)—Total Water Intakes of Community-Living Middle-Old and Oldest-Old Adults	3-21
3.3.2.17. Sebastian et al. (2011)—Drinking Water Intake in the United States; Rosinger et al. (2016)—Daily Water Intake among U.S. Men and Women, 2009–2012	3-21

TABLE OF CONTENTS (CONTINUED)

	3.3.2.18. Kahn and Stralka (2009)—Estimated Daily Average per Capita Water Ingestion by Child and Adult Age Categories Based on USDA’s 1994–1996 and 1998 Continuing Survey of Food Intakes by Individuals and Supplemental Data, Kahn (2008).....	3-22
3.4.	PREGNANT AND LACTATING WOMEN.....	3-23
3.4.1.	Key Study on Pregnant and Lactating Women.....	3-23
3.4.1.1.	EPA Analysis of Consumption Data from 2005–2010 National Health and Nutrition Examination Survey	3-23
3.4.2.	Relevant Studies on Pregnant and Lactating Women.....	3-23
3.4.2.1.	Ershow et al. (1991)—Intake of Tap Water and Total Water by Pregnant and Lactating Women	3-23
3.4.2.2.	Shimokura et al. (1998)—Assessment of Water Use for Estimating Exposure to Tap Water Contaminants.....	3-24
3.4.2.3.	Zender et al. (2001)—Exposure to Tap Water during Pregnancy	3-24
3.4.2.4.	Forssén et al. (2007)—Predictors of Use and Consumption of Public Drinking Water among Pregnant Women; Forssén et al. (2009)—Variability and Predictors of Changes in Water Use during Pregnancy	3-24
3.4.2.5.	Kahn and Stralka (2008)—Estimates of Water Ingestion for Women in Pregnant, Lactating, and Nonpregnant and Nonlactating Child-Bearing Age Groups Based on USDA’s 1994–1996, 1998 CSFII	3-25
3.5.	FORMULA-FED INFANTS	3-25
3.5.1.	Key Study on Formula-Fed Infants	3-25
3.5.1.1.	Kahn et al. (2013)—Estimates of Water Ingestion in Formula by Infants and Children Based on USDA’s 1994–1996 and 1998 Continuing Survey of Food Intakes by Individuals.....	3-25
3.5.2.	Relevant Studies on Formula-Fed Infants	3-25
3.5.2.1.	Hilbig et al. (2002)—Measured Consumption of Tap Water in German Infants and Young Children as Background for Potential Health Risk Assessment: Data of the DONALD Study	3-26
3.5.2.2.	Levallois et al. (2008)—Drinking Water Intake by Infants Living in Rural Quebec (Canada)	3-26
3.5.2.3.	Schier et al. (2010)—Perchlorate Exposure from Infant Formula and Comparisons with the Perchlorate Reference Dose.....	3-26
3.6.	HIGH ACTIVITY LEVELS/HOT CLIMATES.....	3-27
3.6.1.	Relevant Studies on High Activity Levels/Hot Climates	3-27
3.6.1.1.	McNall and Schlegel (1968)—Practical Thermal Environmental Limits for Young Adult Males Working in Hot, Humid Environments	3-27
3.6.1.2.	U.S. Army (1983, 1999)—Water Consumption Planning Factors	3-27
3.6.1.3.	Sohn et al. (2001)—Fluid Consumption Related to Climate among Children in the United States.....	3-28
3.6.1.4.	Kant et al. (2009)—Intakes of Plain Water, Moisture in Foods and Beverages, and Total Water in the Adult U.S. Population—Nutritional, Meal Pattern, and Body Weight Correlates: NHANES 1999–2006; Kant and Graubard (2010)—Contributors of Water Intake in U.S. Children and Adolescents: Associations with Dietary and Meal Characteristics—National Health and Nutrition Examination Survey 2005–2006.....	3-28
3.6.1.5.	Yang and Chun (2014)—Consumptions of Plain Water, Moisture in Foods and Beverages, and Total Water in Relation to Dietary Micronutrient Intakes and Serum Nutrient Profiles among U.S. Adults	3-29
3.6.1.6.	Montain and Ely (2010)—Water Requirements and Soldier Hydration.....	3-29
3.7.	WATER INGESTION WHILE SWIMMING AND DIVING	3-30

TABLE OF CONTENTS (CONTINUED)

3. INGESTION OF WATER AND OTHER SELECT LIQUIDS

3.1. INTRODUCTION

This document is an update to Chapter 3 (Ingestion of Water and Selected Liquids) of the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011). New information that has become available since 2011 has been added, and the recommended values have been revised as needed to reflect the additional information. The recommended values for the general population in this chapter have been updated using National Health and Nutrition Examination Survey (NHANES) data for 2005–2010; the 2011 version of this chapter used NHANES data for 2003–2006 for individuals ≥ 3 years of age and Continuing Survey of Food Intake by Individuals (CSFII) data for 1994–1996, and 1998 for children < 3 years of age. Appendix A provides a comparison of the intake rates based on NHANES 2005–2010 data to those based on NHANES 2003–2006 and CSFII 1994–96 and 1998. Data for pregnant and lactating women have also been updated using NHANES 2005–2010 data. This update also provides, for the first time, water intake data for formula-fed infants. Recent relevant studies based on data other than NHANES and CSFII are also summarized to provide additional perspective on drinking water intake.

The chapter includes a comprehensive review of the scientific literature through 2017. The new literature was identified via formal literature searches conducted by EPA library services as well as targeted internet searches conducted by the authors of this chapter. Appendix B provides a list of the key terms that were used in the literature searches. Revisions to this chapter have been made in accordance with the approved quality assurance plan for the *Exposure Factors Handbook*.

Water ingestion is a pathway of exposure to environmental chemicals. Contamination of water may occur at the water supply source (groundwater or surface water); during treatment (for example, toxic by-products may be formed during chlorination); or post-treatment (such as leaching of lead or other materials from plumbing systems). People may be exposed to contaminants in water when consuming water directly as a beverage, indirectly from foods and drinks made with water, or incidentally while swimming or engaging in other water-related activities. Estimating the magnitude of the potential dose of toxics from water ingestion requires information on the quantity of water consumed. The purpose of this section is to describe key and relevant published studies that provide information on water ingestion for various populations and to provide

recommended ingestion rate values for use in exposure assessments. As described in Chapter 1 of the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011), key studies represent those studies that are the most up-to-date and scientifically sound for deriving recommendations for exposure factors, whereas other studies are designated “relevant,” meaning applicable or pertinent, but not necessarily the most important. For example, studies that provide supporting data or information related to the factor of interest (e.g., number of drinking events per day), or have study designs or approaches that make the data less applicable to the population of interest (e.g., studies not conducted in the United States) have been designated as relevant rather than key. Key studies were selected based on the general assessment factors described in Chapter 1 of the handbook. The studies described in this section provide information on ingestion of water consumed as a beverage or in foods or beverages containing tap water, ingestion of other select liquids, and ingestion of water while swimming.

Historically, the Environmental Protection Agency (EPA) has assumed a drinking water ingestion rate of 2 L/day for adults and 1 L/day for infants and children under 10 years of age (U.S. EPA, 2000a). This rate includes water consumed in the form of juices and other beverages containing tap water. The National Research Council (NRC, 1977) estimated that daily consumption of water may vary with levels of physical activity and fluctuations in temperature and humidity. It is reasonable to assume that people engaging in physically demanding activities or living in warmer regions may have higher levels of water ingestion. However, there is limited information on the effects of activity level and climatic conditions on water ingestion.

U.S. EPA’s analysis of 2005–2010 data from the NHANES was selected as the key study of drinking water ingestion for the general population and for pregnant and lactating women. NHANES 2005–2010 contains the most up-to-date information on water intake rate estimates. Kahn et al. (2013) was selected as a key study for formula-fed infants. Kahn et al. (2013) used data from U.S. Department of Agriculture’s (USDA’s) 1994–1996, 1998 CSFII.

The U.S. EPA analysis of NHANES data and the analyses of CSFII data by Kahn et al. (2013) generated ingestion rates for direct and indirect ingestion of water. Direct ingestion is defined as direct consumption of water as a beverage, while indirect ingestion includes water added during food or beverage preparation, but not water intrinsic to purchased foods (i.e., water that is naturally contained in foods) (Kahn and Stralka, 2008). Data for

consumption of water from various sources (i.e., the community water supply, bottled water, and other sources) are also presented. It is noted that the type of water people drink has changed in the last decade, as evidenced by the increase in bottled water consumption (see Appendix A). However, the majority of the U.S. population consumes water from public (i.e., community) water distribution systems; about 15% of the U.S. population obtains their water from private (i.e., household) wells, cisterns, or springs (U.S. EPA, 2002; <https://www.epa.gov/privatewells/about-private-water-wells>). Regardless of the source of the water, the physiological need for water should be the same among populations using community or private water systems. For the purposes of exposure assessments involving site-specific contaminated drinking water, ingestion rates based on the community supply are most appropriate. Given the assumption that bottled water, and purchased foods and beverages that contain water are widely distributed and less likely to contain source-specific water, the use of total water ingestion rates may overestimate the potential exposure to toxic substances present only in local water supplies; therefore, tap water ingestion of community water, rather than total water ingestion, is emphasized in this section.

The key studies on water ingestion for the general population and pregnant and lactating women (NHANES), and the populations of formula-fed infants (CSFII) are based on short-term survey data (2 days). Although short-term data may be suitable for obtaining mean or median ingestion values that are representative of both short- and long-term ingestion distributions, upper- and lower-percentile values may be different for short-term and long-term data. Note too that most currently available water ingestion surveys are based on respondent recall, which may be a source of uncertainty in the estimated ingestion rates because of the subjective nature of this type of survey technique. Percentile distributions for water ingestion are presented in this handbook, where sufficient data are available. Information on ingestion of water based on climate and activity level, and on incidental ingestion of water while swimming, is also provided in this chapter.

Section 3.2 provides the recommendations and confidence ratings for use in risk assessment for community water ingestion among the general population, formula-fed infants, and pregnant and lactating women, and water ingestion among swimmers. Section 3.3.1 provides the key studies for general population water ingestion rates, Section 3.4.1 provides ingestion rates for pregnant and lactating women, Section 3.5.1 provides ingestion rates for

formula-fed infants, Section 3.7 provides ingestion rates for swimmers, and Section 3.8 provides data for other inadvertent water ingestion. For water ingestion at high activity levels or hot climates, no recommendations are provided, but Section 3.6 includes relevant studies on this topic. Relevant studies on all subcategories of water ingestion are also presented to provide the reader with added perspective on the current state of knowledge pertaining to ingestion of water and select liquids.

3.2. RECOMMENDATIONS

3.2.1. Water Ingestion from Consumption of Water as a Beverage and from Food and Drink

The recommended general population water ingestion rate values for the consumption of water as a beverage (direct) and from foods and drinks (indirect) are based on U.S. EPA's analysis of NHANES data from 2005–2010. Table 3-1 presents a summary of the recommended values for direct and indirect ingestion of community water. Per capita mean and 95th percentile values range from 145 mL/day to 956 mL/day and 565 mL/day to 2,976 mL/day, respectively, depending on the age group. Consumer-only mean and 95th percentile values range from 245 mL/day to 1,419 mL/day and 658 mL/day to 3,407 mL/day, respectively, depending on the age group. Per capita intake rates represent intake that has been averaged over the entire population (including those individuals that reported no intake). In general, per capita intake rates are appropriate for use in exposure assessments for which average daily dose estimates are of interest because they represent both individuals who drank water during the survey period and individuals who may drink water at some time but did not consume it during the survey period. Consumer-only intake rates represent the quantity of water consumed only by individuals who reported water intake during the survey period. Table 3-2 presents a characterization of the overall confidence in the accuracy and appropriateness of the recommendations for drinking water intake for use in risk assessments.

3.2.2. Pregnant and Lactating Women

Based upon the results of the U.S. EPA analysis of 2005–2010 NHANES data, per capita mean and 95th percentile values for ingestion of drinking water among pregnant women were 731 mL/day and 2,859 mL/day, respectively. The per capita mean and 95th percentile values for lactating women were 1,075 mL/day and 3,061 mL/day, respectively. Table 3-3 presents a summary of the recommended

values for water ingestion rates. Table 3-4 presents the confidence ratings for these recommendations.

3.2.3. Formula-Fed Infants

The recommended values for drinking water ingestion rates for formula-fed infants are based on the results of Kahn et al. (2013). The mean total direct and indirect water intake values are 505, 627, 699, 691, and 591 mL/day for ages <1 month, 1 to <3 months, 3 to <6 months, 6 to <12 months, and 1 to <2 years, respectively. The 95th percentile total direct and indirect water intake values are 858, 1,096, 1,300, 1,350, and 1,254 for ages <1 month, 1 to <3 months, 3 to <6 months, 6 to <12 months, and 1 to <2 years, respectively. Table 3-5 presents a summary of the recommended values for formula-fed infants, and Table 3-6 presents the confidence ratings for the recommended values for formula-fed infants.

3.2.4. Water Ingestion While Swimming or Diving

Based on the data from Dufour (2017), mean swimming pool water ingestion rates were 38, 44, 33, and 28 mL/hour for ages 6 to <11, 11 to <16, 16 to <21, and 21+ years, respectively. Upper percentile (95th percentile) swimming pool water ingestion rates were 96, 152, 105, and 92 mL/hour for ages 6 to <11, 11 to <16, 16 to <21, and 21+ years, respectively. Although these estimates were derived from swimming pool experiments, Dufour et al. (2006) noted that swimming behavior of recreational pool swimmers may be similar to freshwater swimmers. Estimates may be different for saltwater swimmers and competitive swimmers. Table 3-7 presents a summary of the recommended values for water ingestion rates while swimming. Table 3-8 presents the confidence ratings for these recommendations. Data on the amount of time spent swimming can be found in Chapter 16 (see Table 16-1) of this handbook.

Table 3-2. Confidence in Recommendations for Drinking Water Ingestion Rates ^a		
General Assessment Factors	Rationale	Rating
Soundness		Medium to High
<i>Adequacy of Approach</i>	The survey methodology and data analysis were adequate. The surveys sampled approximately 25,000 (NHANES) individuals; sample size varied with age.	
<i>Minimal (or defined) Bias</i>	No physical measurements were taken. The method relied on recent recall of standardized volumes of drinking water containers.	
Applicability and Utility		High
<i>Exposure Factor of Interest</i>	The key studies were directly relevant to water ingestion.	
<i>Representativeness</i>	The data were demographically representative (based on stratified random sample). Sample sizes for some age groups were limited.	
<i>Currency</i>	NHANES data were collected between 2005 and 2010.	
<i>Data Collection Period</i>	Data were collected for 2 nonconsecutive days. However, long-term variability may be small. Use of a short-term average as a chronic ingestion measure can be assumed.	
Clarity and Completeness		High
<i>Accessibility</i>	NHANES data are publicly available.	
<i>Reproducibility</i>	The methodology was clearly presented; enough information was included to reproduce the results.	
<i>Quality Assurance</i>	NHANES data collection follow strict QA/QC procedures. The FCID Calculator also underwent QA/QC.	
Variability and Uncertainty		High
<i>Variability in Population</i>	Full distributions were developed.	
<i>Uncertainty</i>	Except for data collection based on recall, sources of uncertainty were minimal.	
Evaluation and Review		Medium
<i>Peer Review</i>	NHANES surveys received a high level of peer review. The U.S. EPA analysis of NHANES has not been peer reviewed outside the Agency, but the FCID Consumption Calculator, which was used to conduct the analysis, was internally and externally peer reviewed.	
<i>Number and Agreement of Studies</i>	There was one key study for drinking water ingestion among the general population. Appendix B provides a comparison of the NHANES 2005–2010 and data sets used previously in the <i>Exposure Factors Handbook: 2011 Edition</i> (U.S. EPA, 2011) for estimating water ingestion among the general population (NHANES 2003–2006 and CSFII 1994–1996, 1998).	
Overall Rating		Medium to High, Low for footnote “c” on Table 3-1
^a	See Section 1.5.2 in Chapter 1 of the <i>Exposure Factors Handbook: 2011 Edition</i> (U.S. EPA, 2011) for a detailed description of the evaluation criteria used in this table.	
FCID	= Food Commodity Intake Database.	
QA/QC	= Quality assurance/quality control.	

Table 3-3. Recommended Values for Water Ingestion Rates of Community Water for Pregnant and Lactating Women, and Women of Child-bearing Age (13 to <50 years) ^a

General Assessment Factors	Rationale	Rating
Soundness		Medium
<i>Adequacy of Approach</i>	The survey methodology and data analysis were adequate. Data were available for approximately 700 formula-fed infants overall, but the sample sizes were small for some age ranges.	
<i>Minimal (or defined) Bias</i>	No physical measurements were taken. The method relied on recent recall of volumes of drinking water used to reconstitute infant formula.	
Applicability and Utility		Medium
<i>Exposure Factor of Interest</i>	The key study was directly relevant to water ingestion.	
<i>Representativeness</i>	The data were demographically representative (based on stratified random sample).	
<i>Currency</i>	Data were collected between 1994 and 1998.	
<i>Data Collection Period</i>	Data were collected for 2 nonconsecutive days. However, long-term variability may be small. Use of a short-term average as a chronic ingestion measure can be assumed.	
Clarity and Completeness		Medium
<i>Accessibility</i>	The CSFII data are publicly available. The Kahn et al. (2013) analysis of the CSFII 1994–1996, 1998 data was published in a peer-reviewed journal.	
<i>Reproducibility</i>	The methodology was clearly presented; enough information was included to reproduce the results.	
<i>Quality Assurance</i>	Quality assurance of the CSFII data was good; quality control of the secondary data analysis was not well described.	
Variability and Uncertainty		Medium
<i>Variability in Population</i>	Mean and 95 th percentile values were provided for five age groups of infants (Kahn et al., 2013).	
<i>Uncertainty</i>	Except for data collection based on recall, sources of uncertainty were minimal.	
Evaluation and Review		Medium
<i>Peer Review</i>	The USDA CSFII survey received a high level of peer review. The Kahn et al. (2013) study was published in a peer-reviewed journal.	
<i>Number and Agreement of Studies</i>	There was one key study for formula-fed infants.	
Overall Rating		Medium
^a	See Section 1.5.2 in Chapter 1 of the <i>Exposure Factors Handbook: 2011 Edition</i> (U.S. EPA, 2011) for a detailed description of the evaluation criteria used in this table.	

Table 3-7. Recommended Values for Water Ingestion While Swimming		
Age Group years	Mean	Upper Percentile
	mL/hour	mL/hour
6 to <11	38	96
11 to <16	44	152
16 to <21	33	105
21+	28	92

Table 3-8. Confidence in Recommendations for Water Ingestion While Swimming ^a		
General Assessment Factors	Rationale	Rating
Soundness		Medium
<i>Adequacy of Approach</i>	The approach appears to be appropriate given that cyanuric acid (a tracer used in treated pool water) is not metabolized. The Dufour et al. (2006, 2017) studies analyzed primary data on water ingestion during swimming.	
<i>Minimal (or defined) Bias</i>	Swimmers were asked to swim for approximately 1 hour, but the swimming durations used in calculating the ingestion rates were based on self-reported estimates that may not accurately reflect the actual time spent swimming.	
Applicability and Utility		Low to Medium
<i>Exposure Factor of Interest</i>	The key study was directly relevant to water ingestion while swimming.	
<i>Representativeness</i>	The sample was not representative of the U.S. population. Data were provided for three broad age ranges (i.e., children, teens, adults).	
<i>Currency</i>	The pilot study (Dufour et al., 2006) was conducted in 2005 and the full study (Dufour et al., 2017) was conducted after the pilot study.	
<i>Data Collection Period</i>	Samples were collected after a swimming period of approximately 1 hour.	
Clarity and Completeness		Medium
<i>Accessibility</i>	The Dufour et al. (2006, 2017) studies were published in peer-reviewed journals. Dufour (2017) provided the raw data, which were analyzed to provide additional percentile values for additional age groups.	
<i>Reproducibility</i>	The methodology was clearly presented; enough information was included to reproduce the results.	
<i>Quality Assurance</i>	Quality assurance methods were not described in the study.	
Variability and Uncertainty		Low
<i>Variability in Population</i>	Full distributions were not available in the paper, but the data were provided by the author via personal communications (Dufour, 2017). Data were broken out by broad age groups.	
<i>Uncertainty</i>	The sources of uncertainty were that the sample population may not reflect swimming practices for all swimmers, and the rates were based on self-reported swimming durations.	
Evaluation and Review		Medium
<i>Peer Review</i>	The Dufour et al. (2006, 2017) studies were published in peer-reviewed journals.	
<i>Number and Agreement of Studies</i>	There were two key studies for ingestion of water when swimming (Dufour et al., 2006, 2017).	
^a	See Section 1.5.2 in Chapter 1 of the <i>Exposure Factors Handbook: 2011 Edition</i> (U.S. EPA, 2011) for a detailed description of the evaluation criteria used in this table.	

3.3. DRINKING WATER INGESTION STUDIES

3.3.1. Key Drinking Water Ingestion Study for the General Population

This section provides a summary of the key study on water ingestion among the general population. This key study is the basis for the recommended water estimates for use in risk assessments involving the general population.

3.3.1.1. U.S. EPA Analysis of NHANES 2005–2010 Data

The U.S. EPA used the combined 2005–2006, 2007–2008, and 2009–2010 NHANES data sets to estimate water ingestion rates for the general population. The 2005–2010 data set included information on nearly 25,000 individuals. The U.S. Centers for Disease Control and Prevention surveyed households across the United States and collected food and beverage recall data for 2 nonconsecutive days as part of the NHANES. The first dietary recall interview was conducted in person in a Mobile Examination Center, and the second was collected by telephone 3 to 10 days later on a different day of the week. Each individual in the survey was assigned a sample weight based on his or her demographic data. These weights were taken into account when calculating mean and percentile water ingestion rates from various sources.

The U.S. EPA, Office of Pesticide Programs used NHANES 2005–2010 data to update the Food Commodity Intake Database (FCID) that was developed for earlier analyses of data from the USDA's CSFII (USDA, 2000; U.S. EPA, 2000a, b) and NHANES 2003–2006 (U.S. EPA, 2011). In the FCID, NHANES data on the foods people reported eating were converted to the quantities of agricultural commodities eaten, including water that was added in the preparation of foods and beverages. The updated FCID is available at: <http://fcid.foodrisk.org/>, along with the FCID Consumption Calculator which was used to develop the estimates provided in this chapter for various age groups of the population. This calculator may also be used to develop estimates for other age groups or population, customized to the users' needs.

U.S. EPA derived mean and percentile estimates of daily average water ingestion for the following age categories: Birth to <1 month, 1 to <3 months, 3 to <6 months, 6 to <12 months, 1 to <2 years of age, 2 to <3 years, 3 to <6 years, 6 to <11 years, 11 to <16 years, 16 to <21 years of age, adults 21 years and older in 10-year increments, and all ages. Intake estimates are also provided for some additional age ranges that may be of use to risk assessors, including ages birth to

<2 years, 2 to <16 years, 16 to <70 years, 21 to <50 years, and 50+ years.

Consumer-only and per capita water ingestion estimates were generated for four water source categories: community water, bottled water, other sources, and all sources. Consumer-only intake represents the quantity of water consumed by individuals during the survey period. These data are generated by averaging intake across only the individuals in the survey who reported consumption of water. Per capita intake rates are generated by averaging consumer-only intakes over the entire population (including those individuals that reported no intake). In general, per capita intake rates are appropriate for use in exposure assessments for which average dose estimates are of interest because they represent both individuals who drank water during the survey period and individuals who may drink water at some time but did not consume it during the survey period. "All sources" included water from all supply sources such as community water supply (i.e., tap water), bottled water, other sources, and missing/unknown sources. "Community water" included tap water from a community or municipal water supply. "Other sources" included wells, springs, cisterns, other nonspecified sources, and missing/unknown sources that the survey respondent was unable to identify. The water ingestion estimates for community water, other sources, and all sources included both water ingested directly as a beverage (direct water) and water added to foods and beverages during final preparation at home or by local food service establishments such as school cafeterias and restaurants (indirect water). Bottled water estimates include direct ingestion only. Commercial water added by a manufacturer (i.e., water contained in soda or beer) and intrinsic water in foods and liquids (i.e., milk and natural undiluted juice) were not included in the estimates. NHANES water consumption respondent data were averaged over both days of dietary data. Intake rate distributions were provided in units of mL/day and mL/kg-day. The body weights of survey participants were used in developing intake rate estimates in units of mL/kg-day.

Tables 3-9 to 3-24 present full distributions for the various water source categories (community water, bottled water, other sources, and all sources). Tables 3-9 to 3-12 provide per capita water ingestion estimates in mL/day for the various water source categories (i.e., community, bottled, other, and all sources). Tables 3-13 to 3-16 present the same information as Tables 3-9 to 3-12, but in units of mL/kg-day. Tables 3-17 to 3-20 provide consumers-only water ingestion estimates in mL/day for the various source categories. Tables 3-21 to 3-24

present the same information as Tables 3-17 to 3-20, but in units of mL/kg-day. Estimates that do not meet the minimum sample size as described in the *Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: NHIS/NCHS Analytical Working Group Recommendations* (NCHS, 1993), are flagged in the tables. The design effect used to determine the minimum required sample size was domain specific (i.e., calculated separately for various age groups).

When indexed to body weight, the per capita ingestion rate of water from all sources combined for children under 6 months of age was more than 4 times higher than that of adults ≥ 21 years (see Table 3-16). Among consumers-only younger than 6 months of age, the ingestion rate for all sources combined was more than 5 times that of adults when indexed to body weight (see Table 3-24). The pattern of decreasing water ingestion per unit of body weight was also observed in per capita and consumers-only estimates of community water (see Tables 3-13 and 3-21), and other sources (see Tables 3-15 and 3-23). However, this trend was not observed in estimates of bottled water.

The advantages of U.S. EPA's analysis of the 2005–2010 NHANES surveys are (1) that the surveys were designed to obtain a statistically valid sample of the civilian noninstitutionalized U.S. population (i.e., the sampling frame was organized using 2000 U.S. population census estimates); (2) several sets of sampling weights were available for use with the intake data to facilitate proper analysis of the data; (3) the sample size was sufficient to allow categorization within narrowly defined age categories, and the large sample provided useful information on the overall distribution of ingestion by the population and should adequately reflect the range among respondent variability; (4) the survey was conducted over 2 nonconsecutive days, which improved the variance over consecutive days of consumption; and (5) the most current FCID data set was used. One limitation of the data is that the data were collected over only 2 days and do not necessarily represent "usual" intake. "Usual dietary intake" refers to the long-term average of daily intakes by an individual. Thus, water ingestion estimates based on short-term data may differ from long-term rates, especially at the tails of the distribution. There are, however, several limitations associated with these data. Water intake estimates for some age groups, particularly at the tails of the distribution, are less statistically reliable due to small sample sizes, as noted in Tables 3-9 to 3-24. In addition, NHANES does not allow for the allocation of indirect water intake in estimating bottled water consumption. Another limitation of these data is that

the survey design, while being well tailored for the overall population of the United States and conducted throughout the year to account for seasonal variation, is of limited use for assessing small and potentially at-risk populations based on ethnicity, medical status, geography/climate, or other factors such as activity level.

3.3.2. Relevant Drinking Water Ingestion Studies for the General Population

The sections that follow provide summaries of studies on water ingestion among the general population that have been categorized as relevant rather than key. Studies were classified as relevant if they provided supporting water ingestion data (e.g., older studies, studies that provided information on the source of water) or information related to the factor of interest (e.g., physiologic need for water), or the study design or approach makes the data less applicable to the population of interest (e.g., small sample size, limited to certain age groups).

3.3.2.1. Wolf (1958)—Body Water Content

Wolf (1958) provided information on the water content of human bodies, stating that a newborn baby is about 77% water while an adult male is about 60% water by weight. An adult male gains and loses about 2,750 mL of water each day. Water intake in dissimilar mammals varies according to 0.88 power of body weight.

3.3.2.2. National Research Council (1977)—Drinking Water and Health

NRC (1977) calculated the average per capita water (liquid) consumption per day to be 1.63 L. This figure was based on a survey of the following literature sources: Starling (1941); Bourne and Kidder (1953); Walker et al. (1957); Wolf (1958); Guyton (1968); McNall and Schlegel (1968); Randall (1973); NRC (1974); and Pike and Brown (1975) as cited in NRC (1977). Although the calculated average intake rate was 1.63 L/day, NRC (1977) adopted a larger rate (2 L/day) to represent the intake of the majority of water consumers. This value is relatively consistent with the total tap water intakes rate estimated from the key study presented in this chapter. However, the use of the term "liquid" was not clearly defined in this study, and it is not known whether the populations surveyed are representative of the adult U.S. population. Consequently, the results of this study are of limited use in recommending total tap water intake rates, and this study is not considered a key study.

3.3.2.3. Pennington (1983)—Revision of the Total Diet Study Food List and Diets

Based on data from the U.S. Food and Drug Administration's Total Diet Study, Pennington (1983) reported average intake rates for various foods and beverages for five age groups of the population. The Total Diet Study is conducted annually to monitor the nutrient and contaminant content of the U.S. food supply and to evaluate trends in consumption. Representative diets were developed based on 24-hour recall and 2-day diary data from the 1977–1978 USDA Nationwide Food Consumption Survey (NFCS) and 24-hour recall data from the Second National Health and Nutrition Examination Survey (NHANES II). The numbers of participants in NFCS and NHANES II were approximately 30,000 and 20,000, respectively. The diets were developed to “approximate 90% or more of the weight of the foods usually consumed” (Pennington, 1983). The source of water (bottled water as distinguished from tap water) was not stated in the Pennington study. For the purposes of this report, the consumption rates for the food categories defined by Pennington (1983) were used to calculate total fluid and total water intake rates for five age groups. Total water includes water, tea, coffee, soft drinks, and soups and frozen juices that are reconstituted with water. Reconstituted soups were assumed to be composed of 50% water, and juices were assumed to contain 75% water. Total fluids include total water in addition to milk, ready-to-use infant formula, milk-based soups, carbonated soft drinks, alcoholic beverages, and canned fruit juices. Table 3-25 presents these intake rates. Based on the average intake rates for total water for the two adult age groups, 1.04 and 1.26 L/day, the average adult intake rate is about 1.15 L/day. These rates should be more representative of the amount of source-specific water consumed than are total fluid intake rates. This study, which used both USDA 1978 data and NHANES II data, was designed to measure food intake. Consequently, no systematic attempt was necessarily made to define tap water intake per se, as distinguished from bottled water. For this reason, it is not considered a key tap water study in this document.

3.3.2.4. U.S. EPA (1984)—An Estimation of the Daily Average Food Intake by Age and Sex for Use in Assessing the Radionuclide Intake of the General Population

Using data collected by USDA in the 1977–1978 NFCS, U.S. EPA (1984) determined daily food and beverage intake levels by age to be used in assessing radionuclide intake through food consumption. Tap water, water-based drinks, and soups were identified

subcategories of the total beverage category. Table 3-26 presents daily intake rates for tap water, water-based drinks, soup, and total beverages. As seen in Table 3-26, mean tap water intake for different adult age groups (age 20 years and older) ranged from 0.62 to 0.76 L/day, water-based drinks intake ranged from 0.34 to 0.69 L/day, soup intake ranged from 0.04 to 0.06 L/day, and mean total beverage intake levels ranged from 1.48 to 1.73 L/day. Total tap water intake rates were estimated by combining the average daily intakes of tap water, water-based drinks, and soups for each age group. For adults (ages 20 years and older), mean total tap water intake rates range from 1.04 to 1.47 L/day, and for children (ages <1 to 19 years), mean intake rates range from 0.19 to 0.90 L/day. The total tap water intake rates, derived by combining data on tap water, water-based drinks, and soup should be more representative of source-specific drinking water intake than the total beverage intake rates reported in this study. The chief limitation of the study is that the data were collected in 1978 and do not reflect the expected increase in the U.S. consumption of soft drinks and bottled water or changes in the diet within the last three decades. Because the data were collected for only a 3-day period, the extrapolation to chronic intake is uncertain. Also, these intake rates do not include reconstituted infant formula. For these reasons, this is not considered a key study in this document.

3.3.2.5. Cantor et al. (1987)—Bladder Cancer, Drinking Water Source, and Tap Water Consumption

The National Cancer Institute, in a population-based, case control study investigating the possible relationship between bladder cancer and drinking water, interviewed approximately 8,000 adult white individuals, 21 to 84 years of age (2,805 cases and 5,258 controls) in their homes, using a standardized questionnaire (Cantor et al., 1987). The cases and controls resided in one of five metropolitan areas (Atlanta, Detroit, New Orleans, San Francisco, and Seattle) and five states (Connecticut, Iowa, New Jersey, New Mexico, and Utah). The individuals interviewed were asked to recall the level of intake of tap water and other beverages in a typical week during the winter prior to the interview. Total beverage intake was divided into the following two components: (1) beverages derived from tap water and (2) beverages from other sources. Tap water used in cooking foods and in ice cubes was apparently not considered. Participants also supplied information on the primary source of the water consumed (i.e., private well, community supply, bottled water, etc.). The

control population was randomly selected from the general population and frequency matched to the bladder cancer case population in terms of age, sex, and geographic location of residence. The case population consisted of whites only and had no people under the age of 21 years; 57% were over the age of 65 years. The fluid intake rates for the bladder cancer cases were not used because their participation in the study was based on selection factors that could bias the intake estimates for the general population. Based on responses from 5,258 white controls (3,892 males; 1,366 females), average tap water intake rates for a “typical” week were compiled by sex, age group, and geographic region. Table 3-27 lists these rates. The average total fluid intake rate was 2.01 L/day for men, of which 70% (1.4 L/day) was derived from tap water, and 1.72 L/day for women, of which 79% (1.35 L/day) was derived from tap water. Table 3-28 presents frequency distribution data for the 5,228 controls, for which the authors had information on both tap water consumption and cigarette smoking habits. These data follow a lognormal distribution having an average value of 1.30 L/day and an upper 90th percentile value of approximately 2.40 L/day. These values were determined by graphically interpolating the data of Table 3-28 after plotting it on log probability graph paper. These values represent the usual level of intake for this population of adults in the winter. Limitations associated with this data set are that the population surveyed was older than the general population and consisted exclusively of whites. Also, the intake data are based on recall of behavior during the winter only. Extrapolation of the data to other seasons is difficult.

The authors presented data on person-years of residence with various types of water supply sources (municipal vs. private, chlorinated vs. nonchlorinated, and surface vs. well water). Unfortunately, these data cannot be used to draw conclusions about the national average apportionment of surface versus groundwater because a large fraction (24%) of municipal water intake in this survey could not be specifically attributed to either ground or surface water.

3.3.2.6. Ershow and Cantor (1989)—Total Water and Tap Water Intake in the United States: Population-Based Estimates of Quantities and Sources

Ershow and Cantor (1989) estimated water intake rates based on data collected by the USDA 1977–1978 NFCS. The survey was conducted through interviews and diary entries. Daily intake rates for tap water and total water were calculated for various age groups for males, females, and both sexes combined. Tap water was defined as “all water from the household tap

consumed directly as a beverage or used to prepare foods and beverages.” Total water was defined as tap water plus “water intrinsic to foods and beverages” (i.e., water contained in purchased food and beverages). The authors showed that the age, sex, and racial distribution of the surveyed population closely matched the estimated 1977 U.S. population.

Table 3-29 presents daily total tap water intake rates, expressed as mL/day by age group. These data follow a lognormal distribution. Table 3-30 presents the same data, expressed as mL/kg-day. This shows that the mean and 90th percentile intake rates for adults (ages 20 to 65+) are approximately 1,410 mL/day and 2,280 mL/day, and for all ages, the mean and 90th percentile intake rates are 1,193 mL/day and 2,092 mL/day. Note that older adults have greater intakes than do adults between ages 20 and 64, an observation bearing on the interpretation of the Cantor et al. (1987) study, which surveyed a population that was older than the national average (see Section 3.3.2.8).

Ershow and Cantor (1989) also measured total water intake for the same age groups and concluded that it averaged 2,070 mL/day for all groups combined and that tap water intake (1,190 mL/day) is 55% of the total water intake. Table 3-31 presents total tap water intake as a percentage of total water intake for various age groups. Ershow and Cantor (1989) also concluded that, for all age groups combined, the proportion of tap water consumed as drinking water or used to prepare foods and beverages is 54, 10, and 36%, respectively. (Table 3-32 presents the detailed data on the proportion of tap water consumed for various age groups). Ershow and Cantor (1989) also observed that males of all age groups had higher total water and tap water consumption rates than females; the variation of each from the combined-sexes mean was about 8%.

With respect to region of the country, the Northeast had slightly lower average tap water intake (1,200 mL/day) than the three other regions (which were approximately equal at 1,400 mL/day).

This survey has an adequately large size (26,446 individuals), and it is a representative sample of the U.S. population with respect to age distribution and residential location. The data, however, are more than 20 years old and may not be entirely representative of current patterns of water intake.

3.3.2.7. Roseberry and Burmaster (1992)—Lognormal Distributions for Water Intake

Roseberry and Burmaster (1992) fit lognormal distributions to the water intake data population-wide distributions for total fluid and total tap water intake based on proportions of the population in each age group. Their publication shows the data and the fitted

lognormal distributions graphically. The mean was estimated as the zero intercept, and the standard deviation (SD) was estimated as the slope of the best-fit line for the natural logarithm of the intake rates plotted against their corresponding *z*-scores (Roseberry and Burmaster, 1992). Least squares techniques were used to estimate the best-fit straight lines for the transformed data. Table 3-33 presents summary statistics for the best-fit lognormal distribution. In this table, the simulated balanced population represents an adjustment to account for the difference in the age distribution of the U.S. population in 1988 from the age distribution in 1978 when Ershow and Cantor (1989) collected their data. Table 3-34 summarizes the quantiles and means of tap water intake as estimated from the best-fit distributions. The mean total tap water intake rates for the two adult populations (ages 20 to 65 years, and 65+ years) were estimated to be 1.27 and 1.34 L/day.

These intake rates were based on the data originally presented by Ershow and Cantor (1989). Consequently, the same advantages and disadvantages associated with the Ershow and Cantor (1989) study apply to this data set.

3.3.2.8. *Levy et al. (1995)—Infant Fluoride Intake from Drinking Water Added to Formula, Beverages, and Food*

Levy et al. (1995) conducted a study to determine fluoride intake by infants through drinking water and other beverages prepared with water and baby foods. The study was longitudinal and covered the ages from birth to 9 months old. A total of 192 mothers, recruited from the postpartum wards of two hospitals in Iowa City, completed mail questionnaires and 3-day beverage and food diaries for their infants at ages 6 weeks, and 3, 6, and 9 months (Levy et al., 1995). The questionnaire addressed feeding habits, water sources and ingestion, and the use of dietary fluoride supplements during the preceding week (Levy et al., 1995). It also collected data on the quantity of water consumed by itself or as an additive to infant formula, other beverages, or foods. In addition, the questionnaire addressed the infants' ingestion of cow's milk, breast milk, ready-to-feed (RTF) infant products (formula, juices, beverages, baby food), and table foods.

Mothers were contacted for any clarifications of missing data and discrepancies (Levy et al., 1995). Levy et al. (1995) assessed nonresponse bias and found no significant differences in the reported number of adults or children in the family, water sources, or family income at 3, 6, or 9 months. Table 3-35 provides the range of water ingestion from

water by itself and from addition to selected foods and beverages. The percentage of infants ingesting water by itself increased from 28% at 6 weeks to 66% at 9 months, respectively, and the mean intake increased slightly over this time frame. During this time frame, the largest proportion of the infants' water ingestion (i.e., 36% at 9 months to 48% at 6 months) came from the addition of water to formula. Levy et al. (1995) noted that 32% of the infants at age 6 weeks and 23% of the infants at age 3 months did not receive any water from any of the sources studied. Levy et al. (1995) also noted that the proportion of children ingesting some water from all sources gradually increased with age.

The advantages of this study are that it provides information on water ingestion of infants starting at 6 weeks old, and the data are for water only and for water added to beverages and foods. The limitations of the study are that the sample size was small for each age group, it captured information from a select geographical location, and data were collected through self-reporting. The authors noted, however, that the 3-day diary has been shown to be a valid assessment tool. Levy et al. (1995) also stated that (1) for each time period, the ages of the infants varied by a few days to a few weeks, and are, therefore, not exact and could, at early ages, have an effect on age-specific intake patterns; and (2) the same number of infants were not available at each of the four time periods.

3.3.2.9. *USDA (1995)—Food and Nutrient Intakes by Individuals in the United States, 1 Day, 1989–1991*

USDA (1995) collected data on the quantity of "plain drinking water" and various other beverages consumed by individuals in 1 day during 1989 through 1991. The data were collected as part of USDA's CSFII. The data used to estimate mean per capita intake rates combined 1-day dietary recall data from 3 survey years, 1989, 1990, and 1991, during which 15,128 individuals supplied 1-day intake data. Individuals from all income levels in the 48 conterminous states and Washington D.C. were included in the sample. A complex three-stage sampling design was employed, and the overall response rate for the study was 58%. To minimize the biasing effects of the low response rate and adjust for the seasonality, a series of weighting factors was incorporated into the data analysis. Table 3-36 presents the intake rates based on this study. Table 3-36 includes data for (1) "plain drinking water," which might be assumed to mean tap water directly consumed rather than bottled water; (2) coffee and tea, which might be assumed to be constituted from tap water; (3) fruit drinks and ades, which might

be assumed to be reconstituted from tap water rather than canned products; and (4) the total of the three sources. With these assumptions, the mean per capita total intake of water is estimated to be 1,416 mL/day for adult males (i.e., 20 years of age and older), 1,288 mL/day for adult females (i.e., 20 years of age and older), and 1,150 mL/day for all ages and both sexes combined. Although these assumptions appear reasonable, a close reading of the definitions used by USDA (1995) reveals that the word “tap water” does not occur, and this uncertainty prevents the use of this study as a key study of tap water intake.

The advantages of using these data are that (1) the survey had a large sample size and (2) the authors attempted to represent the general U.S. population by oversampling low-income groups and by weighting the data to compensate for low response rates. The disadvantages are that (1) the word “tap water” was not defined, and the assumptions that must be used to compare the data with the other tap water studies might not be valid; (2) the data collection period reflects only a 1-day intake period and may not reflect long-term drinking water intake patterns; (3) data on the percentiles of the distribution of intakes were not given; and (4) the data are almost 20 years old and may not be entirely representative of current intake patterns.

3.3.2.10. U.S. EPA (1996)—*Descriptive Statistics from a Detailed Analysis of the National Human Activity Pattern Survey (NHAPS) Responses*

The U.S. EPA collected information on the number of glasses of drinking water and juice reconstituted with tap water consumed by the general population as part of the National Human Activity Pattern Survey (NHAPS) (U.S. EPA, 1996). NHAPS was conducted between October 1992 and September 1994. Over 9,000 individuals in the 48 contiguous United States provided data on the duration and frequency of selected activities and the time spent in selected microenvironments via 24-hour diaries. Over 4,000 NHAPS respondents also provided information on the number of 8-ounce glasses of water and the number of 8-ounce glasses of juice reconstituted with water that they drank during the 24-hour survey period (see Tables 3-37 and 3-38). The median number of glasses of tap water consumed was 1–2, and the median number of glasses of juice with tap water consumed was 1–2.

For both individuals who drank tap water and individuals who drank juices reconstituted with tap water, the number of glasses consumed in a day ranged from 1 to 20 glasses. The highest percentage of the

population (37.1%) who drank tap water, consumed in the range of 3–5 glasses a day, and the highest percentage of the population (51.5%) who consumed juice reconstituted with tap water consumed 1–2 glasses in a day. Based on the assumption that each glass contained 8 ounces of water (226.4 mL), the total volume of tap water and juice with tap water consumed would range from 0.23 L/day (1 glass) to 4.5 L/day (20 glasses) for respondents who drank tap water. Using the same assumption, the volume of tap water consumed for the population who consumed 3–5 glasses would be 0.68 L/day to 1.13 L/day, and the volume of juice with tap water consumed for the population who consumed 1–2 glasses would be 0.23–0.46 L/day. Assuming the average individual consumes 3–5 glasses of tap water plus 1–2 glasses of juice with tap water, the range of total tap water intake for this individual would range from 0.9 L/day to 1.64 L/day. These values are consistent with the average intake rates observed in other studies.

The advantages of NHAPS are that the data were collected for a large number of individuals and that the data are representative of the U.S. population. However, evaluation of drinking water intake rates was not the primary purpose of the study, and the data do not reflect the total volume of tap water consumed. In addition, using the assumptions described above, the estimated drinking water intake rates from this study are within the same ranges observed for other drinking water studies.

3.3.2.11. Heller et al. (2000)—*Water Consumption and Nursing Characteristics of Infants by Race and Ethnicity*

Heller et al. (2000) analyzed data from the 1994–1996 CSFII to evaluate racial/ethnic differences in the ingestion rates of water in children younger than 2 years old. Using data from 946 children in this age group, the mean amounts of water consumed from eight sources were determined for various racial/ethnic groups, including black non-Hispanic, white non-Hispanic, Hispanic, and “other” (Asian, Pacific Islander, American Indian, Alaskan Native, and other nonspecified racial/ethnic groups). The sources analyzed included (1) plain tap water, (2) milk and milk drinks, (3) reconstituted powdered or liquid infant formula made from drinking water, (4) ready-to-feed and other infant formula, (5) baby food, (6) carbonated beverages, (7) fruit and vegetable juices and other noncarbonated drinks, and (8) other foods and beverages. In addition, Heller et al. (2000) calculated mean plain water and total water ingestion rates for children by age, sex, region, urbanicity, and poverty category. Ages were defined as less than

12 months and 12 to 24 months. Regions were categorized as Northeast, Midwest, South, and West. Heller et al. (2000) did not report the states represented by each of these regions, but it is likely that they defined these regions in the same way Sohn et al. (2001) did. See Section 3.6.1.3 for a discussion on the Sohn et al. (2001) study. Urbanicity of the residence was defined as urban (i.e., being in a metropolitan statistical area [MSA], suburban [outside of an MSA], or rural [being in a non-MSA]). Poverty category was derived from the poverty income ratio. In this study, a poverty income ratio was calculated by dividing the family's annual income by the federal poverty threshold for that size household. The poverty categories used were 0–1.30, 1.31–3.50, and greater than 3.50 times the federal poverty level (Heller et al., 2000).

Table 3-39 provides water ingestion estimates for the eight water sources evaluated, for each of the race/ethnic groups. Heller et al. (2000) reported that black non-Hispanic children had the highest mean plain tap water intake (21 mL/kg-day), and white non-Hispanic children had the lowest mean plain tap water intake (13 mL/kg-day). The only statistically significant difference between the racial/ethnic groups was found to be in plain tap water consumption and total water consumption. Reconstituted baby formula made up the highest proportion of total water intake for all race/ethnic groups. Table 3-40 presents tap water and total water ingestion by age, sex, region, urbanicity, and poverty category. On average, children younger than 12 months of age consumed less plain tap water (11 mL/kg-day) than children aged 12–24 months (18 mL/kg-day). There were no significant differences in plain tap water consumption by sex, region, or urbanicity. Heller et al. (2000) reported a significant association between higher income and lower plain tap water consumption. For total water consumption, ingestion per kg body weight was lower for the 12- to 24-month-old children than for those younger than 12 months of age. Urban children consumed more plain tap water and total water than suburban and rural children. In addition, plain tap water and total water ingestion was found to decrease with increasing poverty category (i.e., higher wealth).

A major strength of the Heller et al. (2000) study is that it provides information on tap water and total water consumption by race, age, sex, region, urbanicity, and family income. A weakness in the CSFII data set is that it includes data collected over only 2 days that may not be entirely representative of long-term intake.

3.3.2.12. Marshall et al. (2003a)—Patterns of Beverage Consumption during the Transition Stage of Infant Nutrition

Marshall et al. (2003a) investigated beverage ingestion during the transition stage of infant nutrition. Mean ingestion of infant formula, cow's milk, combined juice and juice drinks, water, and other beverages was estimated using a frequency questionnaire. A total of 701 children, aged 6 months through 24 months, participated in the Iowa Fluoride Study (IFS). Mothers of newborns were recruited from 1992 through 1995. The parents were sent questionnaires when the children were 6, 9, 12, 16, 20, and 24 months old. Of the 701 children, 470 returned all six questionnaires, 162 returned five, 58 returned four, and 11 returned three, with the minimum criteria being three questionnaires to be included in the data set (Marshall et al., 2003a). The questionnaire was designed to assess the type and quantity of the beverages consumed during the previous week. The validity of the questionnaire was assessed using a 3-day food diary for reference (Marshall et al., 2003a). Table 3-41 presents the percentage of subjects consuming beverages and mean daily beverage ingestion for children with returned questionnaires. Human milk ingestion was not quantified, but the percent of children consuming human milk was provided at each age category (see Table 3-41). Juice (100%) and juice drinks were not distinguished separately but categorized as juice and juice drinks. Water used to dilute beverages beyond normal dilution and water consumed alone were combined. Based on Table 3-41, 97% of the children consumed human milk, formula, or cow's milk throughout the study period, and the percentage of infants consuming human milk decreased with age, while the percent consuming water increased (Marshall et al., 2003a). Marshall et al. (2003a) observed that, in general, lower family incomes were associated with less breast-feeding and increased ingestion of other beverages.

The advantage of this study is that it provides mean ingestion data for various beverages. Limitations of the study are that it is based on samples gathered in one geographical area and may not be reflective of the general population. The authors also noted the following limitations: the parents were not asked to differentiate between 100% juice and juice drinks; the data are parent-reported and could reflect perceptions of appropriate ingestion instead of actual ingestion, and a substantial number of the infants from well-educated, economically secure households dropped out during the initial phase.

3.3.2.13. Marshall et al. (2003b)—Relative Validation of a Beverage Frequency Questionnaire in Children Aged 6 Months through 5 Years Using 3-Day Food and Beverage Diaries

Marshall et al. (2003b) conducted a study based on data taken from 700 children in the IFS. This study compared estimated beverage ingestion rates reported in questionnaires for the preceding week and diaries for the following week. Packets were sent periodically (every 4 to 6 months) to parents of children aged 6 weeks through 5 years of age. This study analyzed data from children, aged 6 and 12 months, and 2 and 5 years of age. Beverages were categorized as human milk, infant formula, cow's milk, juice and juice drinks, carbonated and rehydration beverages, prepared drinks (from powder), and water. The beverage questionnaire was completed by parents and summarized the average amount of each beverage consumed per day by their children. The data collection for the diaries maintained by parents included 1 weekend day and 2 weekdays and included detailed information about beverages consumed. Table 3-42 presents the mean ingestion rates of all beverages for children aged 6 and 12 months and 3 and 5 years. Marshall et al. (2003b) concluded that estimates of beverage ingestion derived from quantitative questionnaires are similar to those derived from diaries. They found that it is particularly useful to estimate ingestion of beverages consumed frequently using quantitative questionnaires.

The advantage of this study is that the survey was conducted in two different forms (questionnaire and diary) and that diaries for recording beverage ingestion were maintained by parents for 3 days. The main limitation is the lack of information on whether the diaries were populated on consecutive or nonconsecutive days. The IFS survey participants may not be representative of the general population of the United States because participants were primarily white, and from affluent and well-educated families in one geographic region of the country.

3.3.2.14. Skinner et al. (2004)—Transition in Infants' and Toddlers' Beverage Patterns

Skinner et al. (2004) investigated the pattern of beverage consumption by infants and children participating in the Feeding Infant and Toddlers Study (FITS) sponsored by Gerber Products Company. The FITS is a cross-sectional study designed to collect and analyze data on feeding practices, food consumption, and usual nutrient intake of U.S. infants and toddlers (Devaney et al., 2004). It included a stratified random sample of 3,022 infants and toddlers between 4 and

24 months of age. Parents or primary caregivers of sampled infants and toddlers completed a single 24-hour dietary recall of all foods and beverages consumed by the child on the previous day by telephone interview. All recalls were completed between March and July 2002. Detailed information on data collection, coding, and analyses related to FITS is provided in Devaney et al. (2004).

Beverages consumed by FITS participants were identified as total milks (i.e., human milk, infant formulas, cow's milk, soy milk, goat's milk), 100% juices, fruit drinks, carbonated beverages, water, and "other" drinks (i.e., tea, cocoa, dry milk mixtures, and electrolyte replacement beverages). There were six age groupings in the FITS study: 4 to 6, 7 to 8, 9 to 11, 12 to 14, 15 to 18, and 19 to 24 months. Skinner et al. (2004) calculated the percentage of children in each age group consuming any amount in a beverage category and the mean amounts consumed. Table 3-43 provides the mean beverage consumption rates in mL/day for the six age categories. Skinner et al. (2004) found that some form of milk beverage was consumed by almost all children at each age; however, total milk ingestion decreased with increasing age. Water consumption also doubled with age, from 163 mL/day in children aged 4 to 6 months old to 337 mL/day in children aged 19 to 24 months old. The percentages of children consuming water increased from 34% at 4 to 6 months of age to 77% at 19 to 24 months of age.

A major strength of the Skinner et al. (2004) study is the large sample size (3,022 children). However, beverage ingestion estimates are based on 1 day of dietary recall data and human milk quantity derived from studies that weighed infants before and after each feeding to determine the quantity of human milk consumed (Devaney et al., 2004); therefore, estimates of total milk ingestion may not be accurate.

3.3.2.15. Barraj et al. (2009)—Within-Day Drinking Water Consumption Patterns: Results from a Drinking Water Consumption Study

In 2000/2001, Barraj et al. (2009) conducted a Drinking Water Consumption Survey (DWCS), funded by Bayer Crop Science, to generate data that could be used to assess acute effects of exposures lasting less than 24 hours. The objective of the study was to determine how often and how much water participants ingested during the day. Data for a nationally representative sample of the U.S. population were collected over 7-day periods during both summer (August) and winter (March) months. The study participants were selected from households within Bayer's Home Testing Institute consumer panel, and diaries were delivered to 3,000 randomly

selected households in summer, and 3,650 households in winter. The response rates were 33 and 36%, respectively, for the summer and winter surveys, with 994 households completing the summer survey, and 1,320 households completing the winter survey. After excluding diaries with missing or incorrect data, the final data set represented 4,198 individuals (1,740 in summer) and 2,458 in winter). The vast majority of participants were white (90.2% for summer and winter combined), and males and females above the age of 50 years accounted for the largest portion of participants (34.5%). Teenage males and females accounted for the smallest percentage of participants (6.7%), and children accounted for approximately 13% of the survey population. Each survey participant was asked to complete a diary to provide details about their water consumption patterns over a 7-day period. Using the diary data for a randomly selected day for each survey participant, the average number of drinking occasions per day, the average amount consumed per drinking occasion, and the average amount of water consumed per day was determined for each sex and age group for each season (see Table 3-44).

For all sex and age groups combined, there were slightly more daily drinking occasions reported for summer (mean of 4.4) than winter (mean of 4.1), and the average amount consumed per drinking occasion was slightly higher in the summer (266 mL/event) compared to the winter (248 mL/event). Based on one randomly selected day for each survey participant, mean daily water intake was higher for summer (1,141 mL/day; $N=1,740$) than for winter (1,023 mL/day; $N=2,458$). Based on all survey days and all participants ($N=27,192$ person-days), the mean drinking water intake rate for both seasons combined, was 1,118 mL/day, and the 95th percentile was 2,957 mL/day. The mean and 95th percentile intakes rates were 1,200 and 3,194 mL/day, respectively, for summer ($N=11,318$ person-days), and 1,056 and 2,780 mL/day, respectively, for winter ($N=15,874$ person-days).

This study was based on a large, nationally representative sample of the U.S. population, and provided data by season. Also, it provided information on the amount of water consumed per event within a 24-hour period, and data were provided by sex and age. The limitations of this study are that hourly time increments and 2-ounce amount increments were used in collecting the diary data. These factors may contribute to uncertainties regarding the exact consumption times and the exact amounts consumed.

3.3.2.16. Zizza et al. (2009)—Total Water Intakes of Community-Living Middle-Old and Oldest-Old Adults

Zizza et al. (2009) used data from NHANES 1999–2002 to estimate total water intake among older Americans, defined as respondents 65 years of age or older ($N=2,054$). Intake was estimated as g/day and as g/body weight/day. Total water was defined as “the sum of the amount of drinking water consumed and the amount of water consumed from food and beverage sources.” The relative contributions of total water intake that was derived from plain drinking water, beverages, and food were also calculated. Total water intake was estimated for three age groups of older survey respondents: young-old (65 to <75 years), middle-old (75 to <85 years), and oldest-old (85+ years). Table 3-45 provides the estimates of total water intake for these three age groups. Zizza et al. (2009) reported that total water intake rates for the middle-old and oldest-old groups were significantly lower than for the young-old group. Plain drinking water accounted for 38.1, 39.4, and 39.5% of total water intake for the young-old, middle-old, and oldest-old age groups respectively. Beverages accounted for 40.8, 38.3, and 36.4% of total water intake and food accounted for 21.1, 22.2, and 24.2% of total water intake for the same three age groups respectively.

This study provides information for a nationally representative population of older Americans. However, the water categories are somewhat different from those used elsewhere in this chapter. For example, plain water category appears to include both tap water and bottled water. Likewise, water from beverages may include both water that is intrinsic to purchased beverages (i.e., widely distributed drinks such as carbonated soft drinks) as well as beverages that are prepared with community tap water.

3.3.2.17. Sebastian et al. (2011)—Drinking Water Intake in the United States; Rosinger et al. (2016)—Daily Water Intake among U.S. Men and Women, 2009–2012

Sebastian et al. (2011) investigated “plain water” intake using data from NHANES 2005–2008. “Plain water” was defined as “tap water and noncarbonated bottled water without sweeteners or other additions. [It] does not include water naturally present in or added as an ingredient to other beverages or foods.” The study authors observed that plain water accounted for approximately one-third of the total water consumed (i.e., total water was defined as plain water plus water contained in foods and beverages). Approximately 69% of plain water was consumed at home and 31% was consumed away from home.

Sebastian et al. (2011) also found that tap water consumed at home accounted for 46% of the plain water consumed; 16% of plain water was tap water consumed away from home. Bottled water consumed at home accounted for 23% of plain water intake, and bottled water consumed away from home accounted for 16% of plain water intake. Using NHANES 2009–2012, Rosinger et al. (2016) estimated that plain water accounted for 30% of total water intake for men and 34% of total intake for women.

These studies provide general information about plain and total water intake in the United States. The Sebastian et al. (2011) data are provided in units of cups/day. The Rosinger et al. (2016) study provides data in units of L/day, but for mean total water only, not distributions.

3.3.2.18. Kahn and Stralka (2009)—Estimated Daily Average per Capita Water Ingestion by Child and Adult Age Categories Based on USDA’s 1994–1996 and 1998 Continuing Survey of Food Intakes by Individuals and Supplemental Data, Kahn (2008)

Kahn and Stralka (2009) analyzed the combined 1994–1996 and 1998 CSFII data sets to examine water ingestion rates of more than 20,000 individuals surveyed, including approximately 10,000 under age 21 and 9,000 under age 11. Previous CSFII analyses conducted using the 1994–1996 data sets were reported in U.S. EPA (2000b). USDA surveyed households in the United States and District of Columbia and collected food and beverage recall data as part of the CSFII (USDA, 1998). Data were collected by an in-home interviewer. The Day 2 interview was conducted 3 to 10 days later and on a different day of the week. Each individual in the survey was assigned a sample weight based on his or her demographic data. These weights were taken into account when calculating mean and percentile water ingestion rates from various sources. Kahn and Stralka (2009) derived mean and percentile estimates of daily average water ingestion for the following age categories: <1 month, 1 to <3 months, 3 to <6 months, 6 to <12 months, 1 to <2 years of age, 2 to <3 years, 3 to <6 years, 6 to <11 years, 11 to <16 years, 16 to <18 years, 18 to <21 years of age, 21 years and older, 65 years and older, and all ages. The increased sample size for children younger than 11 years of age (from 4,339 in the initial 1994–1996 survey to 9,643 children in the combined 1994–1996, 1998 survey) enabled water ingestion estimates to be categorized into the finer age categories recommended by U.S. EPA (2005). Consumer-only and per capita water ingestion estimates were reported in the Kahn

and Stralka (2009) study for two water source categories: all sources and community water. “All sources” included water from all supply sources such as community water supply (i.e., tap water), bottled water, other sources, and missing sources. “Community water” included tap water from a community or municipal water supply. Other sources included wells, springs, and cisterns; missing sources represented water sources that the survey respondent was unable to identify. The water ingestion estimates included both water ingested directly as a beverage (direct water) and water added to foods and beverages during final preparation at home or by local food service establishments such as school cafeterias and restaurants (indirect water). Commercial water added by a manufacturer (i.e., water contained in soda or beer) and intrinsic water in foods and liquids (i.e., milk and natural undiluted juice) were not included in the estimates. Kahn and Stralka (2009) only reported the mean and 90th and 95th percentile estimates of per capita and consumers-only ingestion. The full distributions of ingestion estimates were provided by the author (Kahn, 2008). Tables 3-46 to 3-61 present full distributions of direct and indirect water intake for the various water source categories (community water, bottled water, other sources, and all sources). Tables 3-46 to 3-49 provide per capita ingestion estimates of total water (combined direct and indirect water) in mL/day for the various water source categories (i.e., community, bottled, other, and all sources). Tables 3-50 to 3-53 present the same information as Tables 3-46 to 3-49, but in units of mL/kg-day. Tables 3-54 to 3-57 provide consumers-only combined direct and indirect water ingestion estimates in mL/day for the various source categories. Tables 3-58 to 3-61 present the same information as Tables 3-54 to 3-57 but in units of mL/kg-day. Estimates that do not meet the minimum sample size requirements as described in the *Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: NHIS/NCHS Analytical Working Group Recommendations* (NCHS, 1993) are flagged in the tables.

The CSFII 1994–1996, 1998 data have both strengths and limitations in regard to estimating water ingestion. These are discussed in detail in U.S. EPA (2004) and Kahn and Stralka (2009). The principal advantages of this survey are that (1) it was designed to be representative of the U.S. population, including children and low-income groups; (2) sample weights were provided that facilitated proper analysis of the data and accounted for nonresponse; and (3) the number of individuals sampled (more than 20,000) is sufficient to allow categorization within narrowly

defined age categories. Another advantage is that bottled water estimates include both direct and indirect intake, whereas the bottled water estimates using NHANES 2005–2010 data (see Section 3.3.1.1) include only bottled water consumed directly as a beverage; they do not include bottled water used in the preparation of foods. One limitation of this survey is that data were collected for only 2 days. As discussed in Section 3.3.1.1 in regard to U.S. EPA's analysis of NHANES data, short-term data may not accurately reflect long-term intake patterns, especially at the extremes (i.e., tails) of the distribution of water intake. This study is considered relevant because more recent data are available from NHANES 2005–2010.

3.4. PREGNANT AND LACTATING WOMEN

3.4.1. Key Study on Pregnant and Lactating Women

The section that follows provides a summary of the key study on water ingestion among pregnant and lactating women.

3.4.1.1. EPA Analysis of Consumption Data from 2005–2010 National Health and Nutrition Examination Survey

EPA estimated water intake rates for pregnant, lactating, and all women of child-bearing age (13 to <50 years) using data from the NHANES for the years 2005 to 2010 and the FCID Consumption Calculator available at <http://fcid.foodrisk.org/>, as described in Section 3.3.1.1. NHANES 2005–2010 collected data on dietary recall of food and water consumed over the previous 24-hour period on 2 nonconsecutive days. Two-day data were available for 426 pregnant women, 101 lactating women, and 5,543 women of child-bearing age. In the FCID, NHANES data on the foods people reported eating were converted to the quantities of agricultural commodities eaten, including water that was added in the preparation of foods and beverages. Two-day average intake rates were calculated for each survey respondent for community water, bottled water, other water, and all water sources. Summary statistics were calculated for the populations of pregnant, lactating, and females of child-bearing age (i.e., 13 to <50 years) on both a consumer-only and on a per capita basis. Table 3-62 provides summary statistics for per capita intake of water, and Table 3-63 provides the same data on a consumer-only basis.

As indicated in Section 3.3.1.1, an advantage of using the EPA's analysis of NHANES data is it was designed to be representative of the U.S. population. The data set used in this analysis used 6 years of intake data combined. However, the sample sizes for

pregnant and lactating women were relatively small and short-term dietary data may not accurately reflect long-term eating or drinking patterns and may under-represent infrequent consumers of a given food. This is particularly true for the tails (extremes) of the food-intake distribution.

3.4.2. Relevant Studies on Pregnant and Lactating Women

The sections that follow provide summaries of relevant studies on water ingestion among pregnant and lactating women.

3.4.2.1. Ershow et al. (1991)—Intake of Tap Water and Total Water by Pregnant and Lactating Women

Ershow et al. (1991) used data from the 1977–1978 USDA NFCS to estimate total fluid and total tap water intake among pregnant and lactating women (ages 15–49 years). Data for 188 pregnant women, 77 lactating women, and 6,201 nonpregnant, nonlactating control women were evaluated. The participants were interviewed based on 24-hour recall and then asked to record a food diary for the next 2 days. “Tap water” included tap water consumed directly as a beverage and tap water used to prepare food and tap water-based beverages. “Total water” was defined as all water from tap water and nontap water sources, including water contained in food. Tables 3-64 and 3-65 present estimated total fluid and total tap water intake rates for the three groups, respectively. Lactating women had the highest mean total fluid intake rate (2.24 L/day) compared with both pregnant women (2.08 L/day) and control women (1.94 L/day). Lactating women also had a higher mean total tap water intake rate (1.31 L/day) than pregnant women (1.19 L/day) and control women (1.16 L/day). The tap water distributions are neither normal nor lognormal, but lactating women had a higher mean tap water intake than controls and pregnant women. Ershow et al. (1991) also reported that rural women ($N = 1,885$) consumed more total water (1.99 L/day) and tap water (1.24 L/day) than urban/suburban women ($N = 4,581$, 1.93 and 1.13 L/day, respectively). Total water and tap water intake rates were lowest in the northeastern region of the United States (1.82 and 1.03 L/day) and highest in the western region of the United States (2.06 L/day and 1.21 L/day). Mean intake per unit body weight was highest among lactating women for both total fluid and total tap water intake. Total tap water intake accounted for over 50% of mean total fluid in all three groups of women (see Table 3-65). Drinking water accounted for the largest single proportion of the total fluid intake for

control (30%), pregnant (34%), and lactating women (30%) (see Table 3-66). All other beverages combined accounted for approximately 46, 43, and 45% of the total water intake for control, pregnant, and lactating women, respectively. Food accounted for the remaining portion of total water intake.

The same advantages and limitations associated with the Ershow and Cantor (1989) data also apply to these data sets (see Section 3.3.2.6). A further advantage of this study is that it provides information on estimates of total water and tap water intake rates for pregnant and lactating women. This topic has rarely been addressed in the literature.

3.4.2.2. Shimokura et al. (1998)—Assessment of Water Use for Estimating Exposure to Tap Water Contaminants

Shimokura et al. (1998) evaluated water use among 34 pregnant women and 33 of their male partners living in North Carolina. The women were up to 30 weeks pregnant at the time that the survey was conducted. Most of the women were in their twenties and thirties, were expecting their first child, and were in their second trimester of pregnancy. Approximately three quarters of the women were white and the remainder were of African American and Asian ethnicities. They tended to be highly educated and nonsmokers. Each of the participants completed a daily diary for 3 days, including one nonworking or weekend day, and an interview about their daily water consumption. Information was collected on the volume of all beverages consumed, which was defined as total water, and the volume of drinking water and beverages made with tap water, which was defined as tap water. The temperature of the beverage (i.e., cold or hot), as well as the location where the beverage was consumed, was also recorded. Table 3-67 provides summary statistics for the participants' daily water intake. Daily consumption of total water and tap water were similar for pregnant women and men, but differences based on employment status were observed for daily intake of cold tap water at home. Table 3-68 provides mean intake rates for pregnant women and men according to location, beverage type, and temperature.

This study provides useful information on daily tap water intake for pregnant women. However, the definition of total water differs from that used elsewhere in this chapter (i.e., the water content of foods is not included). Also, the study population is relatively small and may not be entirely representative of the U.S. population.

3.4.2.3. Zender et al. (2001)—Exposure to Tap Water during Pregnancy

Zender et al. (2001) conducted a study in Colorado in 1996 and 1997 to compare tap water intake among pregnant and nonpregnant women. A total of 71 pregnant and 43 nonpregnant women were recruited from Women, Infant, and Children (WIC) clinics. Nearly one-half of the pregnant women were in their second trimester, and one-quarter were in each of the first and third trimesters. Approximately one-half of the women worked outside the home, and nearly all the women had a municipal water source at their home. The women were interviewed in person or by phone and responded to questions about the amount of tap water intake in a day—including the amount consumed at home and at work. Total tap water intake included tap water consumed directly as a beverage and tap water-based cold and hot beverages. Information on the sources of the water consumed (e.g., tap water, bottled water, or filtered water) were also collected. Total tap water intake was slightly higher for pregnant women (3.4 L/day) than nonpregnant women (3.0 L/day) (see Table 3-69). Table 3-70 shows the principal source of drinking water for pregnant and for nonpregnant women. Tap water accounted for 72–75% of total water intake.

The advantage of this study is that it investigated tap water consumption based on location (i.e., at home and at work) and by source (i.e., bottled, filtered, or tap water). However, the sample size was small and the study population may not be representative of the entire United States.

3.4.2.4. Forssén et al. (2007)—Predictors of Use and Consumption of Public Drinking Water among Pregnant Women; Forssén et al. (2009)—Variability and Predictors of Changes in Water Use during Pregnancy

Forssén et al. (2007) evaluated the demographic and behavioral characteristics that would be important in predicting water consumption among pregnant women in the United States. Data were collected through telephone interviews with 2,297 pregnant women in three geographical areas in the southern United States. Women 18 years old and ≤12 weeks pregnant were recruited from the local communities and from both private and public prenatal care facilities. Variables studied included demographic characteristics, health status and history (e.g., diabetes, pregnancy history), behavioral patterns (e.g., exercise, smoking, caffeine consumption), and some physiological characteristics (e.g., prepregnancy weight). Daily amount of water ingestion was estimated based on cup sizes defined in the interview.

Water consumption was reported as cold tap water (filtered and unfiltered) and bottled water. Other behavioral information on water use such as showering and bathing habits, use of swimming pools, hot tubs, and Jacuzzis was also collected. The overall mean cold tap water ingested was 1.7 L/day (percentiles: 25th = 0.5 L/day, 50th = 1.4 L/day, 75th = 2.4 L/day, and 90th = 3.8 L/day). The overall mean bottled water ingested was 0.6 L/day (percentiles: 25th = 0.1 L/day, 50th = 0.2 L/day, 75th = 0.6 L/day, and 90th = 1.8 L/day). Table 3-71 presents water ingestion by the different variables studied, and Table 3-72 presents the percentage of ingested tap water that is filtered and unfiltered by various variables.

Forssén et al. (2009) studied changes in water use over the course of pregnancy based on data for 1,990 women that were still pregnant during a second interview. Mean cold tap water intake increased from prepregnancy (1.5 L/day) through early pregnancy (1.7 L/day) to mid-pregnancy (1.8 L/day) (see Table 3-73). Mean hot tap water intake decreased slightly from prepregnancy (0.18 L/day) to early and mid-pregnancy (0.16 L/day). Bottled water intake was essentially the same during early and mid-pregnancy (0.57 and 0.59 L/day, respectively). The greatest changes in water consumption were reported for cold tap water where 80% of the women reported either increases or decreases in consumption; 33% reported changes (increases or decreases) equal to or greater than 1.0 L/day (see Table 3-74).

The advantage of these studies is that they investigated water consumption in relation to multiple variables, and over the course of pregnancy. However, the study population was not random and may not be representative of the entire United States. There may also be limitations associated with recall bias.

3.4.2.5. Kahn and Stralka (2008)—Estimates of Water Ingestion for Women in Pregnant, Lactating, and Nonpregnant and Nonlactating Child-Bearing Age Groups Based on USDA's 1994–1996, 1998 CSFII

The combined 1994–1996 and 1998 CSFII data sets were analyzed to examine the ingestion of water by various segments of the U.S. population as described in Section 3.3.1.1. Kahn and Stralka (2008) provided water intake data for pregnant, lactating, and child-bearing age women. Mean and upper percentile distribution data were provided. Lactating women had an estimated per capita mean community water ingestion of 1.38 L/day, the highest water ingestion rates of any among the population evaluated. The mean consumer-only rate was 1.67 L/day. Tables 3-75

through 3-82 provide estimated drinking water intakes for pregnant and lactating women, and nonpregnant, nonlactating women aged 15–44 years old. The same advantages and limitations discussed in Section 3.3.1.1 apply to these data. An additional limitation of this analysis is that the sample size was relatively small (i.e., 70 pregnant and 41 lactating women). This study is considered relevant, but not key because more recent data are available for pregnant and lactating women.

3.5. FORMULA-FED INFANTS

3.5.1. Key Study on Formula-Fed Infants

The section that follows provides a summary of the key study on water ingestion among formula-fed infants.

3.5.1.1. Kahn et al. (2013)—Estimates of Water Ingestion in Formula by Infants and Children Based on USDA's 1994–1996 and 1998 Continuing Survey of Food Intakes by Individuals

Kahn et al. (2013) used data from the 1994–1996 and 1998 CSFII to estimate water ingestion among formula-fed infants, ages <1 month, 1 to <3 months, 3 to <6 months, 6 to <12 months, and 1 to <2 years. The same methodology was used as in Kahn and Stralka (2009), as described in Section 3.3.2.18. Indirect water ingestion among “formula-consumers only” was based on the estimated amount of community water used to reconstitute or dilute infant formula. Total indirect and direct water intake among formula-fed infants represented both water used to reconstitute or dilute baby formula and water consumed directly as a beverage. Mean and 95th percentile indirect, and total indirect and direct water ingestion rates for formula-consuming infants are provided in Table 3-83. On a mL/day basis, mean intake rates increased between <1 month and 3 to <6 months and then declined; on a mL/kg-day basis, mean intake declined from <1 month to 1 to <2 years.

The same advantages and disadvantages discussed in Section 3.3.2.18 apply to these data. In addition, as suggested by Kahn et al. (2013), while the more recent data may be available (e.g., NHANES) for this type of analysis, the amount of water ingested by formula-fed infants would not be expected to change significantly because the nutritional needs of infants would not be expected to have varied over time.

3.5.2. Relevant Studies on Formula-Fed Infants

The section that follows provides summaries of the relevant studies on water ingestion among formula-fed infants. Sections 3.3.2.8 (Levy et al., 1995), 3.3.2.11

(Heller et al., 2000), and 3.3.2.12 (Marshall et al., 2003a) also provide some relevant information on ingestion of water used in reconstituting infant formula.

3.5.2.1. Hilbig et al. (2002)—Measured Consumption of Tap Water in German Infants and Young Children as Background for Potential Health Risk Assessment: Data of the DONALD Study

Hilbig et al. (2002) estimated tap water ingestion rates based on 3-day dietary records of 504 German children aged 3, 6, 9, 12, 18, 24, and 36 months. The data were collected between 1990 and 1998 as part of the Dortmund Nutritional and Anthropometric Longitudinally Designed (DONALD) study. The DONALD study was a cohort study that collected data on diet, metabolism, growth, and development from healthy subjects between infancy and adulthood (Sichert-Hellert et al., 2001). Beginning in 1985, approximately 40 to 50 infants were enrolled in the study annually. Mothers of the participants were recruited in hospital maternity wards. Tap water ingestion rates were calculated for three subgroups of children: (1) breast-fed infants ≤ 12 months of age (exclusive and partial breast-fed infants), (2) formula-fed infants ≤ 12 months of age (no human milk, but including weaning food), and (3) mixed-fed young children aged 18 to 36 months. Hilbig et al. (2002) defined “total tap water from household” as water from the tap consumed as a beverage or used in food preparation. “Tap water from food manufacturing” was defined as water used in industrial production of foods, and “Total Tap Water” was defined as tap water consumed from both the household and that used in manufacturing.

Table 3-84 summarizes total tap water ingestion (in mL/day and mL/kg-day) and tap water ingestion from household and manufacturing sources (in mL/kg-day) for breast-fed, formula-fed, and mixed-fed children. Mean total tap water intake during the 1st year of life was higher in formula-fed infants (53 mL/kg-day) than in breast-fed infants (17 mL/kg-day) and mixed-fed young children (19 mL/kg-day). Tap water from household sources constituted 66 to 97% of total tap water ingestion in the different age groups.

The major limitation of this study is that the study sample consists of families from an upper social background in Germany (Hilbig et al., 2002). Because the study was conducted in Germany, the data may not be directly applicable to the U.S. population. However, this study was included in this chapter

because similar data for a U.S. population of infants are limited.

3.5.2.2. Levallois et al. (2008)—Drinking Water Intake by Infants Living in Rural Quebec (Canada)

Levallois et al. (2008) conducted a survey on a population of 2-month-old infants residing in seven agricultural areas of Canada. Eligible newborns were born in this rural area of Quebec between January and April 2002. Infants who were less than 34 weeks of gestation at birth, families who did not speak French, or those served by surface water supplies were excluded from the study. Families who were eligible for participation were sent a letter explaining the survey followed by a phone interview with the infant’s mother. There were 642 mothers who participated in the survey, which was conducted when the infants were 8–9 weeks old. Questions asked during the phone interview included those on feeding practices such as the quantity and number of feedings each day and the specific type and volume of water used for preparing formula, juices, or cereals. Of the 642 participating infants, 38.3% were exclusively breast-fed and, therefore, had no drinking water intake. Almost half of the participating infants (47.5%) were fed either ready-to-use formula or dry formula mixed with water, and 14.2% received mixed breast and formula feedings. Infants who consumed some water comprised 61.2% of the participants, and among these 59, 34, and 7% consumed mostly tap water, bottled water, or both tap and bottled water, respectively. For consumers, mean tap water intake was 564 mL/day (105 mL/kg-day) and mean bottled water intake was 504 mL/day (94 mL/kg-day) (see Table 3-85).

This study provides quantitative estimates of drinking water consumption by a population of 2-month-old infants according to their feeding practices. Limitations of the study include the fact that drinking water intake was not measured, but was provided by the infants’ mothers during telephone interviews. Although the participants resided in rural areas of Canada, which may not be entirely representative of the U.S. population, it is assumed that drinking water intake for formula-fed infants would be similar to that of those in the United States. Therefore, Levallois et al. (2008) was included here as a relevant study.

3.5.2.3. Schier et al. (2010)—Perchlorate Exposure from Infant Formula and Comparisons with the Perchlorate Reference Dose

Schier et al. (2010) estimated perchlorate exposures among 1- and 6-month-old infants consuming reconstituted powdered infant formula,

using measured concentrations of perchlorate in the formula and estimated formula intake rates. Infant formula ingestion rates were estimated as the product of average infant energy intakes in kcal/kg-day and estimated infant body weights, divided by the estimated number of calories in the infant formula in kcal/L formula. The estimated 50th percentile formula intake rate was estimated to be 0.7 L/day for 1-month-old infants and 1.0 L/day for 6-month-old infants. The estimated 90th percentile formula intake rate was estimated to be 1.0 L/day for 1-month-old infants and 1.4 L/day for 6-month-old infants. This study provides an indirect estimate of water intake among formula-fed infants.

3.6. HIGH ACTIVITY LEVELS/HOT CLIMATES

3.6.1. Relevant Studies on High Activity Levels/Hot Climates

The following sections provide summaries of relevant studies on water ingestion associated with various activity levels and climates.

3.6.1.1. McNall and Schlegel (1968)—*Practical Thermal Environmental Limits for Young Adult Males Working in Hot, Humid Environments*

McNall and Schlegel (1968) conducted a study that evaluated the physiological tolerance of adult males working under varying degrees of physical activity. Subjects were required to operate pedal-driven propeller fans for 8-hour work cycles under varying environmental conditions. The activity pattern for each individual was cycled as 15 minutes of pedaling and 15 minutes of rest for each 8-hour period. Two groups of eight subjects each were used. Work rates were divided into three categories as follows: high activity level (0.15 horsepower [hp] per person), medium activity level (0.1 hp per person), and low activity level (0.05 hp per person). Evidence of physical stress (i.e., increased body temperature, blood pressure, etc.) was recorded, and individuals were eliminated from further testing if certain stress criteria were met. The amount of water consumed by the test subjects during the work cycles was also recorded. Water was provided to the individuals on request.

Table 3-86 presents the water intake rates obtained at the three different activity levels and the various environmental temperatures. The data presented are for test subjects with continuous data only (i.e., those test subjects who were not eliminated at any stage of the study due to stress conditions). Water intake was the highest at all activity levels when environmental temperatures were increased. The highest intake rate

was observed at the low activity level at 100°F (0.65 L/hour); however, there were no data for higher activity levels at 100°F. It should be noted that this study estimated intake on an hourly basis during various levels of physical activity. These hourly intake rates cannot be converted to daily intake rates by multiplying by 24 hours/day because they are only representative of intake during the specified activity levels, and the intake rates for the rest of the day are not known. Therefore, comparison of intake rate values from this study cannot be made with values from the previously described studies on drinking water intake.

3.6.1.2. U.S. Army (1983, 1999)—*Water Consumption Planning Factors*

The U.S. Army has developed water consumption planning factors to enable it to transport an adequate amount of water to soldiers in the field under various conditions (U.S. Army, 1983, 1999). Both climate and activity levels were used to determine the appropriate water consumption needs. Consumption factors have been established for the following uses: (1) drinking, (2) heat treatment, (3) personal hygiene, (4) centralized hygiene, (5) food preparation and sanitation, (6) laundry, (7) medical treatment, (8) vehicle and aircraft maintenance, (9) graves registration, and (10) construction. Only personal drinking water consumption factors are described here. Drinking water consumption planning factors are based on the estimated amount of water needed to replace fluids lost by urination, perspiration, and respiration. It assumes that water lost to urinary output averages 1 quart/day (0.9 L/day), and perspiration losses range from almost nothing in a controlled environment to 1.5 quarts/day (1.4 L/day) in a very hot climate where individuals are performing strenuous work. Water losses to respiration are typically very low except in extreme cold where water losses can range from 1 to 3 quarts/day (0.9 to 2.8 L/day). This occurs when the humidity of inhaled air is near zero, but expired air is 98% saturated at body temperature (U.S. Army, 1983).

Drinking water is defined by the U.S. Army (1983, 1999) as “all fluids consumed by individuals to satisfy body needs for internal water.” This includes soups, hot and cold drinks, and tap water. Planning factors have been established for hot, temperate, and cold climates based on the following mixture of activities among the workforce: 15% of the force performing light work, 65% of the force performing medium work, and 20% of the force performing heavy work. Hot climates are defined as tropical and arid areas where the temperature is greater than 80°F. Temperate

climates are defined as areas where the mean daily temperature ranges from 32 to 80°F. Cold regions are areas where the mean daily temperature is less than 32°F. Table 3-87 presents drinking water consumption factors for these three climates. These factors are based on research on individuals and small unit training exercises. The estimates are assumed to be conservative because they are rounded up to account for the subjective nature of the activity mix and minor water losses that are not considered (U.S. Army, 1983, 1999).

The advantage of using these data is that they provide conservative estimates of drinking water intake among individuals performing at various levels of physical activity in hot, temperate, and cold climates. However, the planning factors described here are based on assumptions about water loss from urination, perspiration, and respiration, and are not based on survey data or actual measurements.

3.6.1.3. Sohn et al. (2001)—Fluid Consumption Related to Climate among Children in the United States

Sohn et al. (2001) investigated the relationship between fluid consumption among children aged 1 to 10 years and local climate using data from the NHANES III (1988–1994). Children who completed the 24-hour dietary interview (or proxy interview for the younger children) during the NHANES III survey were selected for the analysis. Breast-fed children were excluded from the analysis. Among 8,613 children who were surveyed, 688 (18%) were excluded due to incomplete data. A total of 7,925 eligible children remained. Because data for climatic conditions were not collected in the NHANES III survey, the mean daily maximum temperature from 1961 to 1990, averaged for the month during which the NHANES III survey was conducted, was obtained for each survey location from the U.S. Local Climate Historical Database. Of the 7,925 eligible children with complete dietary data, temperature information was derived for only 3,869 children (48.8%) because detailed information on survey location, in terms of county and state, was released only for counties with a population of more than a half million.

Sohn et al. (2001) calculated the total amount of fluid intake for each child by adding the fluid intake from plain drinking water and the fluid intake from foods and beverages other than plain drinking water provided by NHANES III. Sohn et al. (2001) identified major fluid sources as milk (and milk drinks), juice (fruit and vegetable juices and other noncarbonated drinks), carbonated drinks, and plain water. Fluid intake from sources other than these

major sources was grouped into other foods and beverages. Other foods and beverages included bottled water, coffee, tea, baby food, soup, water-based beverages, and water used for diluting food.

Table 3-88 presents mean fluid ingestion rates of selected fluids for the total sample population and for the subsets of the sample population with and without temperature information. The estimated mean total fluid and plain water ingestion rates for the 3,869 children for whom temperature information was obtained are presented in Table 3-89 according to age (years), sex, race/ethnicity, poverty:income ratio, region, and urbanicity. Poverty:income ratio was defined as the ratio of the reported family income to the federal poverty level. The following categories were assigned: low socioeconomic status (SES) = 0.000 to 1.300 times the poverty:income ratio; medium SES = 1.301 to 3.500 times the poverty/income level; and high SES = 3.501 or greater times the poverty/income level. Regions were Northeast, Midwest, South, and West, as defined by the U.S. Census Bureau (see Table 3-89). Sohn et al. (2001) did not find a significant association between mean daily maximum temperature and total fluid or plain water ingestion, either before or after controlling for sex, age, SES, and race or ethnicity. However, significant associations between fluid ingestion and age, sex, socioeconomic status, and race and ethnicity were reported.

The main strength of the Sohn et al. (2001) study is the evaluation of water intake as it relates to weather data. The main limitations of this study were that northeastern and western regions were over-represented because temperature data were only available for counties with populations over one-half million. In addition, whites were under-represented compared to other racial or ethnic groups. Other limitations include lack of data for children from extremely cold or hot weather conditions.

3.6.1.4. Kant et al. (2009)—Intakes of Plain Water, Moisture in Foods and Beverages, and Total Water in the Adult U.S. Population—Nutritional, Meal Pattern, and Body Weight Correlates: NHANES 1999–2006; Kant and Graubard (2010)—Contributors of Water Intake in U.S. Children and Adolescents: Associations with Dietary and Meal Characteristics—National Health and Nutrition Examination Survey 2005–2006

Using data from NHANES 1999–2004, Kant et al. (2009) estimated water intake for adults, ages ≥20 years ($N = 4,112$), based on their reported activity

levels. Intake was for plain water (i.e., including tap water, water from a cooler or drinking fountain, spring water, and noncarbonated bottled water), water in beverages and food, and total water (i.e., the sum of plain water and moisture in beverages and food). Beverages included “all types of liquid milk, shakes, fruit or vegetable juices, juice drinks, carbonated and noncarbonated sweetened or unsweetened drinks, coffee, tea, hot chocolate, all alcoholic drinks, and carbonated water.” Multiple linear regression was used to compute adjusted mean water intake based on covariates such as sex, age, race/ethnicity, body mass index, income, education, smoking status, chronic illness, survey wave, survey day, and leisure-time physical activity. Leisure-time physical activity was categorized as having any leisure-time activity lasting ≥ 10 minutes over the previous month, and according to the average activity level on a given day (i.e., mostly sitting, mostly standing, carry light loads or climb hills, or heavy work or carry heavy loads). Table 3-90 provides a summary of water intake for adults according to these activity categories. Higher intake rates of plain and total water were associated with participation in any leisure-time activity. Higher intake of moisture from beverages and total water were associated with higher average activity levels on a usual day (see Table 3-90).

Kant and Graubard (2010) used a similar approach with data from NHANES 2005–2006 to estimate water intake for children ages 2–19 years of age ($N = 3,978$). However, the activity level definitions differed from those used for adults in Kant and Graubard (2009). Kant and Graubard (2010) classified activity levels for 2- to 11-year-old children based on the number of times per week the child was reported to have played or exercised hard enough to induce sweat. The categories were: 0 times = none, 1–2 = a little, 3–4 = some, and ≥ 5 = a lot. For children 12–19 years of age, activity levels were based on three questions about whether participants had any leisure-time activity lasting ≥ 10 minutes. The three questions pertained to vigorous, moderate, or muscle strengthening activities. The categories were no to all three questions = none, yes to 1 question = a little, yes to 2 questions = some, and yes to all three questions = a lot. Table 3-90 provides water intake estimates based on these activity levels. Kant and Graubard noted that the physical activity level was only weakly associated with plain water intake, but not with the moisture content of beverages or foods, or with total water.

These studies provide information on water intake based on physical activity. However, the water categories are somewhat different from those used elsewhere in this chapter. For example, plain water

category appears to include both tap water and bottled water. Likewise, beverage moisture may include both water that is intrinsic to purchased drinks (i.e., widely distributed beverages such as carbonated soft drinks) as well as beverages that may be prepared with community tap water (e.g., coffee).

3.6.1.5. *Yang and Chun (2014)—Consumptions of Plain Water, Moisture in Foods and Beverages, and Total Water in Relation to Dietary Micronutrient Intakes and Serum Nutrient Profiles among U.S. Adults*

Yang and Chun (2014) conducted a study similar to Kant et al. (2009). They estimated water intake among adults, ages 20 years of age and older, based on activity levels. NHANES 2005–2006 data were used to estimate intake of plain water, water from beverages and food, and total water. The definitions of these water categories were the same as those in Kant et al. (2009), but the levels of physical activity were defined differently. Yang and Chun (2014) based the activity levels on “the metabolic equivalent (MET) score calculated by combining the intensity level of the leisure-time activities reported, mean duration and frequency.” Water intake was evaluated for four activity levels: no activity (0) and three tertiles of the MET score (T1, T2, and T3). The mean daily total water intake for adults was 3,066 g (see Table 3-90). Yang and Chun (2014) reported that the contributions to total water were 46% from beverages, 32% from plain water, and 22% from food, and higher activity was associated with higher total water intake.

Like the Kant et al. (2009) study, this study provides information on total water intake based on activity levels. However, the water categories differ from those used elsewhere in this chapter.

3.6.1.6. *Montain and Ely (2010)—Water Requirements and Soldier Hydration*

Montain and Ely (2010) provided an overview of factors that affect soldiers’ hydration and water balance, including environment, physical activity and load, and body size and gender. For example, increasing temperature and relative humidity increase sweating and the need for water replacement. The type of clothing worn and the load being carried can also affect the rate of perspiration and need for water replacement. Factors affecting water needs in cold climates include: cold-induced diuresis (increased urine loss), respiratory water loss from breathing cold dry air, clothing insulation that induces sweating, and the metabolic cost of movement in cold terrain. High altitude hypoxia can also contribute to water loss. Because sweat losses are dependent on exercise

intensity and duration, water needs increase as energy expenditure increases (Montain and Ely, 2010). Energy expenditure and the need for water replacement also increases with carrying increasingly heavy loads. Montain and Ely (2010) suggested that activity-related caloric costs increase with increasing body size; thus, larger individuals may require larger amounts of water. Likewise, men may require more water than women because they “are heavier and sweat more profusely than women.” Montain and Ely (2010) stated that “an individual soldier’s daily water requirements to sustain hydration can range from 2 L/day to an excess of 12 L/day, depending on weather conditions, physical activity, and physical size.

This report provides useful information on the factors influencing water losses during military operations. The values presented here are consistent with the recommended planning factors summarized in U.S. Army (1983, 1999) and Section 3.6.1.2.

3.7. WATER INGESTION WHILE SWIMMING AND DIVING

3.7.1. Key Studies on Water Ingestion While Swimming

The section that follows provides a summary of the key study on water ingestion that may occur while swimming.

3.7.1.1. *Dufour et al. (2006)—Water Ingestion during Swimming Activities in a Pool: A Pilot Study; Dufour et al. (2017)—Ingestion of Swimming Pool Water by Recreational Swimmers*

Dufour et al. (2006) estimated the amount of water ingested while swimming, using cyanuric acid as an indicator of pool water ingestion exposure. Cyanuric acid is a breakdown product of chloroisocyanates, which are commonly used as disinfectant stabilizers in recreational water treatment. Because ingested cyanuric acid passes through the body unmetabolized (Allen et al., 1982), the volume of water ingested can be estimated based on the amount of cyanuric acid measured in the pool water and in the urine of swimmers, as follows:

$$V_{\text{pool water ingested}} = V_{\text{urine}} \times (CA_{\text{urine}} \div CA_{\text{pool}})$$

(Eqn. 3-1)

where:

$V_{\text{pool water ingested}}$ = volume of pool water ingested (mL),

V_{urine} = volume of urine collected over a 24-hour period (mL),
 CA_{urine} = concentration of cyanuric acid in urine (mg/L), and
 CA_{pool} = concentration of cyanuric acid in pool water (mg/L).

The assumption that ingested cyanuric acid passes through the body unmetabolized is based on a study by Allen et al. (1982) in which two volunteers ingested known amounts of cyanuric acid and collected their own urine for 24 hours thereafter. Allen et al. (1982) estimated the recovery of ingested cyanuric acid to be 98%. Also, according to Dufour et al. (2006), dermal absorption of cyanuric acid has been shown to be negligible. Thus, the concentration in urine was assumed to represent the amount ingested. Dufour et al. (2006) estimated pool water intake among 53 swimmers that participated in a pilot study at an outdoor swimming pool treated with chloroisocyanate. This pilot study population included 12 adults (4 males and 8 females) and 41 children under 18 years of age (20 males and 21 females). The study participants were asked not to swim for 24 hours before or after a 45-minute period of active swimming in the pool. Pool water samples were collected prior to the start of swimming activities, and swimmers’ urine was collected for 24 hours after the swimming event ended. The pool water and urine sample were analyzed for cyanuric acid.

Table 3-91 presents the results of this pilot study. The mean volumes of water ingested over a 45-minute period were 16 mL (16 mL/0.75 hr = 21 mL/hr) for adults and 37 mL (37 mL/0.75 hr = 49 mL/hr) for children. The maximum volume of water ingested by adults was 53 mL/0.75 hr (71 mL/hr) and by children, was 154 mL/0.75 hr (205 mL/hr). The 97th percentile volume of water ingested by children was approximately 90 mL/0.75 hr (120 mL/hr).

This study is one of the first attempts to measure water ingested while swimming. However, the number of study participants was low, and data cannot be broken out by the recommended age categories (U.S. EPA, 2005).

Using the same approach as in the pilot study reported in Dufour et al. (2006), Dufour et al. (2017) investigated the ingestion of swimming pool water among a study population of 549 individuals at nine public swimming pools in the Columbus, Ohio area that had been disinfected with chloroisocyanurate. The study participants included both males and females in approximately equal numbers. The participants represented three age groups: children 6–10 years old ($N = 66$), teens 11–15 years old ($N = 121$), and adults,

defined as individuals 16 years and older ($N = 362$). Study participants were asked to perform normal swimming activities for approximately one hour and collect their own urine over the following 24 hours.

For all swimmers, the arithmetic mean pool water volume ingested was 32 mL/event and the geometric mean was 14 mL/event (Dufour et al., 2017). Table 3-92 provides the ingestion rates in units of mL/hour by age and sex, as reported by Dufour et al. (2017). Children 6–10 years old ingested more water per swimming event and spent nearly twice as much time in the water as older children and adults. The estimated geometric mean ingestion rate for children 6–10 years, and teens 11–15 years was 24 mL/hour. The estimated geometric mean ingestion rate for adults (ages 16 years and older) was 12 mL/hour, but adult males ingested water at a higher rate (16 mL/hour) than adult females (9 mL/hour). The 95th percentile ingestion rates were 96 mL/hour for children, 152 mL/hour for teens, and 105 mL/hour for adults (Dufour and Wymer, 2017).

Using data obtained from the authors (Dufour, 2017), arithmetic mean ingestion rates and additional percentiles of the distributions were estimated for additional age groups of children as shown in Table 3-93. The arithmetic mean ingestion rates were 38, 44, 33, and 28 mL/hour for ages 6 to <11, 11 to <16, 16 to <21, and 21+ years, respectively. The 95th percentile ingestion rates were 96, 152, 105, and 92 mL/hour for ages 6 to <11, 11 to <16, 16 to <21, and 21+ years, respectively.

This study provides estimated swimming pool water ingestion rates based on a large sample population, and the volumes of water ingested per event are relatively consistent with those of the pilot study. According to Dufour et al. (2017) “Caution must be taken in interpreting these derived numbers [i.e., ingestion rates] too strictly, given they are based on self-reported data (minutes in the water); thus, they could be less reliable because of the anecdotal propensity of children, and even adults, to under- or over-estimate how much time is spent in the water.” As noted by Dufour et al. (2006), swimming behavior of pool swimmers may be similar to freshwater swimmers, but may differ from saltwater swimmers.

3.7.2. Relevant Studies on Water Ingestion While Swimming, Diving, or Engaging in Recreational Water Activities

The sections that follows provide summaries of the relevant studies on water ingestion while engaging in recreational water activities.

3.7.2.1. Schijven and de Roda Husman (2006)—*A Survey of Diving Behavior and Accidental Occupational and Sport Divers to Assess the Risk of Infection with Waterborne Pathogenic Microorganisms*

Schijven and de Roda Husman (2006) estimated the amount of water ingested by occupational and sports divers in the Netherlands. Questionnaires were used to obtain information on the number of dives for various types of water bodies, and the approximate volume of water ingested per dive. Estimates of the amount of water ingested were made by comparing intake to common volumes (i.e., a few drops = 2.75 mL; shot glass = 25 mL; coffee cup = 100 mL; soda glass = 190 mL). The study was conducted among occupational divers in 2002 and among sports divers in 2003 and included responses from more than 500 divers. Table 3-94 provides the results of this study. On average, occupational divers ingested 9.8 mL/dive in marine water and 5.7 mL/dive in fresh water. Sports divers wearing an ordinary diving mask ingested 9.0 mL/dive marine water and 13 mL/dive fresh recreational water. Sports divers who wore full face masks ingested less water. The main limitation of this study is that no measurements were taken. It relies on estimates of the perceived amount of water ingested by the divers. Although these data are from the Netherlands, it is assumed that water ingestion among divers in the United States would be similar, and studies involving U.S. divers were not identified.

3.7.2.2. Schets et al. (2011)—*Exposure Assessment for Swimmers in Bathing Waters and Swimming Pools*

Schets et al. (2011) collected exposure data for swimmers in fresh water, seawater, and swimming pools in 2007 and 2009. Information on the frequency, duration, and amount of water swallowed were collected via questionnaires administered to nearly 10,000 people in the Netherlands. Individuals 15 years of age and older were considered adults and answered questions for themselves, and a parent answered the questions for their eldest child under 15 years of age. Survey participants estimated the amount of water that they swallowed while swimming by responding in one of four ways: (1) none or only a few drops; (2) one or two mouthfuls; (3) three to five mouthfuls; or (4) six to eight mouthfuls. Schets et al. (2011) conducted a series of experiments to measure the amount of water that corresponded to a mouthful of water and converted the data in the four response categories to volumes of water ingested. Monte Carlo analyses were used to combine the distribution of volume

(i.e., mouthful) measurements with the distribution of responses in the four response categories to generate distributions of the amount of water swallowed per event for adult men and women, and children less than 15 year of age. Table 3-95 presents the means and 95% confidence intervals for the duration of swimming and amount of water ingested during swimming. Frequency data were also provided by Schets et al. (2011), but these data are not presented here because they are for the population of the Netherlands and may not be representative of swimming frequency in the United States. According to Schets et al. (2011), the mean volume of water ingested by children (<15 years) during an average swimming pool event lasting 81 minutes was 51 mL or 0.63 mL/min (38 mL/hour). The values for children were slightly lower for swimming in fresh water and seawater. For adults, the mean volume of water ingested ranged from 18 to 34 mL over swimming events lasting 41 to 68 minutes (see Table 3-95).

The advantages of this study are that it is based on a relatively large sample size and that data are provided for various types of swimming environments (i.e., pools, fresh water, and seawater). Although these data are from the Netherlands, and based primarily on self-reported estimates, the mean values reported in this study are similar to those based on measurements of cyanuric acid in the urine of U.S. swimmers as reported by Dufour et al. (2006).

3.7.2.3. Dorevitch et al. (2011)—Water Ingestion during Water Recreation

Dorevitch et al. (2011) estimated the volumes of water ingested during “limited contact water recreation activities.” These activities included canoeing, fishing, kayaking, motor boating, rowing, wading and splashing, and walking. Full contact scenarios (i.e., swimming and immersion) were also evaluated. Dorevitch et al. (2011) estimated water intake among individuals greater than 6 years of age using two different methods in studies conducted in 2009. In the first surface water study, self-reported estimates of ingestion were obtained via interview of 2,705 individuals after they had engaged in recreation activities in Chicago area surface waters. A total of 2,705 participants reported whether they swallowed no water, a drop or two, a teaspoon, or one or more mouthfuls of water during one of the five limited contact recreational activities (i.e., canoeing, fishing, kayaking, motor boating, and rowing). A second study was conducted in swimming pools where 662 participants engaged in limited contact scenarios (i.e., canoeing, simulated fishing, kayaking, motor boating, rowing, wading/splashing, and walking), as

well as full contact activities such as swimming and immersion. Participants were interviewed after performing their water activity and reported on their estimated water ingestion. In addition, 24-hour urine samples were collected for analysis of cyanuric acid, a tracer of swimming pool water. Translation factors for each of the reported categories of ingestion (e.g., none, drop/teaspoon, mouthful) were developed using the results of the urine analyses. These translation factors were used to estimate the volume of water ingested for the various water activities evaluated in this study (Dorevitch et al., 2011). Table 3-96 presents the estimated volumes of water ingested for the limited and full contact scenarios. Swimmers had the highest estimated water intake (mean = 10 mL/hr; 95% upper confidence limit = 35 mL/hr) among the activities evaluated.

The advantage of this study is that it provides information on the estimated volume of water ingested during both limited and full contact recreational activities. However, the data are based on self-reporting, and data are not provided for individual age groups of the population.

3.7.2.4. Suppes et al. (2014)—Assessment of Swimmers Behaviors on Pool Water Ingestion

Suppes et al. (2014) conducted a study at four swimming pools in Tucson, AZ in 2012. Pool water ingestion was estimated based on the concentration of cyanuric acid in the urine as in the Dufour et al. (2006, 2017) studies. Environmental sensors and videography techniques were also used to identify activities that might lead to increased water ingestion (e.g., head submersion, splashes of water to the face, duration of swimming activities). Questionnaires were used to collect information on age, gender, and type of swimming activity that participants engaged in (e.g., playing, diving, sitting, lap swimming). A total of 64 swimmers, ages 5 to 52 years old, participated in the study, and 35 of those who were videotaped also submitted useable 24-hour urine samples after swimming for a 45-minute period. The mean pool water ingestion rates for these 35 swimmers was reported to be 13.7 mL/hr (see Table 3-97). The age-group-specific ingestion rates were 3.5 mL/hr for adults (>18 years of age, $N = 19$) and 25.7 mL/hr for children (≤ 18 years of age, $N = 16$). The mean ingestion rate for children in this study was similar to the geometric mean ingestion rate for children (6 to 15 years of age) observed by Dufour et al. (2017). Leisure swimmers were more likely to ingest pool water than lap swimmers, and splashes of the water to the face, were associated with higher ingestion rates.

Associations between the number and duration of head submersions, as estimated by videography, and pool water ingestion rates were not observed. The environmental sensors were found to be less accurate for assessing the number and duration of head submersions when compared to use of videography. This study provides additional evidence of pool water ingestion among swimmers, but is based on a relatively small sample; the data for children were not provided according to age categories, and upper percentile (e.g., 90th or 95th percentile) values were not provided.

3.7.2.5. *Sinclair et al. (2016a)—Variability in 24-Hour Excretion of Cyanuric Acid: Implications for Water Exposure Assessment*

Sinclair et al. (2016a) tested the assumption that the cyanuric acid ingested while swimming is completely excreted within 24 hours. In the Sinclair et al. (2016a) study, 26 volunteers (20–56 years of age; mostly male) drank a solution containing 1 mg of cyanuric acid and collected their own urine for 24 hours thereafter. The urine samples were then analyzed for cyanuric acid to estimate the amount that was excreted over the 24 hours post ingestion. The recovery of cyanuric acid over 24 hours varied among the 26 participants. The mean value was 85.3%, and the median was 94.5%, with 16 of the 26 individuals having excretion values ranging from 89 to 105%.

This study provides information on the excretion of cyanuric acid. The information is relevant to studies that use cyanuric acid levels in urine to estimate swimming pool water ingestion. The study was conducted in Australia, but excretion of cyanuric acid among that population would not be expected to differ from U.S. populations.

3.7.2.6. *DeFlorio-Barker et al. (2017)—Child Environmental Exposures to Water and Sand at the Beach: Findings from Studies of Over 68,000 Subjects at 12 Beaches*

DeFlorio-Barker et al. (2017) estimated the amount of water ingested per beach water contact event by conducting simulations based on self-reported time spent in the water and the amount of water swallowed per minute. Data for the time spent in the water were based on data from interviews conducted in 2003–2009 at temperate beaches in the contiguous United States. (DeFlorio-Barker et al., 2017; Arnold et al., 2016). The survey data represented a total of 68,685 beachgoers; 21,015 at 4 freshwater beaches and 47,670 at 8 marine beaches. At both freshwater and marine beaches, approximately

67% of beachgoers had some form of contact with the water (e.g., wading, swimming, playing); 13,568 had water contact at freshwater beaches and 31,685 had water contact at marine beaches. Data on the amount of water swallowed per minute were based on swimming pool studies conducted by Dufour et al. (2017) using cyanuric acid as a biomarker of exposure, as described in Section 3.7.1.1.

Table 3-98 presents age-specific estimates of the amount of water swallowed per water contact event for freshwater, marine, and all types of beach locations combined based on these simulations. Children were found to ingest more water per event than adults, males were found to ingest more than females, and ingestion by individuals recreating at marine beaches tended to be higher than for those at freshwater beaches.

The advantage of this study is that it provides estimates of the volume of water ingested while recreating at freshwater and marine beaches. The estimates are based on the time spent in the water, and represent the amount swallowed per event in units of mL/event. These data may not be applicable to other types of water contact activities (e.g., water skiing or diving, swimming in a pool) where the time spent in the water may differ from that of beachgoers. Also, any uncertainties associated with recall data on the time spent in the water would also be applicable to these estimates.

3.8. OTHER INADVERTENT WATER INGESTION

3.8.1. *Sinclair et al. (2016b)—Measuring Water Ingestion from Spray Exposures*

Sinclair et al. (2016b) estimated the volume of water ingested from spray exposures. Twenty-six study participants, aged 18 to 25 years, engaged in a 10-minute simulated car wash activity using a high-pressure spray device and water treated with cyanuric acid. Study participants were asked not to swim in a cyanuric acid-treated swimming pool for 48 hours prior to the simulation and provided presimulation urine samples for a subset of the participants to verify the absence of cyanuric acid in the urine. All participants wore protective coveralls, gloves, waterproof footwear, and safety glasses during the simulation. After the simulations, 24-hour urine samples were collected and analyzed for cyanuric acid. Among the 26 participants, 18 had quantifiable levels of cyanuric acid in their urine after engaging in the simulation exercise; 6 had trace levels, and 2 had no detectable levels. As in the Dufour et al. (2006, 2017) studies, it was assumed that 100% of the cyanuric acid that was ingested was excreted in the urine (see Section 3.7.1.1). The maximum volume of

water ingested was estimated to be 3.79 mL, and the 10th, 50th, and 90th percentiles were 0.019, 0.175, and 1.84 mL, respectively. When the data were adjusted for potential variability in excretion among individuals, based on data from Sinclair et al. (2016a; see Section 3.7.2.5), the mean and 95th percentile volumes of water ingested were estimated to be 0.438 (SD 1.24) and 1.93 mL, respectively.

This study is based on a relatively small sample, but provides data for a scenario in which water may be inadvertently ingested. As noted by Sinclair et al. (2016b), while it is assumed that this exposure scenario represents ingestion alone, inhalation may have accounted for a portion of the exposures that occurred during the simulation. Thus, the ingestion estimates provided in Sinclair et al. (2016b) would be conservative estimates of ingestion exposures.

Table 3-9. Two-Day Average^a per Capita^b Estimates of Combined Direct and Indirect^c Water Ingestion Based on National Health and Nutrition Examination Survey (NHANES) 2005–2010: Community Water (mL/day) (Continued)

- ^a Based on the average of 2 days of consumption reported for each NHANES respondent. If the respondent reported zero consumption on 1 of the 2 days and nonzero consumption on the other day, his/her average consumption would be the average of zero and nonzero consumption. Single day rates can be generated using <http://fcid.foodrisk.org/>.
- ^b Includes all participants whether or not they ingested any water from the source during survey period.
- ^c Direct water is defined as water ingested directly as a beverage; indirect water is defined as water added in the preparation of food or beverages.
- ^d Represents the percentage of individuals consuming at least once over the 2-day survey period.
- ^e Estimates are less statistically reliable based on guidance published in the *Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations* (NCHS, 1993).
- HNIS = Human Nutrition Information Service.
- NCHS = National Center for Health Statistics.
- SE = Standard error.

Table 3-11. Two-Day Average^a per Capita^b Estimates of Combined Direct and Indirect^c Water Ingestion Based on National Health and Nutrition Examination Survey (NHANES) 2005–2010: Other Sources (mL/day) (Continued)

- ^a Based on the average of 2 days of consumption reported for each NHANES respondent. If the respondent reported zero consumption on 1 of the 2 days and nonzero consumption on the other day, his/her average consumption would be the average of zero and nonzero consumption. Single day rates can be generated using <http://fcid.foodrisk.org/>.
- ^b Includes all participants whether or not they ingested any water from the source during survey period.
- ^c Direct water is defined as water ingested directly as a beverage; indirect water is defined as water added in the preparation of food or beverages.
- ^d Represents the percentage of individuals consuming at least once over the 2-day survey period.
- ^e Estimates are less statistically reliable based on guidance published in the *Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations* (NCHS, 1993).
- HNIS = Human Nutrition Information Service.
- NCHS = National Center for Health Statistics.
- SE = Standard error.

Table 3-15. Two-Day Average^a per Capita^b Estimates of Combined Direct and Indirect^c Water Ingestion Based on National Health and Nutrition Examination Survey (NHANES) 2005–2010: Other Sources (mL/kg-day) (Continued)

- ^a Based on the average of 2 days of consumption reported for each NHANES respondent. If the respondent reported zero consumption on 1 of the 2 days and nonzero consumption on the other day, his/her average consumption would be the average of zero and nonzero consumption. Single day rates can be generated using <http://fcid.foodrisk.org/>.
- ^b Includes all participants whether or not they ingested any water from the source during survey period.
- ^c Direct water is defined as water ingested directly as a beverage; indirect water is defined as water added in the preparation of food or beverages.
- ^d Represents the percentage of individuals consuming at least once over the 2-day survey period.
- ^e Estimates are less statistically reliable based on guidance published in the *Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations* (NCHS, 1993).
- HNIS = Human Nutrition Information Service.
- NCHS = National Center for Health Statistics.
- SE = Standard error.

Table 3-18. Two-Day Average^a Consumer-Only^b Estimates of Direct^c Water Ingestion Based on National Health and Nutrition Examination Survey (NHANES) 2005–2010: Bottled Water (mL/day) (Continued)

^a	Based on the average of 2 days of consumption reported for each NHANES respondent. If the respondent reported zero consumption on 1 of the 2 days and nonzero consumption on the other day, his/her average consumption would be the average of zero and nonzero consumption. Single day rates can be generated using http://fcid.foodrisk.org/ .
^b	Excludes individuals who did not ingest water from the source during the survey period.
^c	Direct water is defined as water ingested directly as a beverage; indirect water, defined as water added in the preparation of food or beverages, was not accounted for in the estimation of bottled water intake.
^d	Estimates are less statistically reliable based on guidance published in the <i>Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations</i> (NCHS, 1993).
HNIS	= Human Nutrition Information Service.
NCHS	= National Center for Health Statistics.
SE	= Standard error.

Table 3-21. Two-Day Average^a Consumer-Only^b Estimates of Combined Direct and Indirect^c Water Ingestion Based on National Health and Nutrition Examination Survey (NHANES) 2005–2010: Community Water (mL/kg-day) (Continued)

^a	Based on the average of 2 days of consumption reported for each NHANES respondent. If the respondent reported zero consumption on 1 of the 2 days and nonzero consumption on the other day, his/her average consumption would be the average of zero and nonzero consumption. Single day rates can be generated using http://fcid.foodrisk.org/ .
^b	Excludes individuals who did not ingest water from the source during the survey period.
^c	Direct water is defined as water ingested directly as a beverage; indirect water is defined as water added in the preparation of food or beverages.
^d	Estimates are less statistically reliable based on guidance published in the <i>Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations</i> (NCHS, 1993).
HNIS	= Human Nutrition Information Service.
NCHS	= National Center for Health Statistics.

Table 3-24. Two-Day Average^a Consumer-Only^b Estimates of Combined Direct and Indirect^c Water Ingestion Based on National Health and Nutrition Examination Survey (NHANES) 2005–2010: All Sources (mL/kg-day) (Continued)

- ^a Based on the average of 2 days of consumption reported for each NHANES respondent. If the respondent reported zero consumption on 1 of the 2 days and nonzero consumption on the other day, his/her average consumption would be the average of zero and nonzero consumption. Single day rates can be generated using <http://fcid.foodrisk.org/>.
- ^b Excludes individuals who did not ingest water from the source during the survey period.
- ^c Direct water is defined as water ingested directly as a beverage; indirect water is defined as water added in the preparation of food or beverages. Does not include indirect consumption of bottled water.
- ^d Estimates are less statistically reliable based on guidance published in the *Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations* (NCHS, 1993).
- HNIS = Human Nutrition Information Service.
- NCHS = National Center for Health Statistics.
- SE = Standard error.

- ^a Weighted percentages, adjusted for over-sampling, nonresponse, and under-representation of some racial and ethnic groups.
- ^b Amounts consumed only by those children who had a beverage from this beverage category. Converted from ounces/day; 1 fluid ounce = 29.57 mL.
- ^c Includes human milk, infant formula, cow's milk, soy milk, and goat's milk.
- ^d Fruit or vegetable juices with no added sweeteners.
- ^e Includes beverages with less than 100% juice and often with added sweeteners; some were fortified with one or more nutrients.
- ^f "Other" beverages category included tea, cocoa, and similar dry milk beverages, and electrolyte replacement beverages for infants.
- N* = Number of observations.

- ^a Based on the average of 2 days of consumption reported for each NHANES respondent. If the respondent reported zero consumption on 1 of the 2 days and nonzero consumption on the other day, his/her average consumption would be the average of zero and nonzero consumption. Single day rates can be generated using <http://fcid.foodrisk.org/>.
- ^b Represents the percentage of individuals consuming at least once over the 2-day survey period.
- ^c All water sources: water, community supply (direct and indirect water consumption); water, bottled (direct water consumption only); water, well or rain cistern (direct and indirect water consumption); water, spring (direct and indirect water consumption); water, don't drink tap water (direct and indirect water consumption); water, other (direct and indirect water consumption); water, don't know (direct and indirect water consumption).
- ^d Estimates are less statistically reliable based on guidance published in the Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations (NCHS, 1993).
- ^e Community water: water, community supply (direct and indirect water consumption).
- ^f Other sources: water, well or rain cistern (direct and indirect water consumption); water, spring (direct and indirect water consumption); water, don't drink tap water (direct and indirect water consumption); water, other (direct and indirect water consumption); water, don't know (direct and indirect water consumption).
- ^g Bottled water: water, bottled (direct water consumption only).
- HNIS = Human Nutrition Information Service.
- N = Sample size.
- SE = Standard error.

Chapter 4—Non-Dietary Ingestion Factors

4. NON-DIETARY INGESTION FACTORS**4.1. INTRODUCTION**

Adults and children have the potential for exposure to toxic substances through non-dietary ingestion pathways other than soil and dust ingestion (e.g., ingesting pesticide residues that have been transferred from treated surfaces to the hands or objects that are mouthed). Adults mouth objects such as cigarettes, pens and pencils, or their hands. Young children mouth objects, surfaces, or their fingers as they explore their environment. Mouthing behavior includes all activities in which objects, including fingers, are touched by the mouth or put into the mouth—except for eating and drinking—and includes licking, sucking, chewing, and biting (Groot et al., 1998). In addition, the sequence of events can be important, such as when a hand-washing occurs relative to contact with soil and hand-to-mouth contact. Videotaped observations of children's mouthing behavior demonstrate the intermittent nature of hand-to-mouth and object-to-mouth behaviors in terms of the number of contacts recorded per unit of time (Ko et al., 2007).

Adult and children's mouthing behavior can potentially result in ingestion of toxic substances (Lepow et al., 1975). Only one study was located that provided data on mouthing frequency or duration for adults, but Cannella et al. (2006) indicated that adults with developmental disabilities frequently exhibit excessive hand-mouthing behavior. In a large non-random sample of children born in Iowa, parents reported non-nutritive sucking behaviors to be very common in infancy, and to continue for a substantial proportion of children up to the 3rd and 4th birthdays (Warren et al., 2000). Hand-to-mouth behavior has been observed in both preterm and full-term infants (Takaya et al., 2003; Blass et al., 1989; Rochat et al., 1988). Infants are born with a sucking reflex for breast-feeding, and within a few months, they begin to use sucking or mouthing as a means to explore their surroundings. Sucking also becomes a means of comfort when a child is tired or upset. In addition, teething normally causes substantial mouthing behavior (i.e., sucking or chewing) to alleviate discomfort in the gums (Groot et al., 1998).

There are three general approaches to gather data on children's mouthing behavior: real-time hand recording, in which trained observers manually record information (Davis et al., 1995); video-transcription, in which trained videographers tape a child's activities and subsequently extract the pertinent data manually or with computer software (Black et al., 2005; Zartarian et al., 1998, 1997a; Zartarian et al., 1997b); and questionnaire, or survey

response, techniques (Stanek et al., 1998). With real-time hand recording, observations made by trained professionals—rather than parents—may offer the advantage of consistency in interpreting visible behaviors and may be less subjective than observations made by someone who maintains a caregiving relationship to the child. On the other hand, young children's behavior may be influenced by the presence of unfamiliar people (Davis et al., 1995). Groot et al. (1998) indicated that parent observers perceived that deviating from their usual care giving behavior by observing and recording mouthing behavior appeared to have influenced their children's behavior. With video-transcription methodology, an assumption is made that the presence of the videographer or camera does not influence the child's behavior. This assumption may result in minimal biases introduced when filming newborns, or when the camera and videographer are not visible to the child. However, if the children being studied are older than newborns and can see the camera or videographer, biases may be introduced. Ferguson et al. (2006) described apprehension caused by videotaping as well as situations where a child's awareness of the videotaping crew caused “play-acting” to occur, or parents indicated that the child was behaving differently during the taping session, although children tend to ignore the presence of the camera after some time has passed. Another possible source of measurement error may be introduced when children's movements or positions cause their mouthing not to be captured by the camera. Data transcription errors can bias results in either the negative or positive direction. Finally, measurement error can occur if situations arise in which caregivers are absent during videotaping and researchers must stop videotaping and intervene to prevent risky behaviors (Zartarian et al., 1995). Meanwhile, survey response studies rely on responses to questions about a child's mouthing behavior posed to parents or caregivers. Measurement errors from these studies could occur for a number of different reasons, including language/dialect differences between interviewers and respondents, question wording problems and lack of definitions for terms used in questions, differences in respondents' interpretation of questions, and recall/memory effects.

Some researchers express mouthing behavior as the frequency of occurrence (e.g., contacts per hour or contacts per minute). Others describe the duration of specific mouthing events, expressed in units of seconds or minutes. This chapter does not address issues related to contaminant transfer from thumbs, fingers, or objects or surfaces, into the mouth, and subsequent ingestion. Examples of how to use

Chapter 4—Non-Dietary Ingestion Factors

mouth frequency and duration data can be found in a U.S. Environmental Protection Agency (U.S. EPA) Office of Pesticide Programs guidance document for conducting residential exposure assessments (U.S. EPA, 2009). This guidance document provides a standard method for estimating potential dose among toddlers from incidental ingestion of pesticide residues from previously treated turf. This scenario assumes that pesticide residues are transferred to the skin of toddlers playing on treated yards and are subsequently ingested as a result of hand-to-mouth transfer. A second scenario assumes that pesticide residues are transferred to a child's toy and are subsequently ingested as a result of object-to-mouth transfer. Neither scenario includes residues ingested as a result of soil ingestion.

The recommendations for mouthing frequency and duration for children only are provided in the next section, along with a summary of the confidence ratings for these recommendations. The recommended values for the children are based on key studies identified by the U.S. EPA for this factor. Although some studies in Sections 4.3.1 and 4.4.1 are classified as key, they were not directly used to provide the recommendations. They are included as key because they were used by Xue et al. (2007) or Xue et al. (2010) in meta-analyses, which are the primary sources of the recommendations provided in this chapter for hand-to-mouth and object-to-mouth frequency, respectively. Following the recommendations, key and relevant studies on mouthing frequency (see Section 4.3) and duration (see Section 4.4) are summarized and the methodologies used in the key and relevant studies are described. Information on the prevalence of mouthing behavior is presented in Section 4.5.

4.2. RECOMMENDATIONS

The key studies described in Section 4.3 and Section 4.4 were used to develop recommended values for mouthing frequency and duration, respectively, among children. Only one relevant study was located that provided data on mouthing frequency or duration for adults. The recommended hand-to-mouth frequencies are based on data from Xue et al. (2007). Xue et al. (2007) conducted a secondary analysis of data from several of the studies summarized in this chapter, as well as data from unpublished studies. Xue et al. (2007) provided data for the age groups in U.S. EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005) and categorized the data according to indoor and outdoor contacts. The

recommendations for frequency of object-to-mouth contact are based on data from Xue et al. (2010). Xue et al. (2010) conducted a secondary analysis of data from several of the studies summarized in this chapter, as well as data from an unpublished study. Recommendations for duration of object-to-mouth contacts are based on data from Juberg et al. (2001), Greene (2002), and Beamer et al. (2008). Recommendations on duration of object-to-mouth contacts pre-dated the U.S. EPA's (2005) guidance on age groups. For cases in which age groups of children in the key studies did not correspond exactly to U.S. EPA's recommended age groups, the closest age group was used.

Table 4-1 shows recommended mouthing frequencies, expressed in units of contacts per hour, between either any part of the hand (including fingers and thumbs) and the mouth or between an object or surface and the mouth. Recommendations for hand-to-mouth duration are not provided since the algorithm to estimate exposures from this pathway is not time dependent. Table 4-2 presents the confidence ratings for the recommended values. The overall confidence rating is low for both frequency and duration of hand-to-mouth and object-to-mouth contact.

Chapter 4—Non-Dietary Ingestion Factors

Table 4-1. Summary of Recommended Values for Mouthing Frequency and Duration					
Age Group	Hand-to-Mouth				Source
	Indoor Frequency (contacts/hour)		Outdoor Frequency (contacts/hour)		
	Mean	95 th percentile	Mean	95 th percentile	
Birth to <1 month	-	-	-	-	Xue et al. (2007)

Chapter 4—Non-Dietary Ingestion Factors

Table 4-2. Confidence in Mouthing Frequency and Duration Recommendations

General Assessment Factor	Rationale	Rating
Soundness		Low
<i>Adequacy of Approach</i>	The approaches for data collection and analysis used were adequate for providing estimates of children's mouthing frequencies and durations. Sample sizes were very small relative to the population of interest. Xue et al. (2007) and (2010) meta-analysis of secondary data was considered to be of suitable utility for the purposes for developing recommendations.	
<i>Minimal (or defined) Bias</i>	Bias in either direction likely exists in both frequency and duration estimates; the magnitude of bias is unknown.	
Applicability and Utility		Low
<i>Exposure Factor of Interest</i>	Key studies for older children focused on mouthing behavior while the infant studies were designed to research developmental issues.	
<i>Representativeness</i>	Most key studies were of samples of U.S. children, but, due to the small sample sizes and small number of locations under study, the study subjects may not be representative of the overall U.S. child population.	
<i>Currency</i>	The studies were conducted over a wide range of dates. However, the currency of the data is not expected to affect mouthing behavior recommendations.	
<i>Data Collection Period</i>	Extremely short data collection periods may not represent behaviors over longer time periods.	
Clarity and Completeness		Low
<i>Accessibility</i>	The journal articles are in the public domain, but, in many cases, primary data were unavailable.	
<i>Reproducibility</i>	Data collection methodologies were capable of providing results that were reproducible within a certain range.	
<i>Quality Assurance</i>	Several of the key studies applied and documented quality assurance/quality control measures.	
Variability and Uncertainty		Low
<i>Variability in Population</i>	The key studies characterized inter-individual variability to a limited extent, and they did not characterize intra-individual variability over diurnal or longer term time frames.	
<i>Description of Uncertainty</i>	The study authors typically did not attempt to quantify uncertainties inherent in data collection methodology (such as the influence of observers on behavior), although some described these uncertainties qualitatively. The study authors typically did attempt to quantify uncertainties in data analysis methodologies (if video-transcription methods were used). Uncertainties arising from short data collection periods typically were unaddressed either qualitatively or quantitatively.	
Evaluation and Review		Medium
<i>Peer Review</i>	All key studies appear in peer-review journals.	
<i>Number and Agreement of Studies</i>	Several key studies were available for both frequency and duration, but data were not available for all age groups. The results of studies from different researchers are generally in agreement.	
Overall rating		Low

Chapter 4—Non-Dietary Ingestion Factors

**4.3. NON-DIETARY INGESTION—
MOUTHING FREQUENCY STUDIES****4.3.1. Key Studies of Mouthing Frequency****4.3.1.1. Zartarian et al. (1997b)—*Quantifying Videotaped Activity Patterns: Video Translation Software and Training Technologies*/Zartarian et al. (1997a)—*Quantified Dermal Activity Data From a Four-Child Pilot Field Study*/Zartarian et al. (1998)—*Quantified Mouthing Activity Data From a Four-Child Pilot Field Study***

Zartarian et al. (1998, 1997a; 1997b) conducted a pilot study of the video-transcription methodology to investigate the applicability of using videotaping for gathering information related to children's activities, dermal exposures, and mouthing behaviors. The researchers had conducted studies using the real-time hand recording methodology. These studies demonstrated poor inter-observer reliability and observer fatigue when working for long periods of time. This prompted the investigation into using videotaping with transcription of the children's activities at a point in time after the videotaped observations occurred.

Four Mexican American farm worker children in the Salinas Valley of California each were videotaped with a hand-held video camera during their waking hours, excluding time spent in the bathroom, over one day in September 1993. The boys were 2 years 10 months old and 3 years 9 months old; the girls were 2 years and 5 months old, and 4 years and 2 months old. Time of videotaping was 6.0 hours for the younger girl, 6.6 hours for the older girl, 8.4 hours for the younger boy and 10.1 hours for the older boy. The videotaping gathered information on detailed micro-activity patterns of children to be used to evaluate software for videotaped activities and translation training methods. The researchers reported measures taken to assess inter-observer reliability and several problems with the video-transcription process.

The hourly data showed that non-dietary object mouthing occurred in 30 of the 31 hours of tape time, with one child eating during the hour in which no non-dietary object mouthing occurred. Mean object-to-mouth contacts for the four children were reported to be 11 contacts per hour (median = 9 contacts per hour), with an average per child range of 1 to 29 contacts per hour (Zartarian et al., 1998). Objects mouthed included bedding/towels, clothes, dirt, grass/vegetation, hard surfaces, hard toys, paper/card, plush toy, and skin (Zartarian et al., 1998). Average hand-to-mouth contacts for the four children were 13 contacts per hour [averaging the sum of left hand

and right hand-to-mouth contacts and averaging across children, from Zartarian et al. (1997a)], with the average per child ranging from 9 to 19 contacts per hour.

This study's primary purpose was to develop and evaluate the video-transcription methodology; a secondary purpose was collection of mouthing behavior data. The sample of children studied was very small and not likely to be representative of the national population. As with other video-transcription studies, the presence of non-family-member videographers and a video camera may have influenced the children's behavior.

4.3.1.2. Reed et al. (1999)—*Quantification of Children's Hand and Mouthing Activities Through a Videotaping Methodology*

In this study, Reed et al. (1999) used a video-transcription methodology to quantify the frequency and type of children's hand and mouth contacts, as well as a survey response methodology, and compared the videotaped behaviors with parents' perceptions of those behaviors. Twenty children ages 3 to 6 years old selected randomly at a daycare center in New Brunswick, NJ, and 10 children ages 2 to 5 years old at residences in Newark and Jersey City, NJ who were not selected randomly, were studied (sex not specified). For the video-transcription methodology, inter-observer reliability tests were performed during observer training and at four points during the two years of the study. The researchers compared the results of videotaping the ten children in the residences with their parents' reports of the children's daily activities. Mouthing behaviors studied included hand-to-mouth and hand bringing object-to-mouth.

Table 4-3 presents the video-transcription mouthing contact frequency results. The authors analyzed parents' responses on frequencies of their children's mouthing behaviors and compared those responses with the children's videotaped behaviors, which revealed certain discrepancies: Parents' reported hand-to-mouth contact of "almost never" corresponded to overall somewhat lower videotaped hand-to-mouth frequencies than those of children whose parents reported "sometimes," but there was little correspondence between parents' reports of object-to-mouth frequency and videotaped behavior.

The advantages of this study were that it compared the results of video-transcription with the survey response methodology results and that it described quality assurance steps taken to assure reliability of transcribed videotape data. However, only a small number of children were studied, some

Chapter 4—Non-Dietary Ingestion Factors

were not selected for observation randomly, and the sample of children studied may not be representative of either the locations studied or the national population. Because of the children's ages, the presence of unfamiliar persons following the children with a video camera may influence the video-transcription results. The parents' survey responses also may be influenced by recall/memory effects and other limitations of survey methodologies.

4.3.1.3. Freeman et al. (2001)—Quantitative Analysis of Children's Micro-Activity Patterns: The Minnesota Children's Pesticide Exposure Study

Freeman et al. (2001) conducted a survey response and video-transcription study of some of the respondents in a phased study of children's pesticide exposures in the summer and early fall of 1997. A probability-based sample of 168 families with children ages 3 to <14 years old in urban (Minneapolis/St. Paul) and non-urban (Rice and Goodhue Counties) areas of Minnesota answered questions about children's mouthing of paint chips, food-eating without utensils, eating of food dropped on the floor, mouthing of non-food items, and mouthing of thumbs and fingers. For the survey response portion of the study, parents provided the responses for children ages 3 and 4 years and collaborated with or assisted older children with their responses. Of the 168 families responding to the survey, 102 were available, selected, and agreed to measurements of pesticide exposure. Of these 102 families, 19 agreed to videotaping of the study children's activities for a period of 4 consecutive hours.

Based on the survey responses for 168 children, the 3-year olds had significantly more positive responses for all reported behavior compared to the other age groups. The authors stated that they did not know whether parent reporting of 3-year olds' behavior influenced the responses given. Table 4-4 shows the percentage of children, grouped by age, who were reported to exhibit non-food related mouthing behaviors. Table 4-5 presents the mean and median number of mouthing contacts by age for the 19 videotaped children. Among the four age categories of these children, object-to-mouth activities were significantly greater for the 3- and 4-year olds than any other age group, with a median of 3 and a mean of 6 contacts per hour ($p = 0.002$, Kruskal Wallis test comparison across four age groups). Hand-to-mouth contacts had a median of 3.5 and mean of 4 contacts per hour for the three 3- and 4-year olds observed, median of 2.5 and mean of

8 contacts per hour for the seven 5- and 6-year olds observed, median of 3 and mean of 5 contacts per hour for the four 7- and 8-year olds observed, and median of 2 and mean of 4 for the five 10-, 11-, and 12-year olds observed. Sex differences were observed for some of the activities, with boys spending significantly more time outdoors than girls. Hand-to-mouth and object-to-mouth activities were less frequent outdoors than indoors for both boys and girls.

For the 19 children in the video-transcription portion of the study, inter-observer reliability checks and quality control checks were performed on randomly sampled tapes. For four children's tapes, comparison of the manual video-transcription with a computerized transcription method (Zartarian et al., 1995) also was performed; no significant differences were found in the frequency of events recorded using the two techniques. The frequency of six behaviors (hand-to-mouth, hand-to-object, object-to-mouth, hand-to-smooth surface, hand-to-textured surface, and hand-to-clothing) was recorded. The amount of time each child spent indoors, outdoors, and in contact with soil or grass, as well as whether the child was barefoot was also recorded. For the four children whose tapes were analyzed with the computerized transcription method, which calculates event durations, the authors stated that most hand-to-mouth and object-to-mouth activities were observed during periods of lower physical activity, such as television viewing.

An advantage to this study is that it included results from two separate methodologies, and included quality assurance steps taken to assure reliability of transcribed videotape data. However, the children in this study may not be representative of all children in the United States. Variation in who provided the survey responses (sometimes parents only, sometimes children with parents) may have influenced the responses given. Children studied using the video-transcription methodology were not chosen randomly from the survey response group. The presence of unfamiliar persons following the children with a video camera may have influenced the video-transcription methodology results.

4.3.1.4. Tulse et al. (2002)—Frequency of Mouthing Behavior in Young Children

Tulse et al. (2002) coded the unpublished Davis et al. (1995) data for location (indoor and outdoor) and activity type (quiet or active) and analyzed the subset of the data that consisted of indoor mouthing behavior during quiet activity (72 children, ranging in age from 11 to 60 months). A total of one hundred

Chapter 4—Non-Dietary Ingestion Factors

eighty-six 15-minute observation periods were included in the study, with the number of observation periods per child ranging from 1 to 6. Tolve et al. (2002) used the Davis et al. (1995) data from which the children were selected randomly based on date of birth through a combination of birth certificate records and random digit dialing of residential telephone numbers.

Results of the data analyses indicated that there was no association between mouthing frequency and sex, but a clear association between mouthing frequency and age was observed. The analysis indicated that children ≤ 24 months had the highest frequency of mouthing behavior (81 events/hour) and that children > 24 months had the lowest (42 events/hour) (see Table 4-6). Both groups of children were observed to mouth toys and hands more frequently than household surfaces or body parts other than hands.

An advantage of this study is that the randomized design may mean that the children studied were relatively representative of young children living in the study area, although they may not be representative of the U.S. population. Due to the ages of the children studied, the observers' use of headphones and manual recording of mouthing behavior on observation sheets may have influenced the children's behavior.

4.3.1.5. AuYeung et al. (2004)—Young Children's Mouthing Behavior: An Observational Study via Videotaping in a Primarily Outdoor Residential Setting

AuYeung et al. (2004) used a video-transcription methodology to study a group of 38 children (20 females and 18 males; ages 1 to 6 years), 37 of whom were selected randomly via a telephone screening survey of a 300 to 400 square mile portion of the San Francisco, CA peninsula, along with one child selected by convenience because of time constraints. Families who lived in a residence with a lawn and whose annual income was $> \$35,000$ were asked to participate. Videotaping took place between August 1998 and May 1999 for approximately two hours per child. Videotaping by one researcher was supplemented with field notes taken by a second researcher who also was present during taping. Most of the videotaping took place during outdoor play, however, data were included for several children (one child < 2 years old and eight children > 2 years old) who had more than 15 minutes of indoor play during their videotaping sessions.

The videotapes were translated into American Standard Code for Information Interchange (ASCII)

computer files using Virtual Timing Device™ software described in Zartarian et al. (1997b). Both frequency and duration (see Section 4.4.2.5 of this chapter) were analyzed. Between 5% and 10% of the data files translated were randomly chosen for quality control checks for inter-observer agreement. Ferguson et al. (2006) described quality control aspects of the study in detail.

For analysis, the mouthing contacts were divided into indoor and outdoor locations and 16 object/surface categories. Mouthing frequency was analyzed by age and sex separately and in combination. Mouthing contacts were defined as contact with the lips, inside of the mouth, and/or the tongue; dietary contacts were ignored. Table 4-7 shows mouthing frequencies for indoor locations. For the one child observed that was ≤ 24 months of age, the total mouthing frequency was 84.8 contacts/hour; for children > 24 months, the median indoor mouthing frequency was 19.5 contacts/hour. Outdoor median mouthing frequencies (see Table 4-8) were very similar for children ≤ 24 months of age (13.9 contacts/hour) and > 24 months (14.6 contacts/hour).

Non-parametric tests, such as the Wilcoxon rank sum test, were used for the data analyses. Both age and sex were found to be associated with differences in mouthing behavior. Girls had significantly higher frequencies of mouthing contacts with the hands and non-dietary objects than boys ($p = 0.01$ and $p = 0.008$, respectively).

This study provides distributions of outdoor mouthing frequencies with a variety of objects and surfaces. Although indoor mouthing data also were included in this study, the results were based on a small number of children ($N = 9$) and a limited amount of indoor play. The sample of children may be representative of certain socioeconomic strata in the study area, but it is not likely to be representative of the national population. Because of the children's ages, the presence of unfamiliar persons following the children with a video camera may have influenced the video-transcription methodology results.

4.3.1.6. Black et al. (2005)—Children's Mouthing and Food-Handling Behavior in an Agricultural Community on the U.S./Mexico Border

Black et al. (2005) studied mouthing behavior of children in a Mexican-American community along the Rio Grande River in Texas, during the spring and summer of 2000, using a survey response and a video-transcription methodology. A companion study

Chapter 4—Non-Dietary Ingestion Factors

of this community (Shalat et al., 2003) identified 870 occupied households during the April 2000 U.S. Census and contacted 643 of these via in-person interview to determine the presence of children under the age of 3 years. Of the 643 contacted, 91 had at least one child under the age of 3 years (Shalat et al., 2003). Of these 91 households, the mouthing and food-handling behavior of 52 children (26 boys and 26 girls) from 29 homes was videotaped, and the children's parents answered questions about children's hygiene, mouthing and food-handling activities (Black et al., 2005). The study was of children ages 7 to 53 months, grouped into four age categories: infants (7 to 12 months), 1-year olds (13 to 24 months), 2-year olds (25 to 36 months), and preschoolers (37 to 53 months).

The survey asked questions about children's ages, sexes, reported hand-washing, mouthing and food-handling behavior ($N = 52$), and activities ($N = 49$). Parental reports of thumb/finger placement in the mouth showed decreases with age. The researchers attempted to videotape each child for 4 hours. The children were followed by the videographers through the house and yard, except for times when they were napping or using the bathroom. Virtual Timing Device™ software, mentioned earlier, was used to analyze the videotapes.

Based on the results of videotaping, most of the children (49 of 52) spent the majority of their time indoors. Of the 39 children who spent time both indoors and outdoors, all three behaviors (hand-to-mouth, object-to-mouth and food handling) were more frequent and longer while the child was indoors. Hand-to-mouth activity was recorded during videotaping for all but one child, a 30 month old girl.

For the four age groups, the mean hourly hand-to-mouth frequency ranged from 11.9 (2-year olds) to 22.1 (preschoolers), and the mean hourly object-to-mouth frequency ranged from 7.8 (2-year olds) to 24.4 (infants). No significant linear trends were seen with age or sex for hand-to-mouth hourly frequency. A significant linear trend was observed for hourly object-to-mouth frequency, which decreased as age increased (adjusted $R^2 = 0.179$; $p = 0.003$). Table 4-9 shows the results of this study.

Because parental survey reports were not strongly correlated with videotaped hand or object mouthing, the authors suggested that future research might include alternative methods of asking about mouthing behavior to improve the correlation of questionnaire data with videotaped observations.

One advantage of this study is that it compared survey responses with videotaped information on mouthing behavior. A limitation is that the sample

was fairly small and was from a limited area (mid-Rio Grande Valley) and is not likely to be representative of the national population. Because of the children's ages, the presence of unfamiliar persons following the children with a video camera may have influenced the video-transcription methodology results.

4.3.1.7. *Xue et al. (2007)—A Meta-Analysis of Children's Hand-to-Mouth Frequency Data for Estimating Non-Dietary Ingestion Exposure*

Xue et al. (2007) gathered hand-to-mouth frequency data from nine available studies representing 429 subjects and more than 2,000 hours of behavior observation (Beamer et al., 2008; Black et al., 2005; Hore, 2003; Greene, 2002; Tulve et al., 2002; Freeman et al., 2001; Leckie et al., 2000; Reed et al., 1999; Zartarian et al., 1998). Two of these studies [i.e., Leckie et al. (2000); Hore (2003)] are unpublished data sets and are not summarized in this chapter. The remaining seven studies are summarized elsewhere in this chapter. Xue et al. (2007) conducted a meta-analysis to study differences in hand-to-mouth behavior. The purpose of the analysis was to

1. examine differences across studies by age [using the new U.S. EPA recommended age groupings (U.S. EPA, 2005)], sex, and indoor/outdoor location;
2. fit variability distributions to the available hand-to-mouth frequency data for use in one-dimensional Monte Carlo exposure assessments;
3. fit uncertainty distributions to the available hand-to-mouth frequency data for use in two-dimensional Monte Carlo exposure assessments; and
4. assess hand-to-mouth frequency data needs using the new U.S. EPA recommended age groupings (U.S. EPA, 2005).

The data were sorted into age groupings. Visual inspection of the data and statistical methods (i.e., method of moments and maximum likelihood estimation) were used, and goodness-of-fit tests were applied to verify the selection among lognormal, Weibull, and normal distributions (Xue et al., 2007). Analyses to study inter- and intra-individual variability of indoor and outdoor hand-to-mouth frequency were conducted. It was found that age and location (indoor vs. outdoor) were important factors

Chapter 4—Non-Dietary Ingestion Factors

contributing to hand-to-mouth frequency, but study and sex were not (Xue et al., 2007). Distributions of hand-to-mouth frequencies were developed for both indoor and outdoor activities. Table 4-10 presents distributions for indoor settings while Table 4-11 presents distributions for outdoor settings. Hand-to-mouth frequencies decreased for both indoor and outdoor activity as age increased, and they were higher indoors than outdoors for all age groups (Xue et al., 2007).

A strength of this study is that it is the first effort to fit hand-to-mouth distributions of children in different locations while using U.S. EPA's recommended age groups. Limitations of the studies used in this meta-analysis apply to the results from the meta-analysis as well; the uncertainty analysis in this study does not account for uncertainties arising out of differences in approaches used in the various studies used in the meta-analysis.

4.3.1.8. Beamer et al. (2008)—Quantified Activity Pattern Data From 6 to 27-Month-Old Farm Worker Children for Use in Exposure Assessment

Beamer et al. (2008) conducted a follow-up to the pilot study performed by Zartarian et al. (1998, 1997a; 1997b), described in Sections 4.3.1.1 and 4.4.2.2. For this study, a convenience sample of 23 children residing in the farm worker community of Salinas Valley, CA, was enrolled. Participants were 6- to 13-month-old infants or 20- to 26-month-old toddlers. Two researchers videotaped each child's activities for a minimum of 4 hours and kept a detailed written log of locations visited and objects and surfaces contacted by the child. A questionnaire was administered to an adult in the household to acquire demographic data, housing and cleaning characteristics, eating patterns, and other information pertinent to the child's potential pesticide exposure.

Table 4-12 presents the distribution of object/surface contact frequency for infants and toddlers in events/hour. The mean hand-to-mouth frequency was 18.4 events/hour. The mean mouthing frequency of non-dietary objects was 29.2 events/hour. Table 4-13 presents the distributions for the mouthing frequency and duration of non-dietary objects, and it highlights the differences between infants and toddlers. Toddlers had higher mouthing frequencies with non-dietary items associated with pica (i.e., paper) while infants had higher mouthing frequencies with other non-dietary objects. In addition, boys had higher mouthing frequencies than girls. The advantage of this study is that it included both infants and toddlers.

Differences between the two age groups, as well as sex differences, could be observed. As with other video-transcription studies, the presence of non-family-member videographers and a video camera may have influenced the children's behavior.

4.3.1.9. Xue et al. (2010)—A Meta-Analysis of Children's Object-to-Mouth Frequency Data for Estimating Non-Dietary Ingestion Exposure

Xue et al. (2010) gathered object-to-mouth frequency data from 7 available studies representing 438 subjects and approximately 1,500 hours of behavior observation. The studies used in this analysis included six published studies that were also individually summarized in this chapter (Beamer et al., 2008; AuYeung et al., 2004; Greene, 2002; Tulve et al., 2002; Freeman et al., 2001; Reed et al., 1999) as well as one unpublished data set (Hore, 2003). These data were used to conduct a meta-analysis to study differences in object-to-mouth behavior. The purpose of the analysis was to

1. "examine differences across studies by age [using the new U.S. EPA recommended age groupings (U.S. EPA, 2005)], sex, and indoor/outdoor location;
2. fit variability distributions to the available object to-mouth frequency data for use in one dimensional Monte Carlo exposure assessments;
3. fit uncertainty distributions to the available object-to-mouth frequency data for use in two dimensional Monte Carlo exposure assessments; and
4. assess object-to-mouth frequency data needs using the new U.S. EPA recommended age groupings (U.S. EPA, 2005)."

The data were sorted into age groupings. Visual inspection of the data and statistical methods (i.e., method of moments and maximum likelihood estimation) were used, and goodness-of-fit tests were applied to verify the selection among lognormal, Weibull, and normal distributions (Xue et al., 2010). Analyses to study inter- and intra-individual variability of indoor and outdoor object-to-mouth frequency were conducted. It was found that age, location (indoor vs. outdoor), and study were important factors contributing to object-to-mouth frequency, but study and sex were not (Xue et al., 2010). Distributions of object-to-mouth frequencies

Chapter 4—Non-Dietary Ingestion Factors

were developed for both indoor and outdoor activities. Table 4-14 presents distributions for indoor settings while Table 4-15 presents distributions for outdoor settings. Object-to-mouth frequencies decreased for both indoor and outdoor activity as age increased (i.e., after age <6 to 12 months for indoor activity; and after <3 to 6 years for outdoor activity), and were higher indoors than outdoors for all age groups (Xue et al., 2010).

A strength of this study is that it is the first effort to fit object-to-mouth distributions of children in different locations while using U.S. EPA's recommended age groups. Limitations of the studies used in this meta-analysis apply to the results from the meta-analysis as well; the uncertainty analysis in this study does not account for uncertainties arising out of differences in approaches used in the various studies used in the meta-analysis.

4.3.2. Relevant Studies of Mouthing Frequency

4.3.2.1. Davis et al. (1995)—Soil Ingestion in Children With Pica: Final Report

In 1992, under a Cooperative Agreement with U.S. EPA, the Fred Hutchinson Cancer Research Center conducted a survey response and real-time hand recording study of mouthing behavior data. The study included 92 children (46 males, 46 females) ranging in age from <12 months to 60 months, from Richland, Kennewick, and Pasco, WA. The children were selected randomly based on date of birth through a combination of birth certificate records and random digit dialing of residential telephone numbers. For each child, data were collected in one 7-day period during January to April, 1992. Eligibility included residence within the city limits, residence duration >1 month, and at least one parent or guardian who spoke English. Most of the adults who responded to the survey reported their marital status as being married (90%), their race as Caucasian (89%), their household income in the >\$30,000 range (56%), or their housing status as single-family home occupants (69%).

The survey asked questions about thumb-sucking and frequency questions about pacifier use, placing fingers, hands and feet in the mouth, and mouthing of furniture, railings, window sills, floor, dirt, sand, grass, rocks, mud, clothes, toys, crayons, pens, and other items. Table 4-16 shows the survey responses for the 92 study children. For most of the children in the study, the mouthing behavior real-time hand recording data were collected simultaneously by parents and by trained observers who described and quantified the mouthing behavior of the children in their home environment. The observers recorded

mouth and tongue contacts with hands, other body parts, natural objects, surfaces, and toys every 15 seconds during 15-minute observation periods spread over 4 days. Parents and trained observers wore headphones that indicated elapsed time (Davis et al., 1995). If all attempted observation periods were successful, each child would have a total of sixteen 15-minute observation periods with sixty 15-second intervals per 15-minute observation period, or nine hundred sixty 15-second intervals in all. The number of successful intervals of observation ranged from 0 to 840 per child. Comparisons of the inter-observer reliability between the trained observers and parents showed

“a high degree of correlation between the overall degree of both mouth and tongue activity recorded by parents and observers. For total mouth activity, there was a significant correlation between the rankings obtained according to parents and observers, and parents were able to identify the same individuals as observers as being most and least oral in 60% of the cases” (Davis et al., 1995).

One advantage of this study is the simultaneous observations by both, parents and trained observers, that allow comparisons regarding the consistency of the recorded observations. The random nature in which the population was selected may provide a representative population of the study area, within certain limitations, but not of the national population. In addition, this study was considered relevant because the data were not analyzed for deriving estimates of mouthing contact. These data were analyzed by Tolve et al. (2002) (see Section 4.3.1.4). Simultaneous collection of food, medication, fecal, and urine samples that occurred as part of the overall study (not described in this summary) may have contributed a degree of deviation from normal routines within the households during the 7 days of data collection and may have influenced children's usual behaviors. Wearing of headphones by parents and trained observers during mouthing observations, presence of non-family-member observers, and parents' roles as observers as well as caregivers also may have influenced the results; the authors state “Having the child play naturally while being observed was challenging. Usually the first day of observation was the most difficult in this respect, and by the third or fourth day of observation the child generally paid little attention to the observers.”

Chapter 4—Non-Dietary Ingestion Factors

4.3.2.2. *Lew and Butterworth (1997)—The Development of Hand-Mouth Coordination in 2- to 5-Month-Old Infants: Similarities With Reaching and Grasping*

Lew and Butterworth (1997) studied 14 infants (10 males, 4 females; mostly first-borns) in Stirling, United Kingdom, in 1990 using a video-transcription methodology. Attempts were made to study each infant within 1 week of the infant's 2-, 3-, 4-, and 5-month birthdays. After becoming accustomed to the testing laboratory, and with their mothers present, infants were placed in semi-reclining seats and filmed during an experimental protocol in which researchers placed various objects into the infants' hands. Infants were observed for two baseline periods of 2 minutes each. The researchers coded all contacts to the face and mouth that occurred during baseline periods (prior to and after the object handling period) as well as contacts occurring during the object handling period. Hand-to-mouth contacts included contacts that landed directly in or on the mouth as well as those in which the hand landed on the face first and then moved to the mouth. The researchers assessed inter-observer agreement using a rater not involved with the study, for a random proportion (approximately 10%) of the movements documented during the object handling period, and reported inter-observer agreement of 0.90 using Cohen's kappa for the location of contacts. The frequency of contacts ranged between zero and one contact per minute.

The advantages of this study were that use of video cameras could be expected to have minimal effect on infant behavior for infants of these ages, and the researchers performed tests of inter-observer reliability. A disadvantage is that the study included baseline observation periods of only 2 minutes' duration, during which spontaneous hand-to-mouth movements could be observed. The extent to which these infants' behavior is representative of other infants of these ages is unknown.

4.3.2.3. *Tudella et al. (2000)—The Effect of Oral-Gustatory, Tactile-Buccal, and Tactile-Manual Stimulation on the Behavior of the Hands in Newborns*

Tudella et al. (2000) studied the frequency of hand-to-mouth contact, as well as other behaviors, in 24 full-term Brazilian newborns (10 to 14 days old) using a video-transcription methodology. Infants were in an alert state, in their homes in silent and previously heated rooms in a supine position and had been fed between 1 and 1 1/2 hours before testing. Infants were studied for a 4-minute baseline period without stimuli before experimental stimuli were

administered. Results from the four-minute baseline period, without stimuli, indicated that the mean frequency of hand-to-mouth contact (defined as right hand or left hand touching the lips or entering the buccal cavity, either with or without rhythmic jaw movements) was almost 3 right hand contacts and slightly more than 1.5 left hand contacts, for a total hand-to-mouth contact frequency of about 4 contacts in the 4-minute period. The researchers performed inter-observer reliability tests on the videotape data and reported an inter-coder Index of Concordance of 93%.

The advantages of this study were that use of video cameras could be expected to have virtually no effect on newborns' behavior, and inter-observer reliability tests were performed. However, the study data may not represent newborn hand-to-mouth contact during non-alert periods such as sleep. The extent to which these infants' behavior is representative of other full-term 10- to 14-day-old infants' behavior is unknown.

4.3.2.4. *Ko et al. (2007)—Relationships of Video Assessments of Touching and Mouthing Behaviors During Outdoor Play in Urban Residential Yards to Parental Perceptions of Child Behaviors and Blood Lead Levels*

Ko et al. (2007) compared parent survey responses with results from a video-transcription study of children's mouthing behavior in outdoor settings, as part of a study of relationships between children's mouthing behavior and other variables with blood lead levels. A convenience sample of 37 children (51% males, 49% females) 14 to 69 months old was recruited via an urban health center and direct contacts in the surrounding area, apparently in Chicago, IL. Participating children were primarily Hispanic (89%). The mouth area was defined as within 1 inch of the mouth, including the lips. Items passing beyond the lips were defined as in the mouth. Placement of an object or food item in the mouth along with part of the hand was counted as both hand and food or hand and object in mouth. Mouthing behaviors included hand-to-mouth area both with and without food, hand-in-mouth with or without food, and object-in-mouth including food, drinks, toys, or other objects.

Survey responses for the 37 children who also were videotaped included parents reporting children's inserting hand, toys, or objects in mouth when playing outside, and inserting dirt, stones, or sticks in mouth. Video-transcription results of outdoor play for these 37 children indicated 0 to 27 hand-in-mouth and 3 to 69 object-in-mouth touches per hour for the

Chapter 4—Non-Dietary Ingestion Factors

13 children reported to frequently insert hand, toys, or objects in mouth when playing outside; 0 to 67 hand-in-mouth, and 7 to 40 object-in-mouth touches per hour for the 10 children reported to “sometimes” perform this behavior; 0 to 30 hand-in-mouth and 0 to 125 object in mouth touches per hour for the 12 children reported to “hardly ever” perform this behavior, and 1 to 8 hand-in-mouth and 3 to 6 object-in-mouth touches per hour for the 2 children reported to “never” perform this behavior.

Videotaping was attempted for 2 hours per child over two or more play sessions, with videographers trying to avoid interacting with the children. Children played with their usual toys and partners, and no instructions were given to parents regarding their supervision of the children’s play. The authors stated that during some portion of the videotape time, children’s hands and mouths were out of camera view. Videotape transcription was performed manually, according to a modified version of the protocol used in the Reed et al. (1999) study. Inter-observer reliability between three video-transcribers was checked with seven 30-minute video segments.

One strength of this study is its comparison of survey responses with results from the video-transcription methodology. A limitation is that the non-randomly selected sample of children studied is unlikely to be representative of the national population. Comparing results from this study with results from other video-transcription studies may be problematic because of inclusion of food handling with hand-to-mouth and object-to-mouth frequency counts. Due to the children’s ages, their behavior may have differed from normal patterns because of the presence of strangers who videotaped them.

4.3.2.5. Nicas and Best (2008)—A Study Quantifying the Hand-to-Face Contact Rate and Its Potential Application to Predicting Respiratory Tract Infection

Nicas and Best (2008) conducted an observational study on adults (five women and five men; ages not specified), in which individuals were videotaped while performing office-type work for a 3-hour period. The videotapes were viewed by the investigators, who counted the number of hand-to-face touches the subjects made while they worked on a laptop computer, read, or wrote. Following the observations, the sample mean and standard deviation were computed for the number of times each subject touched his or her eyes, nostrils, and lips. For the three combinations of touch frequencies (i.e., lips-eyes, lips-nostrils,

eyes-nostrils), Spearman rank correlation coefficients were computed and tests of the hypothesis that the rank correlation coefficients exceeded zero were performed.

Table 4-17 shows the frequency of hand-to-face contacts with the eyes, nostrils, and lips of the subjects, and the sum of these counts. There was considerable inter-individual variability among the subjects. During the 3-hour continuous study period, the total number of hand contacts with the eyes, lips and nostrils ranged from 3 to 104 for individual subjects, with a mean of 47. The mean per hour contact rate was 15.7. There was a positive correlation between the number of hand contacts with lips and eyes and with lips and nostrils (subjects who touched their lips frequently also touched their eyes and nostrils frequently). The Spearman rank correlation coefficients for contacts between different facial targets were 0.76 for the lips and eyes; 0.66 for the lips and nostrils, and 0.44 for the eyes and nostrils.

The study’s primary purpose was to quantify hand-to-face contacts in order to determine the application of this contact rate in predicting respiratory tract infection. The authors developed an algebraic model for estimating the dose of pathogens transferred to target facial membranes during a defined exposure period. The advantage of this study is that it determined the frequency of hand-to-face contacts for adults. A limitation of the study is that there were very few subjects (five women and five men) who may not have been representative of the U.S. population. In addition, as with other video-transcription studies, the presence of videographers and a video camera may have influenced the subjects’ behaviors.

4.4. NON-DIETARY INGESTION—MOUTHING DURATION STUDIES

4.4.1. Key Mouthing Duration Studies

4.4.1.1. Juberg et al. (2001)—An Observational Study of Object Mouthing Behavior by Young Children

Juberg et al. (2001) studied 385 children ages 0 to 36 months in western New York State, with parents collecting real-time hand-recording mouthing behavior data, primarily in the children’s own home environments. The study consisted of an initial pilot study conducted in February 1998, a second phase conducted in April 1998, and a third phase conducted at an unspecified later time. The study’s sample was drawn from families identified in a child play research center database or whose children attended a child care facility in the same general area; some

Chapter 4—Non-Dietary Ingestion Factors

geographic variation within the local area was obtained by selecting families with different zip codes in the different study phases. The pilot phase had 30 children who participated out of 150 surveys distributed; the second phase had 187 children out of approximately 300 surveys distributed, and the third phase had 168 participants out of 300 surveys distributed.

Parents were asked to observe their child's mouthing of objects only; hand-to-mouth behavior was not included. Data were collected on a single day (pilot and second phases) or 5 days (third phase); parents recorded the insertion of objects into the mouth by noting the "time in" and "time out" and the researchers summed the recorded data to tabulate total times spent mouthing the various objects during the days of observation. Thus, the study data were presented as minutes per day of object mouthing time. Mouthed items were classified as pacifiers, teethingers, plastic toys, or other objects.

Table 4-18 shows the results of the combined pilot and second phase data. For both age groups, mouthing time for pacifiers greatly exceeded mouthing time for non-pacifiers, with the difference more acute for the older age group than for the younger age group. Histograms of the observed data show a peak in the low end of the distribution (0 to 100 minutes per day) and a rapid decline at longer durations.

A third phase of the study focused on children between the ages of 3 and 18 months and included only non-pacifier objects. Subjects were observed for 5 non-consecutive days over a 2-month period. A total of 168 participants returned surveys for at least one day, providing a total of 793 person-days of data. The data yielded a mean non-pacifier object mouthing duration of 36 minutes per day; the mean was the same when calculated on the basis of 793 person-days of data as on the basis of 168 daily average mouthing times.

One advantage of this study is the large sample size (385 children); however, the children apparently were not selected randomly, although some effort was made to obtain local geographic variation among study participants. There is no description of the socioeconomic status or racial and ethnic identities of the study participants. The authors do not describe the methodology parents used to record mouthing event durations (e.g., using stopwatches, analog or digital clocks, or guesses). The authors stated that using mouthing event duration units of minutes rather than seconds may have yielded observations rounded to the nearest minute.

4.4.1.2. Greene (2002)—A Mouthing Observation Study of Children Under Six Years of Age

The U.S. Consumer Product Safety Commission conducted a survey response and real-time hand recording study between December 1999 and February 2001 to quantify the cumulative time per day that young children spend awake, not eating, and mouthing objects. "Mouthing" was defined as children sucking, chewing, or otherwise putting an object on their lips or into their mouth. Participants were recruited via a random digit dialing telephone survey in urban and nearby rural areas of Houston, TX and Chicago, IL. Of the 115,289 households surveyed, 1,745 households had a child under the age of 6 years and were willing to participate. In the initial phase of the study, 491 children ages 3 to 81 months participated. Parents were instructed to use watches with second hands or to count seconds to estimate mouthing event durations. Parents also were to record mouthing frequency and types of objects mouthed. Parents collected data in four separate, non-consecutive 15-minute observation periods. Initially, parents were called back by the researchers and asked to provide their data over the telephone. Of the 491 children, 43 children (8.8%) had at least one 15-minute observation period with mouthing event durations recorded as exceeding 15 minutes. Due to this data quality problem, the researchers excluded the parent observation data from further analysis.

In a second phase, trained observers used stopwatches to record the mouthing behaviors and mouthing event durations of the subset of 109 of these children ages 3 to 36 months and an additional 60 children (total in second phase, 169), on 2 hours of each of 2 days. The observations were done at different times of the day at the child's home and/or child care facility. Table 4-19 shows the prevalence of observed mouthing among the 169 children in the second phase. All children were observed to mouth during the 4 hours of observation time; 99% mouthed parts of their anatomy. Pacifiers were mouthed by 27% in an age-declining pattern ranging from 47% of children less than 12 months old to 10% of the 2- to <3-year olds.

Table 4-20 provides the average mouthing time by object category and age in minutes per hour. The average mouthing time for all objects ranged from 5.3 to 10.5 minutes per hour, with the highest mouthing time corresponding to children <1 year of age and the lowest to the 2 to <3 years of age category. Among the objects mouthed, pacifiers represented about one third of the total mouthing time, with 3.4 minutes per hour for the youngest children, 2.6 minutes per hour for the children

Chapter 4—Non-Dietary Ingestion Factors

between 1 and 2 years and 1.8 minutes per hour for children 2 to <3 years old. The next largest single item category was anatomy. In this category, children under 1 year of age spent 2.4 minutes per hour mouthing fingers and thumbs; this behavior declined with age to 1.2 minutes per hour for children 2 to <3 years old.

Of the 169 children in the second phase, data were usable on the time awake and not eating (or “exposure time”) for only 109; data for the remaining 60 children were missing. Thus, in order to develop extrapolated estimates of daily mouthing time for the 109 children, from the 2 hours of observation per day for two days, the researchers developed a statistical model that accounted for the children’s demographic characteristics, that estimated exposure times for the 60 children with missing data, and then computed statistics for the extrapolated daily mouthing times for all 169 children, using a “bootstrap” procedure. Using this method, the estimated mean daily mouthing time of objects other than pacifiers ranged from 37 minutes/day to 70 minutes/day with the lowest number corresponding to the 2 to <3-year-old children and the largest number corresponding to the 3 to <12-month-old children.

The 551 child participants were 55% males, 45% females. The study’s sample was drawn in an attempt to duplicate the overall U.S. demographic characteristics with respect to race, ethnicity, socioeconomic status and urban/suburban/rural settings. The sample families’ reported annual incomes were generally higher than those of the overall U.S. population.

This study’s strength was that it consisted of a randomly selected sample of children from both urban and non-urban areas in two different geographic areas within the United States. However, the observers’ presence and use of a stopwatch to time mouthing durations may have affected the children’s behavior.

4.4.1.3. Beamer et al. (2008)—Quantified Activity Pattern Data From 6- to 27-Month-Old Farm Worker Children for Use in Exposure Assessment

Beamer et al. (2008) conducted a follow-up to the pilot study performed by Zartarian et al. (1998, 1997a; 1997b), described in Sections 4.3.1.1 and 4.4.2.2. For this study, a convenience sample of 23 children residing in the farm worker community of Salinas Valley, CA was enrolled. Participants were 6- to 13-month-old infants or 20- to 26-month-old toddlers. Two researchers videotaped each child’s activities for a minimum of 4 hours, and kept a

detailed written log of locations visited and objects and surfaces contacted by the child. A questionnaire was administered to an adult in the household to acquire demographic data, housing and cleaning characteristics, eating patterns, and other information pertinent to the child’s potential pesticide exposure.

Table 4-21 presents the object/surface hourly contact duration in minutes/hour. The mean hourly mouthing duration for hands and non-dietary objects was 1.4 and 3.5 minutes/hour, respectively. Infants had higher hourly mouthing duration with toys and all non-dietary objects than toddlers. Girls had higher contact durations than boys.

The advantage of this study is that it included both infants and toddlers. Differences between the two age groups, as well as sex differences, could be observed. As with other video-transcription studies, the presence of non-family-member videographers and a video camera may have influenced the children’s behavior.

4.4.2. Relevant Mouthing Duration Studies

4.4.2.1. Barr et al. (1994)—Effects of Intra-Oral Sucrose on Crying, Mouthing, and Hand-Mouth Contact in Newborn and Six-Week-Old Infants

Barr et al. (1994) studied hand-to-mouth contact, as well as other behaviors, in 15 newborn (eight males, seven females) and fifteen 5- to 7-week old (eight males, seven females) full-term Canadian infants using a video-transcription methodology. The newborns were 2- to 3-days old, were in a quiet, temperature-controlled room at the hospital, were in a supine position and had been fed between 2 1/2 and 3 1/2 hours before testing. Barr et al. (1994) analyzed a 1-minute baseline period, with no experimental stimuli, immediately before a sustained crying episode lasting 15 seconds. For the newborns, reported durations of hand-to-mouth contact during 10-second intervals of the 1-minute baseline period were in the range of 0 to 2%. The 5- to 7-week old infants apparently were studied at primary care pediatric facilities when they were in bassinets inclined at an angle of 10 degrees. For these slightly older infants, the baseline periods analyzed were less than 20 seconds in length, but Barr et al. (1994) reported similarly low mean percentages of the 10-second intervals (approximately 1% of the time with hand-to-mouth contact). Hand-to-mouth contact was defined as “any part of the hand touching the lips and/or the inside of the mouth.” The researchers performed inter-observer reliability tests on the videotape data and reported a mean inter-observer reliability of 0.78 by Cohen’s kappa.

Chapter 4—Non-Dietary Ingestion Factors

The advantages of this study were that use of video cameras could be expected to have virtually no effect on newborns' or five to seven week old infants' behavior, and that inter-observer reliability tests were performed. The study data did not represent newborn or 5- to 7-week-old infant hand-to-mouth contact during periods in which infants of these ages were in a sleeping or other non-alert state, and data may only represent behavior immediately prior to a state of distress (sustained crying episode). The extent to which these infants' behavior is representative of other full-term infants of these ages is unknown.

4.4.2.2. Zartarian et al. (1997b)—Quantifying Videotaped Activity Patterns: Video Translation Software and Training Technologies/Zartarian et al. (1997a)—Quantified Dermal Activity Data From a Four-Child Pilot Field Study/Zartarian et al. (1998)—Quantified Mouthing Activity Data From a Four-Child Pilot Field Study

As described in Section 4.3.1.1, Zartarian et al. (1998, 1997a; 1997b) conducted a pilot study of the video-transcription methodology to investigate the applicability of using videotaping for gathering information related to children's activities, dermal exposures and mouthing behaviors. The researchers had conducted studies using the real-time hand recording methodology. These studies demonstrated poor inter-observer reliability and observer fatigue when attempted for long periods of time. This prompted the investigation into using videotaping with transcription of the children's activities at a point in time after the videotaped observations occurred.

Four Mexican-American farm worker children in the Salinas Valley of California each were videotaped with a hand-held videocamera during their waking hours, excluding time spent in the bathroom, over 1 day in September 1993. The boys were 2 years 10 months old and 3 years 9 months old; the girls were 2 years 5 months old and 4 years 2 months old. Time of videotaping was 6.0 hours for the younger girl, 6.6 hours for the older girl, 8.4 hours for the younger boy and 10.1 hours for the older boy. The videotaping gathered information on detailed micro-activity patterns of children to be used to evaluate software for videotaped activities and translation training methods.

The four children mouthed non-dietary objects an average of 4.35% (range 1.41 to 7.67%) of the total observation time, excluding the time during which the children were out of the camera's view (Zartarian et al., 1998). Objects mouthed included

bedding/towels, clothes, dirt, grass/vegetation, hard surfaces, hard toys, paper/card, plush toy, and skin (Zartarian et al., 1998). Frequency distributions for the four children's non-dietary object contact durations were reported to be similar in shape. Reported hand-to-mouth contact presumably is a subset of the object-to-mouth contacts described in Zartarian et al. (1997b), and is described in Zartarian et al. (1997a). The four children mouthed their hands an average of 2.35% (range 1.0 to 4.4%) of observation time (Zartarian et al., 1997a). The researchers reported measures taken to assess inter-observer reliability and several problems with the video-transcription process.

This study's primary purpose was to develop and evaluate the video-transcription methodology; a secondary purpose was collection of mouthing behavior data. The sample of children studied was very small and not likely to be representative of the national population. Thus, U.S. EPA did not judge it to be suitable for consideration as a key study of children's mouthing behavior. As with other video-transcription studies, the presence of non-family member videographers and a video camera may have influenced the children's behavior.

4.4.2.3. Groot et al. (1998)—Mouthing Behavior of Young Children: An Observational Study

In this study, Groot et al. (1998) examined the mouthing behavior of 42 Dutch children (21 boys and 21 girls) between the ages of 3 and 36 months in late July and August 1998. Parent observations were made of children in 36 families. Parents were asked to observe their children 10 times per day for 15-minute intervals (i.e., 150 minutes total per day) for two days and measure mouthing times with a stopwatch. In this study, *mouthing* was defined as "all activities in which objects are touched by mouth or put into the mouth except for eating and drinking. This term includes licking as well as sucking, chewing and biting."

For the study, a distinction was made between toys meant for mouthing (e.g., pacifiers, teething rings) and those not meant for mouthing. Inter- and intra-observer reliability was measured by trained observers who co-observed a portion of observation periods in three families and who co-observed and repeatedly observed some video transcriptions made of one child. Another quality assurance procedure performed for the extrapolated total mouthing time data was to select 12 times per hour randomly during the entire waking period of four children during 1 day, in which the researchers recorded activities and total mouthing times.

Chapter 4—Non-Dietary Ingestion Factors

Although the sample size was relatively small, the results provided estimates of mouthing times, other than pacifier use, during 1 day. The results were extrapolated to the entire day based on the 150 minutes of observation per day, and the mean value for each child for the 2 days of observations was interpreted as the estimate for that child. Table 4-22 shows summary statistics. The standard deviation in all four age categories except the 3- to 6-month old children exceeded the estimated mean. The 3 to 6 month children ($N = 5$) were estimated to have mean non-pacifier mouthing durations of 36.9 minutes per day, with toys as the most frequently mouthed product category, while the 6 to 12 month children ($N = 14$) were estimated to have 44 minutes per day (fingers most frequently mouthed). The 12- to 18-month olds' ($N = 12$) estimated mean non-pacifier mouthing time was 16.4 minutes per day, with fingers most frequently mouthed, and 18- to 36-month olds' ($N = 11$) estimated mean non-pacifier mouthing time was 9.3 minutes per day (fingers most frequently mouthed).

One strength of this study is that the researchers recognized that observing children might affect their behavior and emphasized to the parents the importance of making observations under conditions that were as normal as possible. In spite of these efforts, many parents perceived that their children's behavior was affected by being observed and that observation interfered with caregiving responsibilities such as comforting children when they were upset. Other limitations included a small sample size that was not representative of the Dutch population and that also may not be representative of U.S. children. Technical problems with the stopwatches affected at least 14 of 36 parents' data.

4.4.2.4. Smith and Norris (2003)—Reducing the Risk of Choking Hazards: Mouthing Behavior of Children Aged 1 Month to 5 Years/Norris and Smith (2002)—Research Into the Mouthing Behavior of Children up to 5 Years Old

Smith and Norris (2003) conducted a real-time hand recording study of mouthing behavior among 236 children (111 males, 125 females) in the United Kingdom (exact locations not specified) who were from 1 month to 5 years old. Children were observed at home by parents, who used stopwatches to record the time that mouthing began, the type of mouthing, the type of object being mouthed, and the time that mouthing ceased. Children were observed for a total of 5 hours over a 2-week period; the observation time

consisted of twenty 15-minute periods spread over different times and days during the child's waking hours. Parents also recorded the times each child was awake and not eating meals so that the researchers could extrapolate estimates of total daily mouthing time from the shorter observation periods. Mouthing was defined as licking/lip touching, sucking/trying to bite and biting or chewing, with a description of each category, together with pictures, given to parents as guidance for what to record.

Table 4-23 shows the results of the study. While no overall pattern could be found in the different age groups tested, a Kruskal-Wallis test on the data for all items mouthed indicated that there was a significant difference between the age groups. Across all age groups and types of items, licking and sucking accounted for 64% of all mouthing behavior. Pacifiers and fingers exhibited less variety on mouthing behavior (principally sucking), while other items had a higher frequency of licking, biting, or other mouthing.

The researchers randomly selected 25 of the 236 children for a single 15-minute observation of each child (total observation time across all children: 375 minutes), to compare the mouthing frequency and duration data obtained according to the real-time hand recording and the video-transcription methodologies, as well as the reliability of parent observations versus those made by trained professionals. For this group of 25 children, the total number of mouthing behavior events recorded by video (160) exceeded those recorded by parents (114) and trained observers (110). Similarly, the total duration recorded by video (24 minutes and 15 seconds) exceeded that recorded by observers (parents and trained observers both recorded identical totals of 19 minutes and 44 seconds). The mean and standard deviation of observed mouthing time were both lower when recorded by video versus real-time hand recording. The maximum observed mouthing time also was lower (6 minutes and 7 seconds by video vs. 9 minutes and 43 seconds for both parents and trained observers).

The strengths of this study were its comparison of three types of observation (i.e., parents, trained observers, and videotaping), and its detailed reporting of mouthing behaviors by type, object/item mouthed, and age group. However, the children studied may not be representative of U.S. children. In addition, the study design or approach made the data less applicable for exposure assessment purposes (e.g., data on mouthing behavior that was intended to be used in reducing the risk of choking hazards).

Chapter 4—Non-Dietary Ingestion Factors

4.4.2.5. AuYeung et al. (2004)—Young Children's Mouthing Behavior: An Observational Study via Videotaping in a Primarily Outdoor Residential Setting

As described in Section 4.3.1.5, AuYeung et al. (2004) used a video-transcription methodology to study a group of 38 children (20 females and 18 males; ages 1 to 6 years), 37 of whom were selected randomly via a telephone screening survey of a 300- to 400-square-mile portion of the San Francisco, CA peninsula, along with one child selected by convenience because of time constraints. Families who lived in a residence with a lawn and whose annual income was >\$35,000 were asked to participate. Videotaping took place between August 1998 and May 1999 for approximately 2 hours per child. Videotaping by one researcher was supplemented with field notes taken by a second researcher who was also present during taping. Most of the videotaping took place during outdoor play, however, data were included for several children (one child <2 years old and 8 children >2 years old) who had more than 15 minutes of indoor play during their videotaping sessions.

The videotapes were translated into ASCII computer files using VirtualTimingDevice™ software described in Zartarian et al. (1997b). Both frequency (see Section 4.3.1.5 of this chapter) and duration were analyzed. Between 5 and 10% of the translated data files were randomly chosen for quality control checks for inter-observer agreement. Ferguson et al. (2006) described quality control aspects of the study in detail.

For analysis, the mouthing contacts were divided into indoor and outdoor locations and 16 object/surface categories. Mouthing durations were analyzed by age and sex separately and in combination. *Mouthing contacts* were defined as contact with the lips, inside of the mouth, and/or the tongue; dietary contacts were ignored. Table 4-24 shows mouthing durations (outdoor locations). For the children in all age groups, the median duration of each mouthing contact was 1 to 2 seconds, confirming the observations of other researchers that children's mouthing contacts are of very short duration. For the one child observed that was ≤24 months, the total indoor mouthing duration was 11.1 minutes/hour; for children >24 months, the median indoor mouthing duration was 0.9 minutes/hour (see Table 4-25). For outdoor environments, median contact durations for these age groups decreased to 0.8 and 0.6 minutes/hour, respectively (see Table 4-26).

Non-parametric tests, such as the Wilcoxon rank sum test, were used for the data analyses. Both age and sex were found to be associated with differences in mouthing behavior. Girls' hand-to-mouth contact durations were significantly shorter than for boys ($p = 0.04$).

This study provides distributions of outdoor mouthing durations with various objects and surfaces. Although indoor mouthing data were also included in this study, the results were based on a small number of children ($N = 9$) and a limited amount of indoor play. The sample of children may be representative of certain socioeconomic strata in the study area, but is not likely to be representative of the national population. Because of the children's ages, the presence of unfamiliar persons following the children with a video camera may have influenced the video-transcription methodology results.

4.5. MOUTHING PREVALENCE STUDIES**4.5.1. Stanek et al. (1998)—Prevalence of Soil Mouthing/Ingestion Among Healthy Children Aged 1 to 6**

Stanek et al. (1998) characterized the prevalence of mouthing behavior among healthy children based on a survey response study of parents or guardians of 533 children (289 females, 244 males) ages 1 to 6 years old. Study participants were attendees at scheduled well-child visits at three clinics in western Massachusetts in August through October, 1992. Participants were questioned about the frequency of 28 mouthing behaviors of the children over the preceding month in addition to exposure time (e.g., time outdoors, play in sand or dirt) and children's characteristics (e.g., teething).

Table 4-27 presents the prevalence of reported non-food ingestion/mouthing behaviors by child's age as the percentage of children whose parents reported the behavior in the preceding month. The table includes a column of data for the 3 to <6 year age category; this column was calculated by U.S. EPA as a weighted mean value of the individual data for 3-, 4-, and 5-year olds in order to conform to the standardized age categories used in this handbook. Among all the age groups, 1-year olds had the highest reported daily sucking of fingers/thumb; the proportion dropped for 2-year olds, but rose slightly for 3- and 4-year olds and declined again after age 4. A similar pattern was reported for more than weekly finger/thumb sucking, while more than monthly finger/thumb sucking showed a very slight increase for 6-year olds. Reported pacifier use was highest for 1-year olds and declined with age for daily and more than weekly use; for more than

Chapter 4—Non-Dietary Ingestion Factors

monthly use of a pacifier several 6-year olds were reported to use pacifiers, which altered the age-declining pattern for the daily and more than weekly reported pacifier use. A pattern similar to pacifier use existed with reported mouthing of teething toys, with highest reported use for 1-year olds, a decline with age until age 6 when reported use for daily, more than weekly, and more than monthly use of teething toys increased.

The authors developed an outdoor mouthing rate for each child as the sum of rates for responses to four questions on mouthing specific outdoor objects. Survey responses were converted to mouthing rates per week, using values of 0, 0.25, 1, and 7 for responses of never, monthly, weekly, and daily ingestion. Reported outdoor soil mouthing behavior prevalence was found to be higher than reported indoor dust mouthing prevalence, but both behaviors had the highest reported prevalence among 1-year old children and decreased for children 2 years and older. The investigators conducted principal component analyses on responses to four questions relating to ingestion/mouthing of outdoor objects in an attempt to characterize variability. Outdoor ingestion/mouthing rates constructed from the survey responses were that children 1-year old were reported to mouth or ingest outdoor objects 4.73 times per week while 2- to 6-year olds were reported to mouth or ingest outdoor objects 0.44 times per week. The authors developed regression models to identify factors related to high outdoor mouthing rates. The authors found that children who were reported to play in sand or dirt had higher outdoor object ingestion/mouthing rates.

A strength of this study is that it was a large sample obtained in an area with urban and semi-urban residents within various socioeconomic categories and with varying racial and ethnic identities. However, difficulties with parents' recall of past events may have caused either over-estimates or under-estimates of the behaviors studied.

4.5.2. Warren et al. (2000)—Non-Nutritive Sucking Behaviors in Preschool Children: A Longitudinal Study

Warren et al. (2000) conducted a survey response study of a non-random cohort of children born in certain Iowa hospitals from early 1992 to early 1995 as part of a study of children's fluoride exposure. For this longitudinal study of children's non-nutritive sucking behaviors, 1,374 mothers were recruited at the time of their newborns' birth, and more than 600 were active in the study until the children were at least 3 years old. Survey questions

on non-nutritive sucking behaviors were administered to the mothers when the children were 6 weeks, and 3, 6, 9, 12, 16, and 24 months old, and then yearly after age 24 months. Questions were posed regarding the child's sucking behavior during the previous 3 to 12 months.

The authors reported that nearly all children sucked non-nutritive items, including pacifiers, thumbs or other fingers, and/or other objects, at some point in their early years. The parent-reported sucking behavior prevalence peaked at 91% for 3 month old children. At 2 years of age, a majority (53%) retained a sucking habit, while 29% retained the habit at age 3 years and 21% at age 4 years. Parent-reported pacifier use was 28% for 1-year olds, 25% for 2-year olds, and 10% for 3-year olds. The authors cautioned against generalizing the results to other children because of study design limitations.

Strengths of this study were its longitudinal design and the large sample size. A limitation is that the non-random selection of original study participants and the self-selected nature of the cohort of survey respondents who participated over time means that the results may not be representative of other U.S. children of these ages.

5. SOIL AND DUST INGESTION

5.1. INTRODUCTION

This document is an update to Chapter 5 (Soil and Dust Ingestion) of the *Exposure Factors Handbook: 2011 Edition*. New information that has become available since 2011 has been added, and the recommended values have been revised, as needed, to reflect the additional information. The chapter includes a comprehensive review of the scientific literature through 2016. The new literature was identified via formal literature searches conducted by EPA library services as well as targeted internet searches conducted by the authors of this chapter. Appendix A provides a list of the key terms that were used in the literature searches. Revisions to this chapter have been made in accordance with the approved quality assurance plan for the *Exposure Factors Handbook*.

The ingestion of soil and dust is a potential route of exposure to environmental chemicals for both adults and children. Children, in particular, may ingest significant quantities of soil and dust due to their tendency to play on the floor indoors and on the ground outdoors and their tendency to mouth objects or their hands. For example, children may ingest soil and dust through deliberate hand-to-mouth movements, or unintentionally by eating food or mouthing objects that have dropped on the floor. Adults may also ingest soil or dust particles that adhere to food, cigarettes, or their hands. Other vulnerable populations may include pregnant women and populations engaging in wilderness and traditional rural lifestyles. Thus, understanding soil and dust ingestion patterns is an important part of estimating overall exposures to environmental chemicals.

Currently, knowledge of soil and dust ingestion patterns within the United States is limited. Only a few researchers have attempted to quantify soil and dust ingestion patterns in U.S. adults or children.

This chapter explains the concepts of soil and dust ingestion, soil pica, and geophagy; defines these terms for the purpose of this handbook's exposure factors; and presents available data from the literature on the amount of soil and dust ingested.

The Centers for Disease Control and Prevention's Agency for Toxic Substances and Disease Registry (ATSDR) held a workshop in June 2000 in which a panel of soil ingestion experts developed definitions for soil ingestion, soil pica, and geophagy to distinguish aspects of soil ingestion patterns that are important from a research perspective (ATSDR, 2001). This chapter uses the

definitions developed by participants in that workshop:

Soil ingestion is the consumption of soil. This may result from various behaviors including, but not limited to, mouthing, contacting dirty hands, eating dropped food, or consuming soil directly.

Soil pica is the recurrent ingestion of unusually high amounts of soil (i.e., on the order of 1,000–5,000 mg/day or more).

Geophagy is the intentional ingestion of earths and is usually associated with cultural practices.

Some studies are of a behavior known as “pica,” and the subset of “pica” that consists of ingesting soil. A general definition of the concept of pica is that of ingesting nonfood substances, or ingesting large quantities of certain particular foods. Definitions of pica often include references to recurring or repeated ingestion of these substances. Soil pica is specific to ingesting materials that are defined as soil, such as clays, yard soil, and flower-pot soil. Although soil pica has been observed among children and adults, information about the prevalence of pica behavior is limited. Gavrelis et al. (2011) reported that the prevalence of nonfood substance consumption varies by age, race, and income level. The behavior was most prevalent among children 1 to <3 years (Gavrelis et al., 2011). Geophagy, on the other hand, is an extremely rare behavior, especially among children, as is soil pica among adults. One distinction between geophagy and soil pica that may have public health implications is the fact that surface soils generally are not the main source of geophagy materials. Instead, geophagy is typically the consumption of clay from known, uncontaminated sources, whereas soil pica involves the consumption of surface soils, usually the top 2–3 inches (ATSDR, 2001).

Researchers in many different disciplines have hypothesized motivations for human soil pica or geophagy behavior, including alleviating hunger, nutritional deficiencies, or gastrointestinal distress (Young, 2010), a desire to remove toxins or self-medicate (Starks and Slabach, 2012), and other physiological or cultural influences (Danford, 1982). Bruhn and Pangborn (1971) and Harris and Harper (1997) suggest a religious context for certain geophagy or soil ingestion practices. Geophagy is characterized as an intentional behavior, whereas soil pica should not be limited to intentional soil ingestion, primarily because children can consume large amounts of soil from their typical behaviors

and because differentiating intentional and unintentional behavior in young children is difficult (ATSDR, 2001). Some researchers have investigated populations that may be more likely than others to exhibit soil pica or geophagy behavior on a recurring basis. These populations might include pregnant women who exhibit soil pica behavior (Simpson et al., 2000), adults and children who practice geophagy (Vermeer and Frate, 1979), institutionalized children (Wong, 1988), and children with developmental delays (Danford, 1983), autism (Kinnell, 1985), or celiac disease (Korman, 1990). However, identifying specific soil pica and geophagy populations remains difficult due to limited research on this topic. ATSDR (2001) has estimated that 33% of children ingest more than 10 grams of soil 1 or 2 days a year. No information was located regarding the prevalence of geophagy behavior.

Because some soil and dust ingestion may be a result of hand-to-mouth behavior, soil properties that relate to adherence to the skin may be important. For example, soil particle size, organic matter content, moisture content, and other soil properties may affect the amount of soil that adheres to the skin and is available for ingestion. Soil particle sizes range from 50–2,000 μm for sand, 2–50 μm for silt, and are <2 μm for clay (USDA, 1999), while typical atmospheric dust particle sizes are in the range of 0.001–30 μm (U.S. OSHA, 1987). Studies on particle size have indicated that finer soil particles (generally <63 μm in diameter) tend to be adhered more efficiently to human hands, whereas adhered soil fractions are independent of organic matter content or soil origin (Choate et al., 2006; Yamamoto et al., 2006). For soils with higher moisture content, a greater number of large particles have been shown to adhere to the skin (Choate et al., 2006). Ikegami et al. (2014) found that approximately 90% of the particles of playground soil that adhered to children's hands were less than 100 μm in size. Beamer et al. (2012) and Bergstrom et al. (2011) found that concentrations of contaminants (e.g., metals) in soil may differ according to particle size. Cao et al. (2012) also described the importance of considering particle size when evaluating exposures to indoor settled dust.

In this handbook, soil, indoor settled dust, and outdoor settled dust are defined generally as the following:

Soil. Particles of unconsolidated mineral and/or organic matter from the earth's surface that are

located outdoors, or are used indoors to support plant growth. It includes particles that have settled onto outdoor objects and surfaces (outdoor settled dust).

Indoor Settled Dust. Particles in building interiors that have settled onto objects, surfaces, floors, and carpeting. These particles may include soil particles that have been tracked or blown into the indoor environment from outdoors, as well as organic matter.

Outdoor Settled Dust. Particles that have settled onto outdoor objects and surfaces due to either wet or dry deposition. Note that it may not be possible to distinguish between soil and outdoor settled dust because outdoor settled dust generally is present on the uppermost surface layer of soil.

For the purposes of this handbook, soil ingestion includes both soil and outdoor settled dust, and dust ingestion includes indoor settled dust only.

Several methodologies related to soil and dust ingestion are represented in the literature. Two methodologies combine biomarker measurements with measurements of the biomarker substance's presence in environmental media. An additional methodology offers modeled estimates of soil/dust ingestion from activity pattern data from observational studies (e.g., videography) or from the responses to survey questionnaires about children's activities, behaviors, and locations.

The first of the biomarker methodologies is the "*tracer element*" methodology. This method uses measured quantities of specific elements present in feces, urine, food and medications, yard soil, house dust, and sometimes community soil and dust. This information is used in combination with certain assumptions about the elements' behavior in the gastrointestinal tract to produce estimates of soil and dust quantities ingested (Davis et al., 1990).

The second biomarker methodology is the "*biokinetic model comparison*" methodology. This method compares results from a biokinetic model of lead exposure and uptake that predicts blood lead levels, with biomarker measurements of lead in blood (Von Lindern et al., 2003). The model predictions are made using assumptions about ingested soil and dust quantities that are based, in part, on results from early versions of the first methodology. Therefore, the comparison with actual measured blood lead levels serves to confirm, to some extent, the assumptions about ingested soil and dust quantities used in the biokinetic model. Lead isotope ratios have also been used as a biomarker to

study sources of lead exposures in children. This technique involves measurements of different lead isotopes in blood and/or urine, food, water, and house dust and compares the ratio of different lead isotopes to infer sources of lead exposure that may include dust or other environmental exposures (Manton et al., 2000). However, application of lead isotope ratios to derive estimates of dust ingestion by children has not been attempted. Therefore, it is not discussed any further in this chapter.

The third, “*activity pattern*” methodology, combines information from hand-to-mouth and object-to-mouth behaviors with microenvironment data (i.e., time spent at different locations) to derive estimates of soil and dust ingestion. Behavioral information often comes from data obtained using videography techniques or from responses to survey questions obtained from adults, caregivers, and/or children. Surveys often include questions about hand-to-mouth and object-to-mouth behaviors, soil and dust ingestion behaviors, frequency, and sometimes quantity (Barltrop, 1966). Moya and Phillips (2014) provide a review of these three methodologies used to estimate soil and dust ingestion.

A fourth methodology uses assumptions regarding ingested quantities of soil and dust that are based on a general knowledge of human behavior, and potentially supplemented or informed by data from other methodologies (Hawley, 1985; Kissel et al., 1998a; Wong et al., 2000). This methodology is not discussed in this chapter because it yields rudimentary estimates of soil ingestion.

Another approach used to estimate soil/dust ingestion consists of measurements of soil/dust loadings on surfaces (mass per surface area) and concentrations of contaminants on those surfaces. Estimates of soil/dust ingestion can be made by making assumptions about children’s hand-to-mouth and object-to-mouth behavior, surfaces contacted, fraction of soil/dust transferred, exposure time, saliva extraction efficiency, and assumptions about the amount of soil/dust reloading on skin or surfaces. This approach results in a different metric of soil/dust ingestion in units of area contacted/day, which can then be used with corresponding contaminant concentrations of soil/dust per surface area. This approach is described in more detail by Wilson et al. (2016).

The recommendations for soil, dust, and soil + dust ingestion rates are provided in the next section, along with a summary of the confidence ratings for these recommendations. The recommended values are based on key studies identified by the U.S. Environmental Protection

Agency (U.S. EPA) for this factor. As described in Chapter 1 of the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011), key studies represent the most up-to-date and scientifically sound for deriving recommendations for exposure factors, whereas other studies are designated “relevant,” meaning applicable or pertinent, but not necessarily the most important. For example, studies that provide supporting data or information related to the factor of interest (e.g., pica prevalence), or have study designs or approaches that make the data less applicable to the population of interest (e.g., studies not conducted in the United States) have been designated as relevant rather than key. Key studies were selected based on the general assessment factors described in Chapter 1 of the Handbook.

Following the recommendations, a description of the three methodologies used to estimate soil and dust ingestion is provided, followed by a summary of key and relevant studies. Because strengths and limitations of each one of the key and relevant studies relate to the strengths and limitations inherent of the methodologies themselves, they are discussed at the end of the key and relevant studies.

5.2. RECOMMENDATIONS

Table 5-1 provides the recommended soil and dust ingestion rates for use in human health risk assessments. The soil ingestion recommendations in Table 5-1 are intended to represent ingestion of a combination of soil and outdoor settled dust, without distinguishing between these sources. The source of the soil in these recommendations could be outdoor soil, indoor containerized soil used to support growth of indoor plants, or a combination of both outdoor soil and containerized indoor soil. The inhalation and subsequent swallowing of soil particles is accounted for in these recommended values; therefore, this pathway does not need to be considered separately. These recommendations are called “soil.” The dust ingestion recommendations in Table 5-1 include soil tracked into the indoor setting, indoor settled dust, and air-suspended particulate matter that is inhaled and swallowed. “Dust” recommendations are provided in the event that assessors need recommendations for an indoor or inside a transportation vehicle scenario in which dust, but not outdoor soil, is the exposure medium of concern. The soil + dust recommendations would include soil, either from outdoor or containerized indoor sources, dust that is a combination of outdoor settled dust, indoor settled dust, and air-suspended particulate matter that is inhaled, subsequently trapped in mucous and moved from the respiratory

system to the gastrointestinal tract, and a soil-origin material located on indoor floor surfaces that was tracked indoors by building occupants.

Many of the key studies predated the age groups recommended for children by U.S. EPA (2005) and were performed on groups of children of varying ages. As a result, central tendency and upper percentile recommendations could only be developed for some combined age categories, as shown in Table 5-1. Published estimates from the key studies have been rounded to one significant figure in Table 5-1.

An important factor to consider when using the recommended values described in the following sections is that they are limited to estimates of soil and dust quantities ingested. The scope of this chapter is limited to quantities of soil and dust taken into the gastrointestinal tract, and does not extend to issues regarding bioavailability of environmental contaminants present in that soil and dust. Information from other sources is needed to address bioavailability. In addition, as more information becomes available regarding gastrointestinal absorption of environmental contaminants, adjustments to the soil and dust ingestion exposure equations may need to be made to better represent the direction of movement of those contaminants within the gastrointestinal tract.

To place the recommended values into context, it may be useful to compare the soil ingestion rates to common measurements. For example, the central tendency recommendation of 40 mg/day or 0.040 g/day of either soil only or dust only for general population children 1 to <6 years old would be equivalent to approximately 1/8 of an aspirin tablet per day because the average aspirin tablet is approximately 325 mg. Likewise, the central tendency recommendation of 80 mg/day or 0.080 g/day, for soil and dust combined, would be equivalent to approximately 1/4 of an aspirin tablet. The 50 g/day ingestion rate recommended to represent geophagy behavior would be roughly equivalent to 150 aspirin tablets per day.

5.2.1 General Population Soil and Dust Ingestion Rates

The key studies described in Sections 5.3.2 and 5.3.3 were used to recommend values for soil and dust ingestion for adults and children in the general population. Table 5-1 shows the central tendency and upper percentile recommendations for daily ingestion of soil + dust, soil only, and dust only in mg/day. Section 5.5 and Table 5-34 provide additional details on the derivation of these recommended values. The recommended values for

soil ingestion only and dust ingestion only are based on the assumption that 45% of the soil + dust ingestion can be attributed to soil and 55% can be attributed to dust. This assumption is based on the defaults used in EPA's Integrated Exposure and Uptake Biokinetic (IEUBK) model (U.S. EPA, 1994a). According to U.S. EPA (1994a), the assumption is based on the relative likelihood of contact with soil/dust in indoor and outdoor locations and "represents [EPA's] best judgement of a properly weighted ratio for this purpose." All recommended values have been rounded to one significant figure due to data limitations.

In general, the "central tendency" recommendations reflect an arithmetic mean (average) of estimated values within a study, across studies within a methodology, and across the three methodologies. However, in some of the tracer studies, (Stanek and Calabrese, 1995a), the central tendency value used was the average of the median values for the four best tracer elements or the average of the median of three tracers (see Section 5.3.3.2). For others (Calabrese et al., 1997a; 1997b) the central tendency value represents the average of the best tracer or the average based on aluminum and silicon. Upper percentile recommendations for daily ingestion are also provided in mg/day. Note that there is considerably more uncertainty related to the upper percentile soil and dust ingestion rate estimates than for the average estimates. Biases due to the errors (e.g., sampling errors, measurement errors, analytical errors) are more likely to affect the upper percentile estimates than the average estimates. Upper percentile recommendations for the general population are provided for soil, dust, and soil + dust ingestion. These values are based on the 95th percentile values from the key studies.

The recommended central tendency soil + dust ingestion estimate for general population infants 0 to <6 months old is 40 mg/day, and the central tendency estimate for 6 months to <1 year of age is 70 mg/day. If a central tendency estimate is needed for soil or dust only, the recommended values are both 20 mg/day for infants 0 to <6 months (i.e., 18 mg/day soil and 22 mg/day dust, both rounded to one significant figure is 20 mg/day). For infants 6 months to <1 year, the recommended soil only estimate is 30 mg/day and the dust only estimate is 40 mg/day.

For risk assessment involving children 1 to <2 and 2 to <6 years of age, the recommended central tendency soil + dust ingestion rates are 90 mg/day and 60 mg/day, respectively. For soil only, the recommended central tendency values are 40 mg/day for 1- to <2-year-olds and 30 mg/day for

2- to <6-year-olds, respectively. For dust only, the recommended central tendency values are 50 mg/day and 30 mg/day for the two age groups, respectively.

When assessing risks for children 1 to <6 years of age who are not expected to exhibit soil pica or geophagy behavior, the recommended central tendency soil + dust ingestion estimate is 80 mg/day. If an estimate for soil only or indoor dust only is needed, the recommendation is 40 mg/day.

For children 6 to <12 years old without pica, the recommended central tendency soil + dust ingestion rate is 60 mg/day. For either soil or dust alone, the estimate is 30 mg/day. For children 12 to <20 years and adults, the recommended central tendency values for use in risk assessment is 30 mg/day, rounded to one significant figure. This recommendation is based on data for adults from Davis and Mirick (2006) and data from Wilson et al. (2013) that indicated that central tendency soil + dust ingestion rates ages 12 to <20 years and adults are similar. For soil only, the recommended value is 10 mg/day, and for dust only, the recommended value is 20 mg/day.

The upper percentile recommendations for soil + dust ingestion among the general population, are based on the 95th percentile values obtained from key studies as shown in Table 5-1, rounded to one significant figure. The recommended values: are 100 mg/day for infants 0 to <6 months (50 mg/day soil and 60 mg/day dust), and 200 mg/day for children 6 months to <1 year, 1 to <2 years, 2 to <6 years, 1 to <6 years, and 6 to <12 years (90 mg/day soil and 100 mg/day dust). For ages 12 years through adults, the recommended upper percentile value is 100 mg/day (50 mg/day soil and 60 mg/day dust).

5.2.2. Soil Pica and Geophagy

Ingestion rates for “soil pica,” and for individuals who exhibit “geophagy” are also provided in Table 5-1. The soil-pica and geophagy recommendations are likely to represent an acute high soil ingestion episode or behavior. The soil pica ingestion estimate in the literature for children up to age 6 years ranges from 1,000 to 6,000 mg/day, averaged over the study period (ATSDR, 2001; Barnes, 1990; Calabrese et al., 1989, 1991, 1997b; Stanek et al., 1998). Due to the short-term nature of these studies and the limited amount of data available for children exhibiting pica behavior, the lower end of this range of 1,000 mg/day is recommended for soil pica for children 1 to <6 years old. However, it is important to note that soil ingestion for these children exhibiting soil pica behavior has been reported as high as 20 to

25 g/day on any given day (Calabrese et al., 1997b). Note too that the recommended soil pica value may be more appropriate for acute exposures. Currently, no data are available for soil pica behavior for children less than 12 months or in children ages 6 to <21 years. Because pica behavior may occur among some children ages ~1 to 21 years old (Hyman et al., 1990), it is prudent to assume that, for some children, soil pica behavior may occur at any age up to 21 years. While pica may also occur among adults, no key studies were available for developing recommended intake rates for adults who exhibit pica.

The recommended geophagy soil estimate is 50,000 mg/day (50 grams) for both adults and children (Vermeer and Frate, 1979). It is important to note that this value may be more representative of acute exposures. Risk assessors should use this value for soil ingestion in for individuals or populations known to exhibit geophagy behaviors.

5.2.3. Wilderness or Traditional Rural Lifestyles

Information on soil ingestion among special populations, such as those engaging in wilderness lifestyles in Canada, are presented as relevant studies in Sections 5.3.4 (Doyle et al., 2012; Irvine et al., 2014). Data from these studies may be appropriate for high soil contact scenarios. For rural populations following traditional rural or wilderness lifestyles as described in these studies, adult soil ingestion rates may be somewhat higher than those of the general population. Based on these two studies the adult mean soil + dust ingestion rate is 50 mg/day and the upper percentile soil + dust ingestion rate is 200 mg/day. Based on personal communication with the authors of these two studies, the 95th percentile of the combined data sets was calculated to be 239 mg/day for aluminum and silicon (for all four tracers the value would be 243 mg/day) (personal communication between M. Stifelman, EPA, and J. Doyle, University of Ottawa, Canada). Rounding to one significant figure, the upper percentile value would also be 200 mg/day. Assuming that soil represents 45% and dust represents 55% of the soil + dust value, the mean and upper percentile soil only values would be 20 mg/day and 90 mg/day, respectively. The mean and upper percentile dust only values would be 30 mg/day and 100 mg/day, respectively.

5.2.4. Confidence Ratings

Section 5.4 gives a detailed explanation of the limitations of the various study methodologies, which are reflected in the confidence ratings for the recommendations shown in Table 5-2. Individual

evaluations of the quality of studies are provided in the specific discussions for each of the individual studies. The confidence ratings are low due to the relatively limited data on which the recommendations are based and the limitations and uncertainties associated with tracer studies described in Section 5.4.1, and the assumptions needed to develop quantitative estimates using the biokinetic modeling (see Section 5.4.2) and activity pattern modeling approaches (see Section 5.4.3). Other uncertainties pertain to the representativeness of the

populations studied. A more detailed discussion about the general assessment factors used to evaluate the confidence in the recommendations is provided in Chapter 1 of the Handbook. For the estimates of soil only and dust only, an additional uncertainty pertains to the assumption that the proportion of soil + dust represented by soil only (45%) and dust only (55%) is the same for all age groups.

Table 5-1. Recommended Values for Daily Soil, Dust, and Soil + Dust Ingestion (mg/day) ^a								
Age Group	Soil + Dust		Soil ^b				Dust ^c	
	General Population Central Tendency ^d	General Population Upper Percentile ^e	General Population Central Tendency ^f	General Population Upper Percentile ^f	Soil Pica ^g	Geophagy ^h	General Population Central Tendency ^f	General Population Upper Percentile ^f
<6 months	40	100	20	50	—	—	20	60
6 months to <1 year	70 (60–80)	200	30	90	—	—	40	100
1 to <2 years	90	200	40	90	1,000	50,000	50	100
2 to <6 years	60	200	30	90	1,000	50,000	30	100
1 to <6 years	80 (60–100)	200	40	90	1,000	50,000	40	100
6 to <12 years	60 (60–60) ⁱ	200	30	90	1,000	50,000	30	100
12 years through adult	30 (4–50) ^j	100 ^j	10	50	—	50,000	20	60
a	Ranges are provided in parentheses, when applicable, and represent the range of means from the various studies. Ranges are not provided for age groups for which the recommendations are based on a single study.							
b	Includes soil and outdoor settled dust.							
c	Includes indoor settled dust only.							
d	Based on the average of the central tendency values from the various studies for each of the three methodologies (tracer, biokinetic modeling, activity pattern), averaged over the three methods. Recommendation for <6 months of age based on Wilson et al. (2013) (note that data for 0 to <7 months in Wilson et al. [2013] were used to represent the 0 to <6 months age group). Recommendations for children 6 months to <1 year based on the average of values from Hogan et al. (1998) and von Lindern et al. (2016). Recommendations for 1- to 2 year-olds and 2- to <6-year-olds based on von Lindern et al. (2016). Recommendations for children ages 1 to <6 years based on the average of values from Calabrese et al. (1989) as reanalyzed in Stanek and Calabrese 1995a (mean of the median values for the best 4 tracers for each child); Calabrese et al. (1997a) (average of the best tracer for each child); Calabrese et al. (1997b) (average of aluminum and silicon); Davis et al. (1990) as reanalyzed by Stanek and Calabrese, 1995a (mean of the median values for 3 tracers for each child); Hogan et al. (1998); Özkaynak et al. (2011); von Lindern et al. (2016); and Wilson et al. (2013). The recommendations for ages 12 years to adults are based on the average of data for teens (ages 12 to <20 years), adults, and seniors from Wilson et al. (2013) and on adults from Davis and Mirick (2006). All recommended values were rounded to one significant figure. See Table 5-34 for additional details.							
e	Based on the average of the 95 th percentile values from the various studies for each of the three methodologies (tracer, biokinetic modeling, activity pattern), averaged over the three methods. Based on the 95 th percentile values for the same studies as used for the central tendency estimates except for age 12 years through adults. Upper percentile recommendation for 12 years of age through adults based on the assumption that the ratio of the 95 th percentile to the mean value for adults is the same as the average of the ratios of 95 th percentiles to means for all other age groups (i.e., average ratio of the 95 th percentile to mean recommendations = 3.2). See Table 5-34 for additional details.							
f	Estimates of soil and dust were derived from the soil + dust values assuming 45% soil and 55% dust, rounded to one significant figure.							
g	Professional judgement based on: ATSDR (2001); Barnes (1990); Calabrese et al. (1997b, 1991, 1989); Stanek et al. (1998).							
h	Vermeer and Frate (1979).							
i	Range based on two studies with estimates of 55 and 56 mg/day; both of these estimates round to 60 mg/day.							
j	Soil + dust ingestion rates may be higher for adults following a traditional rural or wilderness lifestyle. Based on Doyle et al. (2012) and Irvine et al. (2014) the central tendency adult soil + dust ingestion rates is 50 mg/day (20 mg/day soil and 30 mg/day dust) and the upper percentile rate is 200 mg/day (90 mg/day soil and 100 mg/day dust).							
—	= No data.							

Table 5-2. Confidence in Recommendations for Ingestion of Soil and Dust^a		
General Assessment Factors	Rationale	Rating
Soundness <i>Adequacy of Approach</i> <i>Minimal (or defined) Bias</i>	<p>The methodologies have serious limitations. No single study captured all of the information needed (quantities ingested, frequency of high soil ingestion episodes, prevalence of high soil ingestion). Sample selection may have introduced some bias in the results (i.e., children near smelter or Superfund sites, volunteers in nursery schools). The total number of children in key studies were 241 (tracer studies; Calabrese et al., 1989; Davis et al., 1990; Calabrese et al., 1997a,b) and 2,599 (biokinetic modeling; Hogan et al., 1998; von Lindern et al., 2016). Modeled estimates were based on 1,000 simulated individuals (Özkaynak et al., 2011) or 200,000 trials (Wilson et al., 2013). Models may be sensitive to assumptions and the quality and availability of input variables. The response rates for in-person interviews and telephone surveys were often not stated in published articles. Only two key studies provided data for adults.</p> <p>Numerous sources of measurement error exist in the tracer element studies and the biokinetic model comparison studies. Some input variables for the modeled estimates are uncertain. Some of the assumptions used in the modeling studies may underestimate soil ingestion rates. Knowledge of soil and dust contamination may have affected the results of some of the studies.</p>	Low
Applicability and Utility <i>Exposure Factor of Interest</i> <i>Representativeness</i> <i>Currency</i> <i>Data Collection Period</i>	<p>The key tracer studies focused on the soil exposure factor, with little or no focus on the dust exposure factor. The biokinetic model comparison studies accounted for both soil and dust ingestion, but also addressed other factors (e.g., exposure via dietary intake, inhalation). The activity pattern studies focused on soil and dust ingestion.</p> <p>The study samples may not be representative of the United States in terms of race, ethnicity, socioeconomic, and geographical location; studies focused on specific areas. One key study was from Canada (Wilson et al., 2013), but some of the assumptions were derived from U.S. populations.</p> <p>Most of the tracer element studies were conducted in the 1980s and 1990s; activity pattern modeling studies are more recent; biokinetic modeling studies have more recent publication dates, but were generally based on older data.</p> <p>Tracer element studies' data collection periods may not represent long-term behaviors. Biokinetic model comparison and survey response studies represent longer term behaviors. Data used in modeled simulation estimates may not represent long-term behaviors.</p>	Low

Table 5-2. Confidence in Recommendations for Ingestion of Soil and Dust (Continued)		
General Assessment Factors	Rationale	Rating
Clarity and Completeness		Medium
<i>Accessibility</i>	All key studies are available from the peer-reviewed literature.	
<i>Reproducibility</i>	For methodologies used by more than one research group, reproducible results were obtained in some instances.	
<i>Quality Assurance</i>	For some studies, information on quality assurance/quality control was limited or absent.	
Variability and Uncertainty		Low
<i>Variability in Population</i>	Tracer element and activity pattern methodology studies characterized variability among study sample members; the IEUBK model used in the biokinetic approach uses average soil ingestion rates. Day-to-day and seasonal variability was not very well characterized. Numerous factors that may influence variability have not been explored in detail.	
<i>Minimal Uncertainty</i>	Estimates are highly uncertain. Tracer element study designs appear to introduce biases in the results. Modeled estimates may be sensitive to input variables.	
Evaluation and Review		Medium
<i>Peer Review</i>	All key studies appeared in peer-reviewed journals.	
<i>Number and Agreement of Studies</i>	14 key studies, but some key studies are reanalyses of previously published data. Researchers using similar methodologies obtained generally similar results. While there is general agreement between researchers using different methodologies, estimates based on the activity pattern methodology generally yield somewhat lower estimates than both the tracer and biokinetic modeling approaches.	
Overall Rating		Low
^a	See Section 1.5.2 in Chapter 1 of the <i>Exposure Factors Handbook: 2011 Edition</i> for a detailed description of the evaluation criteria used in this table.	

5.3. KEY AND RELEVANT STUDIES

The key tracer element, biokinetic model comparison, and survey response studies are summarized in the following sections. Certain studies were considered “key” and were used as a basis for developing the recommendations, using judgment about the study’s design features, applicability, and utility of the data to U.S. soil and dust ingestion rates, clarity and completeness, and characterization of uncertainty and variability in ingestion estimates. Because the studies often were performed for reasons unrelated to developing long-term soil and dust ingestion recommendations, their attributes that were characterized as “limitations” in this chapter might not be limitations when viewed in the context of the study’s original purpose. However, when studies are used for developing a soil or dust ingestion recommendation, EPA has categorized some studies’ design or implementation as preferable to others. In general, EPA chose studies designed either with a census or randomized sample approach over studies that used a convenience sample, or other nonrandomized approach, as well as studies that more clearly explained various factors in the study’s implementation that affect interpretation of the results. However, in some cases, studies that used a nonrandomized design contain information that is useful for developing exposure factor recommendations (e.g., if they are the only studies of children in a particular age category), and thus may have been designated as “key” studies. Other studies were considered “relevant” but not “key” because they provide useful information for evaluating the reasonableness of the data in the key studies or provide supporting information, but in EPA’s judgment they did not meet the same level of soundness, applicability and utility, clarity and completeness, and characterization of uncertainty and variability that the key studies did or they may not be representative of the U.S. general population. In addition, studies that did not contain information that can be used to develop a specific recommendation for mg/day soil and dust ingestion were classified as relevant rather than key. However, some studies classified as “relevant” may be used as the basis for recommendations for particular exposure settings (e.g., Doyle et al., 2012, Irvine et al., 2014 for populations engaging in rural or wilderness lifestyles).

Some studies are reanalyses of previously published data. For this reason, the sections that follow are organized into key and relevant studies of primary analysis (i.e., studies in which researchers

have developed primary data pertaining to soil and dust ingestion) and key and relevant studies of secondary analysis (i.e., studies in which researchers have interpreted previously published results, or data that were originally collected for a different purpose).

The three methodologies described in this chapter to derive soil and dust ingestion rates have limitations. Because some of these limitations apply equally to all the studies within each methodology, they are discussed in more detail in Section 5.4 separately from the study summaries. Additional limitations specific to each study are described within each study summary. The discussion of limitations does not imply that the studies were conducted inappropriately, rather they are limitations inherent in these methodologies.

5.3.1. Methodologies Used in Key Studies

5.3.1.1. Tracer Element Methodology

The tracer element methodology attempts to quantify the amounts of soil ingested by analyzing samples of soil and dust from residences and/or children’s play areas, and feces or urine. The soil, dust, fecal, and urine samples are analyzed for the presence and quantity of tracer elements—typically, aluminum, silicon, titanium, and other elements. A key underlying assumption is that these elements are not metabolized into other substances in the body or absorbed from the gastrointestinal tract in significant quantities, and thus their presence in feces and urine can be used to estimate the quantity of soil ingested by mouth. Although they are sometimes called mass balance studies, none of the studies attempt to quantify amounts excreted in perspiration, tears, glandular secretions, or shed skin, hair, or finger- and toenails, nor do they account for tracer element exposure via the dermal or inhalation routes, and thus they are not a complete “mass balance” methodology. Early studies using this methodology did not always account for the contribution of tracer elements from nonsoil substances (food, medications, and nonfood sources such as toothpaste) that might be swallowed. U.S. studies using this methodology in or after the mid to late 1980s account for, or attempt to account for, tracer element contributions from these nonsoil sources. Some study authors adjust their soil ingestion estimate results to account for the potential contribution of tracer elements found in household dust as well as soil.

Empirical estimates of soil ingestion rates in children have been made by back-calculating the

mass of soil and/or dust a subject would need to ingest to achieve a tracer element mass measured in collected excreta (i.e., feces and urine). The following is a general expression for the trace element (“tracer”) mass balance:

$$M_{\text{ingested in soil}} = M_{\text{feces+urine}} - M_{\text{non-soil or dust}}$$

(Eqn. 5-1)

where:

$M_{\text{ingested in soil}}$ = mass of tracer in soil or dust that is ingested (mg)
 $M_{\text{feces + urine}}$ = mass of tracer measured in feces and urine (mg)
 $M_{\text{nonsoil or dust}}$ = mass of tracer measured in nonsoil or dust (e.g., food, water, medicine, toothpaste) (mg)

Dividing the mass of tracer in soil or dust that is ingested by the measured tracer concentration in soil (mg/g) yields an estimate of the mass of soil ingested, S (g):

$$S = \frac{M_{\text{ingested in soil}}}{C_{\text{soil or dust}}}$$

where:

S = mass of soil or dust ingested (g)
 $C_{\text{soil or dust}}$ = concentration of tracer in soil or dust (mg/g)

(Eqn. 5-2)

The U.S. tracer element researchers have all assumed a certain offset, or lag time between ingestion of food, medication, and soil, and the resulting fecal and urinary output. The lag times used are typically 24 or 28 hours (Davis and Mirick, 2006; Stanek et al., 2001a; Stanek and Calabrese, 1995b); thus, these researchers subtract the previous day’s food and medication tracer element quantity ingested from the current day’s fecal and urinary tracer element quantity that was excreted. When compositing food, medication, fecal, and urine samples across the entire study period, daily estimates can be obtained by dividing the total estimated soil ingestion by the number of days in which fecal and/or urine samples were collected. A variation of the algorithm that provides slightly higher estimates of soil ingestion is to divide the total

estimated soil ingestion by the number of days on which feces were produced, which by definition would be equal to or less than the total number of days of the study period’s fecal sample collection.

Substituting tracer element dust concentrations for tracer element soil concentrations yields a dust ingestion estimate. Because the actual nonfood, nonmedication quantity ingested is a combination of soil and dust, the unknown true soil and dust ingestion is likely to be somewhere between the estimates based on soil concentrations and those based on dust concentrations. Tracer element researchers have described ingestion estimates for soil that actually represent a combination of soil and dust, but were calculated based on tracer element concentrations in soil. Similarly, they have described ingestion estimates for dust that are actually for a combination of soil and dust, but were calculated based on tracer element concentrations in dust. Other variations on these general soil and dust ingestion algorithms have been published in attempts to account for time spent indoors, time spent away from the house, and other factors that might influence the relative proportion of soil versus dust.

Each individual’s soil and dust ingestion can be represented as an unknown constant in a set of simultaneous equations of soil or dust ingestion represented by different tracer elements. To date, only two of the U.S. research teams (Lásztity et al., 1989; Barnes, 1990) have published estimates calculated for pairs of tracer elements using simultaneous equations.

The U.S. tracer element studies have been performed for only short-duration study periods, and only for 33 adults (Davis and Mirick, 2006) and 241 children (101 in Davis et al. [1990], 12 of whom were studied again in Davis and Mirick [2006]; 64 in Calabrese et al. [1989] and Barnes [1990]; 64 in Calabrese et al. [1997a]; and 12 in Calabrese et al. [1997b]). The studies provide information on quantities of soil and dust ingested for the studied groups for short time periods, but provide limited information on overall prevalence of soil ingestion by U.S. adults and children, and limited information on the frequency of higher soil ingestion episodes.

While there are advantages to using the tracer method (e.g., estimates are provided based on empirical data vs. modeling; direct measurements), there are also sources of uncertainty associated with this method. For example, error sources sometime cause individual soil or dust ingestion estimates for some tracers to be negative, and in some studies, this resulted in median or mean “mass balance” soil ingestion estimates that were also negative for some tracers. Authors of these studies have averaged both

negative and positive numbers together in their estimation of soil ingestion rates. For soil and dust ingestion estimates based on each particular tracer, or averaged across tracers, the net impact of competing upward and downward sources of error is unclear. Other sources of error can influence the estimates in an upward direction (e.g., not accounting for all nonsoil/dust sources of the tracer elements). A more detailed discussion of the uncertainties and limitations associated with the tracer method is provided in Section 5.4.1.

5.3.1.2. Biokinetic Model Comparison Methodology

The Biokinetic Model Comparison methodology compares direct measurements of a biomarker, such as blood or urine levels of a toxicant, with predictions from a biokinetic model of oral, dermal, and inhalation exposure routes with air, food, water, soil, and dust toxicant sources. An example is to compare measured children's blood lead levels with predictions from the IEUBK model. Where environmental contamination of lead in soil, dust, and drinking water has been measured and those measurements can be used as model inputs for the children in a specific community, the model's assumed soil and dust ingestion values can be evaluated by comparing the model's predictions of blood lead levels with those children's measured blood lead levels. It should be noted, however, that such confirmation of the predicted blood lead levels would be confirmation of the net impact of all model inputs, and not just soil and dust ingestions. Under the assumption that (actual) blood lead levels of various groups of children studied were accurately measured, and those measured blood lead levels are consistent with biokinetic model predictions for those groups of children, then the model's default assumptions may correspond to the central tendency, or typical, children in an assessed group of children. Nevertheless, the model's default assumptions for biokinetics and intake rates can be useful for predicting outcomes for highly exposed children if the higher exposure occurs as increased concentrations in the relevant media, and if the default population variability is relevant for the group of children under consideration. Use of the IEUBK in this way assumes that blood lead can be used as a suitable biomarker for soil and dust ingestion. An advantage of this method is that it can be used to indirectly estimate long-term soil and dust intake. A detailed discussion on the limitations and uncertainties associated with this method is provided in Section 5.4.2.

5.3.1.3. Activity Pattern Methodology

The activity pattern methodology combines information on hand-to-mouth and object-to-mouth activities (microactivities) and time spent at various locations (microenvironments) with assumptions about transfer parameters (e.g., soil-to-skin adherence, saliva removal efficiency) and other exposure factors (e.g., frequency of hand washing) to derive estimates of soil and dust ingestion. This methodology has been used in U.S. EPA's stochastic human exposure and dose simulation (SHEDS) model. The SHEDS model is a probabilistic model that can simulate cumulative (multiple chemicals) or aggregate (single chemical) residential exposures for a population of interest over time via multiple routes of exposure for different types of chemicals and scenarios, including those involving soil ingestion (U.S. EPA, 2010).

The activity pattern methodology includes observational studies as well as surveys of adults, children's caretakers, or children themselves, via in-person or mailed questionnaires that ask about mouthing behavior and ingestion of various nonfood items and time spent in various microenvironments. There are three general approaches to gather data on children's mouthing behavior: real-time hand recording, in which trained observers manually record information (Davis et al., 1995); video-transcription, in which trained videographers tape a child's activities and subsequently extract the pertinent data manually or with computer software (Black et al., 2005); and questionnaire, or survey response, techniques (Stanek et al., 1998).

An advantage of this method is that it does not require collection of biologic samples. Also, soil and dust ingestion can be estimated separately. One of the limitations of this approach includes the availability and quality of the input variables. Özkaynak et al. (2011) found that the model is most sensitive to dust loadings on carpets and hard floor surfaces, soil-to-skin adherence factors, hand mouthing frequency, and hand washing frequency (Özkaynak et al., 2011). A detailed discussion of the limitations and uncertainties associated with this method is provided in Section 5.4.3.

5.3.2. Key Studies of Primary Analysis

The sections that follow provide summaries of key studies in which researchers have developed primary data pertaining to soil and dust ingestion.

5.3.2.1. Vermeer and Frate (1979)—Geophagia in Rural Mississippi: Environmental and Cultural Contexts and Nutritional Implications

Vermeer and Frate (1979) performed a survey response study in Holmes County, MS in the 1970s (date unspecified). Questions about geophagy (defined as regular consumption of clay over a period of weeks) were asked of household members ($N = 229$ in 50 households; 56 were women, 33 were men, and 140 were children or adolescents) of a subset of a random sample of nutrition survey respondents. Caregiver responses to questions about 115 children under 13 years old indicate that geophagy was likely to be practiced by a minimum of 18 (16%) of these children; however, 16 of these 18 children were 1 to 4 years old, and only 2 of the 18 were older than 4 years. Of the 56 women, 32 (57%) reported eating clay. There was no reported geophagy among 33 men or 25 adolescent study subjects questioned.

In a separately administered survey, geophagy and pica data were obtained from 142 pregnant women over a period of 10 months. Geophagy was reported by 40 of these women (28%), and an additional 27 respondents (19%) reported other pica behavior, including the consumption of laundry starch, dry powdered milk, and baking soda.

The average daily amount of clay consumed was reported to be about 50 grams, for the adult and child respondents who acknowledged practicing geophagy. Quantities were usually described as either portions or multiples of the amount that could be held in a single, cupped hand. Clays for consumption were generally obtained from the B soil horizon, or subsoil rather than an uppermost layer, at a depth of 50 to 130 cm.

5.3.2.2. Calabrese et al. (1989)—How Much Soil Do Young Children Ingest: An Epidemiologic Study/Barnes (1990)—Childhood Soil Ingestion: How Much Dirt Do Kids Eat?/Calabrese et al. (1991)—Evidence of Soil Pica Behavior and Quantification of Soil Ingested

Calabrese et al. (1989) and Barnes (1990) studied soil ingestion among children using eight tracer elements—aluminum, barium, manganese, silicon, titanium, vanadium, yttrium, and zirconium. A nonrandom sample of 1-, 2-, and 3-year-olds (30 males and 34 females) from the greater Amherst, MA area was studied, presumably in 1987. The children were predominantly from two-parent households where the parents were highly educated.

The study was conducted over a period of 8 days spread over 2 weeks. During each week, duplicate samples of food, beverages, medicines, and vitamins were collected on Monday through Wednesday, while excreta, excluding wipes and toilet paper, were collected for four 24-hour cycles running from Monday/Tuesday through Thursday/Friday. Soil and dust samples were also collected from the children's homes and play areas. Study participants were supplied with toothpaste, baby cornstarch, diaper rash cream, and soap with low levels of most of the tracer elements. Quality control of the analysis yielded recoveries between 88.1% and 100.2% for all tracers except zirconium, which had a low recovery.

Table 5-3 shows the published mean soil ingestion estimates ranging from -294 mg/day based on manganese to 459 mg/day based on vanadium, median soil ingestion estimates ranging from -261 mg/day based on manganese to 96 mg/day based on vanadium, and 95th percentile estimates ranged from 106 mg/day based on yttrium to $1,903$ mg/day based on vanadium. Maximum daily soil ingestion estimates ranged from $1,391$ mg/day based on zirconium to $7,281$ mg/day based on manganese. Dust ingestion estimates calculated using tracer concentrations in dust were often, but not always, higher than soil ingestions calculated using tracer concentrations in soil.

Data for the uppermost 23 subject-weeks (the highest soil ingestion estimates, averaged over the 4 days of excreta collection during each of the 2 weeks) were published in Calabrese et al. (1991). One child's soil pica behavior was estimated in Barnes (1990) using both the subtraction/division algorithm and the simultaneous equations method. On two particular days during the second week of the study period, the child's aluminum-based soil ingestion estimates were 19 g/day ($18,700$ mg/day) and 36 g/day ($35,600$ mg/day), silicon-based soil ingestion estimates were 20 g/day ($20,000$ mg/day) and 24 g/day ($24,000$ mg/day), and simultaneous-equation soil ingestion estimates were 20 g/day ($20,100$ mg/day) and 23 g/day ($23,100$ mg/day) (Barnes, 1990). By tracer, averaged across the entire week, this child's estimates ranged from approximately 10 to 14 g/day during the second week of observation, excluding zirconium, which presented limitations with the analytical protocol (Calabrese et al., 1991, see Table 5-4), and averaged 6 g/day across the entire study period. Additional information about this child's apparent ingestion of soil versus dust during the study period was published in Calabrese and Stanek (1992a).

5.3.2.3. Davis et al. (1990)—Quantitative Estimates of Soil Ingestion in Normal Children between the Ages of 2 and 7 Years: Population-Based Estimates Using Aluminum, Silicon, and Titanium as Soil Tracer Elements

Davis et al. (1990) used a tracer element technique to estimate soil ingestion among children. In this study, 104 children between the ages of 2 and 7 years were randomly selected from a three-city area in southeastern Washington State. Soil and dust ingestion was evaluated by analyzing soil and house dust, feces, urine, and duplicate food, dietary supplement, medication, and mouthwash samples for aluminum, silicon, and titanium. Data were collected for 101 of the 104 children during July, August, or September 1987. In each family, data were collected over a 7-day period, with 4 days of excreta sample collection. Dried soil samples were passed successively through a 20- and 60-mesh (850 and 250 µm, respectively; ASTM, 2017) stainless steel sieve. Participants were supplied with toothpaste with known tracer element content. In addition, information on dietary habits and demographics was collected to identify behavioral and demographic characteristics that influence soil ingestion rates among children. The amount of soil ingested on a daily basis was estimated using Equation 5-3:

$$S_{i,e} = \frac{(((DW_f + DW_p) \times E_f) + 2E_u) - (DW_{fd} \times E_{fd})}{E_{soil}} \quad (\text{Eqn. 5-3})$$

where:

- $S_{i,e}$ = soil ingested for child i based on tracer e (grams)
- DW_f = feces dry weight (grams)
- DW_p = feces dry weight on toilet paper (grams)
- E_f = tracer concentration in feces (µg/g)
- E_u = tracer amount in urine (µg)
- DW_{fd} = food dry weight (grams)
- E_{fd} = tracer concentration in food (µg/g)
- E_{soil} = tracer concentration in soil (µg/g)

The tracer amount in urine (E_u) was multiplied by a factor of 2 to account for the fact that parents were asked to collect half of the total daily urine output. The soil ingestion rates were corrected by adding the amount of tracer in vitamins and

medications to the amount of tracer in food and adjusting the food, fecal, and urine sample weights to account for missing samples. Food, fecal, and urine samples were composited over a 4-day period, and estimates for daily soil ingestion were obtained by dividing the 4-day composited tracer quantities by 4. Davis et al. (1990) reported that recoveries for most analyses were within the quality control limits, $\pm 20\%$ for laboratory samples and $\pm 25\%$ for the matrix spiked samples.

Soil ingestion rates were highly variable, especially those based on titanium. Mean daily soil ingestion estimates were 38.9 mg/day for aluminum, 82.4 mg/day for silicon, and 245.5 mg/day for titanium (see Table 5-5). Median values were 25.3 mg/day for aluminum, 59.4 mg/day for silicon, and 81.3 mg/day for titanium. The investigators also evaluated the extent to which differences in tracer concentrations in house dust and yard soil impacted estimated soil ingestion rates. The value used in the denominator of the soil ingestion estimate equation was recalculated to represent a weighted average of the tracer concentration in yard soil and house dust based on the proportion of time the child spent indoors and outdoors, using an assumption that the likelihood of ingesting soil outdoors was the same as that of ingesting dust indoors. The adjusted mean soil/dust ingestion rates were 64.5 mg/day for aluminum, 160.0 mg/day for silicon, and 268.4 mg/day for titanium. Adjusted median soil/dust ingestion rates were 51.8 mg/day for aluminum, 112.4 mg/day for silicon, and 116.6 mg/day for titanium. The authors also investigated whether nine behavioral and demographic factors could be used to predict soil ingestion. They found family income less than \$15,000/year and swallowing toothpaste to be predictors with silicon-based estimates, residing in one of the three cities to be a significant predictor with aluminum-based estimates, and washing the face before eating significant for titanium-based estimates.

5.3.2.4. Calabrese et al. (1997a)—Soil Ingestion Estimates for Children Residing on a Superfund Site

Calabrese et al. (1997a) estimated soil ingestion rates for children residing on a Superfund site using a methodology in which eight tracer elements were analyzed. The methodology used in this study is similar to that employed in Calabrese et al. (1989), except that rather than using barium, manganese, and vanadium as three of the eight tracers, the researchers replaced them with cerium, lanthanum,

and neodymium. A total of 64 children ages 1 to 4 years (36 males, 28 females) were selected for this study of the Anaconda, MT area. The study was conducted for seven consecutive days during September or September and October, apparently in 1992, shortly after soil was removed and replaced in some residential yards in the area. Duplicate samples of meals, beverages, and over-the-counter medicines and vitamins were collected over the 7-day period, along with fecal samples. In addition, soil and dust samples were collected from the children's home and play areas. Soil samples were sieved through a 2-mm nylon mesh. A subsample was ground and sieved using a 200-mesh (75 μ m; ASTM, 2017) screen. Dust samples were sieved to separate fine dust from larger pieces. Toothpaste containing nondetectable levels of the tracer elements, with the exception of silica, was provided to all of the children. Infants were provided with baby cornstarch, diaper rash cream, and soap, which were found to contain low levels of tracer elements.

Because of the high degree of intertracer variability, Calabrese et al. (1997a) also derived estimates based on the "best tracer methodology" (BTM). This BTM uses food:soil (F:S) tracer concentration ratios in order to correct for errors caused by misalignment of tracer input and outputs, ingestion of nonfood sources, and nonsoil sources (Stanek and Calabrese, 1995a). A low F:S ratio is desired because it minimizes transit time errors. The BTM did not use the results from cerium, lanthanum, and neodymium despite these tracers having low F:S ratios because the soil concentrations for these elements were found to be affected by particle size and more susceptible to source errors. Calabrese et al. (1997a) noted that estimates based on aluminum, silicon, and yttrium in this study may result in lower soil ingestion estimates than the true value because the apparent residual negative errors found for these three tracers for a large majority of subjects. It was noted that soil ingestion estimates for this population may be lower than estimates found by previous studies in the literature because of families' awareness of contamination from the Superfund site, which may have resulted in altered behavior.

Soil ingestion estimates were also examined based on various demographic characteristics. There were no statistically significant differences in soil ingestion based on age, sex, birth order, or house yard characteristics (Calabrese et al., 1997a). Although not statistically significant, soil ingestion rates were generally higher for females, children with lower birth number, children with parents employed as laborers, service professionals,

homemakers, unemployed, and children with pets (Calabrese et al., 1997a).

Table 5-6 shows the estimated soil and dust ingestion by each tracer element and by the BTM. Based on the best tracer, the mean soil ingestion rate was 65.5 mg/day.

5.3.2.5. Stanek et al. (1998)—Prevalence of Soil Mouthing/Ingestion among Healthy Children Aged One to Six/Calabrese et al. (1997b)—Soil Ingestion Rates in Children Identified by Parental Observation as Likely High Soil Ingesters

Stanek et al. (1998) conducted a survey response study using in-person interviews of parents of children attending well visits at three western Massachusetts medical clinics in August, September, and October of 1992. Of 528 children ages 1 to 7 years with completed interviews, parents reported daily mouthing or ingestion of sand and stones in 6%, daily mouthing or ingestion of soil and dirt in 4%, and daily mouthing or ingestion of dust, lint, and dustballs in 1%. Parents reported more than weekly mouthing or ingestion of sand and stones in 16%, more than weekly mouthing or ingestion of soil and dirt in 10%, and more than weekly mouthing or ingestion of dust, lint and dustballs in 3%. Parents reported more than monthly mouthing or ingestion of sand and stones in 27%, more than monthly mouthing or ingestion of soil and dirt in 18%, and more than monthly mouthing or ingestion of dust, lint, and dustballs in 6%.

Calabrese and colleagues performed a follow-up tracer element study (Calabrese et al., 1997b) for a subset ($N = 12$) of the Stanek et al. (1998) children (ages 1 to 3) whose caregivers had reported daily sand/soil ingestion ($N = 17$). The time frame of the follow-up tracer study relative to the original survey response study was not stated; the study duration was 7 days. Of the 12 children in Calabrese et al. (1997b), one exhibited behavior that the authors believed was clearly soil pica; Table 5-7 shows estimated soil ingestion rates for this child during the study period. Estimates ranged from -10 mg/day to 7,253 mg/day depending on the tracer. The mean soil ingestion rate for the pica child, using aluminum and silicon as tracers, is approximately 1,000 mg/day (rounded to one significant figure).

Table 5-8 presents the estimated average daily soil and dust ingestion estimates for the 12 children studied. Estimates calculated based on soil tracer element concentrations only for the 12 subjects ranged from -15 to 1,783 mg/day based on aluminum, -46 to 931 mg/day based on silicon, and

–47 to 3,581 mg/day based on titanium. Estimated average daily dust ingestion estimates ranged from –39 to 2,652 mg/day based on aluminum, –51 to 3,145 mg/day based on silicon, and –98 to 3,632 mg/day based on titanium. Quantities for soil and dust are presented separately and assume that the entire quantity of residual fecal tracers originates entirely from soil or dust. Calabrese et al. (1997b) questioned the validity of retrospective caregiver reports of soil pica on the basis of the tracer element results.

5.3.2.6. Davis and Mirick (2006)—Soil Ingestion in Children and Adults in the Same Family

Davis and Mirick (2006) calculated soil ingestion for children and adults in the same family using a tracer element approach. Data were collected one year after the Davis et al. (1990) study was conducted. Samples were collected and prepared for laboratory analysis and then stored for a 2-year period prior to tracer element quantification with laboratory analysis. Analytical recovery values for spiked samples were within the quality control limits of $\pm 25\%$. The 20 families in this study were a nonrandom subset of the 104 families who participated in the soil ingestion study by Davis et al. (1990). Data collection issues resulted in sufficiently complete data for only 19 of the 20 families consisting of a child participant from the Davis et al. (1990) study ages 3 to 7, inclusive, and a female and male parent or guardian living in the same house. Duplicate samples of all food and medication items consumed, and all feces excreted, were collected for 11 consecutive days. Urine samples were collected twice daily for 9 of the 11 days; for the remaining 2 days, attempts were made to collect full 24-hour urine specimens. Soil and house dust samples were also collected. Soil and dust samples were passed successively through a 20- and 60-mesh (850 and 250 μm , respectively, ASTM, 2017) stainless steel sieves. Only 12 children had sufficiently complete data for use in the soil and dust ingestion estimates.

Tracer elements for this study included aluminum, silicon, and titanium. Toothpaste was supplied for use by study participants. In addition, parents completed a daily diary of activities for themselves and the participant child for 4 consecutive days during the study period.

Table 5-9 shows soil ingestion rates for all three family member participants. The mean and median estimates for children for all three tracers ranged from 36.7 to 206.9 mg/day and 26.4 to 46.7 mg/day, respectively, and fall within the range of those

reported by Davis et al. (1990). Adult soil ingestion estimates ranged from 23.2 to 624.9 mg/day for mean values and from 0 to 259.5 mg/day for median values. This is based on 33 adults with complete food, excreta, and soil data. Adult soil ingestion estimates were more variable than those of children in the study regardless of the tracer. The authors believed that this higher variability may have indicated an important occupational contribution of soil ingestion in some, but not all, of the adults. As in previous studies, the soil ingestion estimates were the highest for titanium. Although toothpaste is a known source of titanium, the titanium content of the toothpaste used by study participants was not determined.

Only three of a number of behaviors examined for their relationship to soil ingestion were found to be associated with increased soil ingestion in this study:

- Reported eating of dirt (for children),
- Occupational contact with soil (for adults), and
- Hand washing before meals (for both children and adults).

Several typical childhood behaviors, however, including thumb-sucking, furniture licking, and carrying around a blanket or toy were not associated with increased soil ingestion for the participating children. Among both parents and children, neither nail-biting nor eating unwashed fruits or vegetables was correlated with increased soil ingestion. However, because duplicate food samples were used to “correct” for dietary intake of tracers, accounting for soil ingestion from eating unwashed fruits or vegetables was not possible. Although eating unwashed fruits or vegetables was not reflected in the soil ingestion estimates in this study, the authors noted that it is a behavior that could lead to soil ingestion. When investigating correlations within the same family, a child’s soil ingestion was not found to be associated with either parent’s soil ingestion, nor did the mother and father’s soil ingestion appear to be correlated.

5.3.3. Key Studies of Secondary Analysis

The following sections provide summaries of key studies of secondary analysis (i.e., studies in which researchers have interpreted previously published results, or data that were originally collected for a different purpose).

5.3.3.1. Calabrese and Stanek (1995)—Resolving Intertracer Inconsistencies in Soil Ingestion Estimation

Calabrese and Stanek (1995) explored sources and magnitude of positive and negative errors in soil ingestion estimates for children on a subject-week and trace element basis. Calabrese and Stanek (1995) identified possible sources of positive errors as follows:

- Ingestion of high levels of tracers before the start of the study and low ingestion during the study period and
- Ingestion of element tracers from a nonfood or nonsoil source during the study period.

Possible sources of negative bias were identified as follows:

- Ingestion of tracers in food that are not captured in the fecal sample either due to slow lag time or not having a fecal sample available on the final study day and
- Sample measurement errors that result in diminished detection of fecal tracers, but not in soil tracer levels.

The authors developed an approach that attempted to reduce the magnitude of error in the individual trace element ingestion estimates. Results from a previous study conducted by Calabrese et al. (1989) were used to quantify these errors based on the following criteria: (1) a lag period of 28 hours was assumed for the passage of tracers ingested in food to the feces (this value was applied to all subject-day estimates), (2) a daily soil ingestion rate was estimated for each tracer for each 24-hour day a fecal sample was obtained, (3) the median tracer-based soil ingestion rate for each subject-day was determined, and (4) negative errors due to missing fecal samples at the end of the study period were also determined. Also, upper- and lower-bound estimates were determined based on criteria formed using an assumption of the magnitude of the relative standard deviation presented in another study conducted by Stanek and Calabrese (1995b). Daily soil ingestion rates for tracers that fell beyond the upper and lower ranges were excluded from subsequent calculations, and the median soil

ingestion rates of the remaining tracer elements were considered the best estimate for that particular day. The magnitude of positive or negative error for a specific tracer per day was derived by determining the difference between the value for the tracer and the median value.

Table 5-10 presents the estimated magnitude of positive and negative error for six tracer elements in the children's study (conducted by Calabrese et al., 1989). The original nonnegative mean soil ingestion rates (see Table 5-3) ranged from a low of 21 mg/day based on zirconium to a high of 459 mg/day based on vanadium. The adjusted mean soil ingestion rate after correcting for negative and positive errors ranged from 97 mg/day based on yttrium to 208 mg/day based on titanium. Calabrese and Stanek (1995) concluded that correcting for errors at the individual level for each tracer element provides more reliable estimates of soil ingestion.

5.3.3.2. Stanek and Calabrese (1995a)—Soil Ingestion Estimates for Use in Site Evaluations Based on the Best Tracer Method

Stanek and Calabrese (1995a) recalculated soil ingestion rates for adults and children from two previous studies using data for eight tracers from Calabrese et al. (1989) and three tracers from Davis et al. (1990). Recalculations were performed using the BTM. This method selected the "best" tracer(s), by dividing the total amount of tracer in a particular child's duplicate food sample by tracer concentration in that child's soil sample to yield a (F:S) ratio. The F:S ratio was small when the tracer concentration in food was low compared to the tracer concentration in soil. Small F:S ratios were desirable because they lessened the impact of transit time error (the error that occurs when fecal output does not reflect food ingestion, due to fluctuation in gastrointestinal transit time) in the soil ingestion calculation.

For adults, Stanek and Calabrese (1995a) used data for eight tracers from the Calabrese et al. (1989) study to estimate soil ingestion by the BTM. The lowest F:S ratios were zirconium and aluminum and the element with the highest F:S ratio was manganese. For soil ingestion estimates based on the median of the lowest four F:S ratios, the tracers contributing most often to the soil ingestion estimates were aluminum, silicon, titanium, yttrium, vanadium, and zirconium. Using the median of the soil ingestion rates based on the best four tracer elements, the average adult soil ingestion rate was estimated to be 64 mg/day with a median of 87 mg/day. The 95th percentile soil ingestion

estimate was 142 mg/day. These estimates are based on 18 subject weeks for the 6 adult volunteers described in Calabrese et al. (1989).

The BTM used a ranking scheme of F:S ratios to determine the best tracers for use in the ingestion rate calculation. To reduce the impact of biases that may occur as a result of sources of fecal tracers other than food or soil, the median of soil ingestion estimates based on the four lowest F:S ratios was used to represent soil ingestion.

Using the lowest four F:S ratios for each individual child, calculated on a per-week ("subject-week") basis, the median of the soil ingestion estimates from the Calabrese et al. (1989) study most often included aluminum, silicon, titanium, yttrium, and zirconium. Table 5-11 presents the soil ingestion estimates based on the median values for aluminum, silicon, and titanium for each child; the median of the best four tracers for each child, and the best tracer for each child. Based on the median of soil ingestion estimates from the best four tracers, the mean soil ingestion rate for children was 132 mg/day and the median was 33 mg/day. The 95th percentile value was 154 mg/day.

For the 101 children in the Davis et al. (1990) study, the mean soil ingestion rate was 69 mg/day and the median soil ingestion rate was 44 mg/day (see Table 5-11). The 95th percentile estimate was 246 mg/day. These data are based on the three tracers (i.e., aluminum, silicon, and titanium) from the Davis et al. (1990) study. When the results for the 128 subject-weeks in Calabrese et al. (1989) and 101 children in Davis et al. (1990) were combined, soil ingestion for children was estimated to be 104 mg/day (mean); 37 mg/day (median); and 217 mg/day (95th percentile), using the BTM.

5.3.3.3. Hogan et al. (1998)—Integrated Exposure Uptake Biokinetic Model for Lead in Children: Empirical Comparisons with Epidemiologic Data

Hogan et al. (1998) used the IEUBK model, to compare model predictions of blood lead levels with epidemiological data to serve as one component of the model validation. Environmental lead measurement data from 478 children (38 were 0.5 to <1 year; 440 were 1 to <7 years) across three epidemiological studies were used as input to the IEUBK model. Model results were compared to blood lead levels from the same children. These children were a subset of the entire population of children living in three historic lead smelting communities (Palmerton, PA; Madison County, IL;

and southeastern Kansas/southwestern Missouri), whose environmental lead exposures (soil and dust lead levels) had been studied as part of public health evaluations in these communities. The study populations were, in general, random samples of children 6 months to 7 years of age. Children who had lived in their residence for less than 3 months or those reported by their parents to be away from home more than 10 hours per week (>20 hours/week for the Pennsylvania data set) were excluded due to lack of information regarding lead exposure at the secondary location. The nature of the soil and dust exposures for the residential study population were typical, with the sample size considered sufficiently large to ensure that a wide enough range of children's behavior would be spanned by the data. Comparisons were made for a number of exposure factors, including age, location, time spent away from home, time spent outside, and whether or not children took food outside to eat.

The IEUBK model is a biokinetic model for predicting children's blood lead levels that uses measurements of lead content in house dust, soil, drinking water, food, and air. Model users use default assumptions for the lead contents and intake rates for each exposure medium (including soil) when they do not have specific information for each child.

Hogan et al. (1998) compared children's measured blood lead levels with biokinetic model predictions (IEUBK version 0.99d) of blood lead levels, using the children's measured drinking water, soil, and dust lead contamination levels together with default IEUBK model inputs for soil and dust ingestion, relative proportions of soil and dust ingestion, lead bioavailability from soil and dust, and other model parameters. Thus, the default soil and dust ingestion rates, and other default assumptions in the model, were tested by comparing measured blood lead levels with the model's predictions for those children's blood lead levels. Most IEUBK model kinetic and intake parameters were drawn independently from published literature (White et al., 1998; U.S. EPA, 1994b). Elimination parameters in particular had relatively less literature to draw upon (few data in children) and were fixed through a calibration exercise using a data set with children's blood lead levels paired with measured environmental lead exposures in and around their homes, while holding the other model parameters constant.

Results for all community-wide children 6 months to 7 years of age were as follows: for Palmerton, PA ($N = 34$), the geometric mean measured blood lead levels (6.8 µg/dL) were slightly over-predicted by the model (7.5 µg/dL); for

southeastern Kansas/southwestern Missouri ($N = 111$), the blood lead levels ($5.2 \mu\text{g/dL}$) were slightly under-predicted ($4.6 \mu\text{g/dL}$), and for Madison County, IL ($N = 333$), the geometric mean measured blood lead levels matched the model predictions ($5.9 \mu\text{g/dL}$ measured and predicted), with very slight differences in the 95% confidence interval. Geometric mean model predictions were within $1 \mu\text{g/dL}$ of the observed geometric mean blood lead levels in the three populations studied. Hogan et al. (1998) noted that results may vary depending on the ability to identify children's playing areas and the use of different environmental sampling methods. In addition, interactions between socioeconomic status, race, and sex can vary across communities and make generalizations of results difficult. For 31 children 6 to 12 months old in the Madison County, IL site only, Hogan et al. (1998) reported a predicted geometric mean blood lead level 1.4-fold higher than the geometric mean blood lead levels observed.

Default soil and dust ingestion rates used in this version of the IEUBK model were: 135 mg/day for 1-, 2-, and 3-year-olds; 100 mg/day for 4-year-olds; 90 mg/day for 5-year-olds; and 85 mg/day for 6-year-olds (U.S. EPA 1994b, 2007). These values represent mean soil and dust ingestion rates; distributional data are not used in the model. The time-averaged daily soil + dust ingestion rate for these 6 years of life was 113 mg/day. Hogan et al. (1998) did not provide information on the particle sizes of the soil analyzed for this study. Because particle size may be an important factor in estimating the concentrations of elements in soil, this adds uncertainties to the results. Regardless of this and other uncertainties, these results suggest that the combination of assumptions used as model input parameters, including soil and dust ingestion rates, are roughly accurate for 440 1- to <7-year-old children in the three locations studied.

5.3.3.4. Özkaynak et al. (2011)—Modeled Estimates of Soil and Dust Ingestion Rates for Children

Özkaynak et al. (2011) developed soil and dust ingestion rates for children 3 to <6 years of age using U.S. EPA's SHEDS model for multimedia pollutants (SHEDS-Multimedia). The authors had two main objectives for this research: (1) to demonstrate an application of the SHEDS model while identifying and quantifying the key factors contributing to the predicted variability and uncertainty in the soil and dust ingestion exposure estimates and (2) to compare the modeled results to existing tracer-element field

measurements. The SHEDS model is a physically based probabilistic exposure model, which combines diary information on sequential time spent in different locations and activities drawn from EPA's Consolidated Human Activity Database (CHAD), with micro-activity data (e.g., hand-to-mouth frequency, hand-to-surface frequency), surface/object soil or dust loadings, and other exposure factors (e.g., soil-to-skin adherence, saliva removal efficiency). The SHEDS model generates simulated individuals, who are then followed through time, generally up to one year. The model computes changes to their exposure at the diary event level.

For this study, an indirect modeling approach was used in which soil and dust were assumed to first adhere to the hands and remain until washed off or ingested by mouthing. The object-to-mouth pathway for soil/dust ingestion was also addressed. For this application of the SHEDS model, however, other avenues of soil/dust ingestion were not considered. Outdoor matter was designated as "soil" and indoor matter as "dust." Estimates for the distributions of exposure factors such as activity, time outdoors, environmental concentrations, soil-skin and dust-skin transfer, hand washing frequency and efficiency, hand-mouthing frequency, area of object or hand mouthed, mouthing removal rates, and other variables were obtained from the literature. These input variables were used in this SHEDS model application to generate estimates of soil and dust ingestion rates for a simulated population of 1,000. Both sensitivity and uncertainty analyses were conducted. Based on the sensitivity analysis, the model results are the most sensitive to dust loadings on carpet and hard floor surfaces, soil-skin adherence factor, hand mouthing frequency, and mean number of hand washes per day. Based on 200 uncertainty simulations that were conducted, the modeling uncertainties were seen to be asymmetrically distributed around the 50th (median) or the central variability distribution.

Table 5-12 shows the predicted soil and dust ingestion rates. Mean total soil and dust ingestion was predicted to be 68 mg/day, with approximately 60% originating from soil ingestion, 30% from dust on hands, and 10% from dust on objects. It is important to note that this is different from the assumptions used in the IEUBK model of 55% dust and 45% soil. Hand-to-mouth soil ingestion was found to be the most important pathway, followed by hand-to-mouth dust ingestion, then object-to-mouth dust ingestion. The authors noted that these modeled estimates were found to be consistent with other soil/dust ingestion values in the literature, but

slightly lower than the central tendency value of 100 mg/day recommended in EPA's *Child-Specific Exposure Factors Handbook* (U.S. EPA, 2008).

The SHEDS methodology can be applied to specific study populations of interest, a wide range of input parameters, and can generate a full range of distributions. One advantage of this methodology is that it produced both ingestion of soil and ingestion of dust. However, data for some of the input variables are lacking. Data needs include additional information on the activities and environments of children in younger age groups, including children with high hand-to-mouth, object-to-mouth, and pica behaviors, and information on skin adherence and dust loadings on indoor objects and floors, and information to evaluate temporal variability. Assumptions used, particularly for the transfer of dust from both bare floors and carpets to hands and soil loadings to hands while playing outdoors, may be considered low for these parameters compared to other experimental data available. The model also assumes that the same hand area is mouthed on each occasion, which may lead to lower dust intake rates. In addition, other age groups of interest were not included because of lack of data for some of the input variables.

5.3.3.5. *Wilson et al. (2013)—Revisiting Dust and Soil Ingestion Rates Based on Hand-to-Mouth Transfer*

Wilson et al. (2013) provided estimates of the ingestion rates of indoor dust and outdoor soil for Canadians using both deterministic and probabilistic methods. An indirect modeling approach was used. Based on data from multiple studies, Wilson et al. (2013) estimated dust and soil ingestion using measures of particle loading to indoor surfaces, the fraction transferred to the hands, hand surface areas, the fraction of hand surface area that may be mouthed or contact food, the frequency of hand-to-mouth contacts, the amount dissolved in saliva, and the exposure time. The following equations were used to estimate indoor dust and outdoor soil ingestion, respectively:

$$DIG = DSL \times FTSS \times SA_{hand} \times FSA_{fingers} \times FQ \times SE \times ET$$

(Eqn. 5-4)

and

$$SIR = SL_{hands} \times SA_{hand} \times FSA_{fingers} \times FQ \times SE \times ET$$

(Eqn. 5-5)

where:

<i>DIG</i>	=	dust ingestion rate (mg/day)
<i>DSL</i>	=	dust surface loading (mg/cm ²)
<i>ET</i>	=	exposure time (hours/day)
<i>FQ</i>	=	frequency of hand-to-mouth events (events/hour)
<i>FSA_{fingers}</i>	=	fractional surface area of hand mouthed
<i>FTSS</i>	=	fraction of dust transferred from surfaces to the skin
<i>SA_{hand}</i>	=	surface area of one hand (cm ²)
<i>SE</i>	=	saliva extraction factor (unitless)
<i>SIR</i>	=	soil ingestion rate (mg/day)
<i>SL_{hands}</i>	=	soil loading (mass of soil adhering to hands) (mg/cm ²)

The input parameters used in these equations are provided in Table 5-13. For FTSS, it was assumed that contact occurred with hard surfaces (e.g., nonporous floor surfaces such as tile or hardwood, countertops, tables, window sills) 50% of the time and with soft surfaces (e.g., carpets, sofas, beds) 50% of the time, except for infants for whom contact was assumed to occur with soft surfaces only (i.e., 100% of the time). In addition, it was assumed that the front surface of the four fingers and the thumb of one hand was the area mouthed.

Mean dust ingestion rates were similar within age groups when using either the deterministic or probabilistic approach based on 200,000 trials (see Table 5-14), ranging from 2.2 mg/day for teenagers (ages 12 to 19 years) to 41 mg/day for toddlers (ages 7 months to 4 years). Mean soil ingestion rates ranged from 1.2 mg/day for seniors (ages 60+ years) to 23 mg/day for children (ages 5 to 11 years) using the probabilistic approach (see Table 5-14). Mean soil ingestion rates using the deterministic approach were similar. Combined dust and soil ingestion rates ranged from 3.7 mg/day for teenagers (ages 12 to 19 years) to 61 mg/day for toddlers (ages 7 months to 4 years). The 95th percentile combined soil and dust ingestion rates ranged from 12.6 mg/day for teenagers to 204 mg/day for toddlers.

Ingestion rates were estimated for a wide range of age groups, and separate ingestion estimates were provided for both dust and soil. However, the study used input values from multiple studies to generate the dust and soil ingestion rates, and each individual study is expected to have its own shortcomings, which also apply to this analysis. Some of these limitations include uncertainties with regard to the methodologies for dust collection in hard and soft surfaces in the studies selected for the analysis,

assumptions of a single hand contact with surfaces, assumptions about the parts of the hand mouthed, and not accounting for effects of soil and hand moisture on soil and dust loadings on the skin. Also, the model does not account for object-to-mouth contact. Many of these assumptions used by Wilson et al. (2013) in the model would tend to underestimate amount of soil and dust ingested.

5.3.3.6. Von Lindern et al. (2016)—Estimating Children's Soil/Dust Ingestion Rates through Retrospective Analyses of Blood Lead Biomonitoring from the Bunker Hill Superfund Site in Idaho

Von Lindern et al. (2016) conducted an analysis to estimate age-specific soil/dust ingestion rates using the IEUBK model for lead in children and soil and house dust lead bioavailability data from the Bunker Hill Mining and Metallurgical Complex Superfund Site in Idaho. A total of 271 soil/dust samples archived during 1986–2002, including 193 house dust samples, 73 yard soil samples, and 5 quality control samples, were retrieved from storage. The samples were matched with blood lead data and information on the child's age and sex, home location, and property remediation status. After sieving to 80-mesh (180 µm; ASTM, 2017), they were analyzed for total lead and in vitro bioaccessibility. In vivo relative and absolute bioavailability was calculated from in vitro bioaccessibility results. A total of 2,176 records of blood/soil/dust/lead concentrations were available.

Structural equations modeling (SEM), which is a statistical multivariate methodology, was used to determine soil and dust partitions, age-specific soil and dust intake rates, and lead uptake from sources other than soil and dust (i.e., air, diet, and water). Von Lindern et al. (2016) calculated the total lead uptake by dividing the measured blood lead levels (µg/L) by the age-specific biokinetic slope factors in the IEUBK model. Total lead uptake is the sum of the uptakes from the four components: air, water, diet, and soil/dust. Soil and dust intake rates were calculated by assigning partition coefficients (i.e., fractional contributions to total soil/dust ingestion by each source) using Equation 5-6.

$$IR_{sd} = 1,000 \times \{UP_{sd} / [(C_d \times PT_d \times ABS_d) + (C_{ys} \times PT_{ys} \times ABS_{ys}) + (C_{cs} \times PT_{cs} \times ABS_{cs}) + (C_{ns} \times PT_{ns} \times ABS_{ns})]\}$$

(Eqn. 5-6)

where:

IR_{sd} = soil/dust intake rate (mg/day)
 UP_{sd} = uptake from soil/dust (µg/day)
 C = concentration from the various sources (i.e., d = dust; ys = yard soil; cs = community soil; ns = neighborhood soil) (mg/kg)
 PT = partition coefficient for the various sources (unitless)
 ABS = absolute bioavailability for the various sources (unitless)

Soil and dust intake rates were calculated for four source partition (PT) scenarios: (1) the IEUBK model default of 55% dust and 45% soil (55/45); (2) the original Bunker Hill Superfund Site model of 40% dust, 30% yard soil, and 30% geometric mean community soil (40/30/30GM); (3) the same partition as in scenario 2, but using the arithmetic mean (40/30/30AM); and (4) the SEM using 50% dust, 25% yard soil, 10% neighborhood soil, and 15% community soil (50/25/10/15). Mean soil and dust absolute bioavailability (ABS) was estimated to be 33% (SD ± 4%) and 28% (SD ± 6%), respectively. These values are similar to the 30% value recommended in the IEUBK model as a default.

Central tendency age-specific soil and dust intake rates for the four partition scenarios were estimated using Equation 5-5, and are presented in Table 5-15. All partition scenarios produced similar central tendency intake rates (von Lindern et al., 2016). For children ages 0.5 to 9 years, the mean soil and dust ingestion rates ranged from 47 mg/day to 100 mg/day. Among the age groups evaluated, children ages 1 to <2 years had the highest mean soil and dust ingestion rates (i.e., 89–100 mg/day), and children older than 2 years, had estimated soil and dust ingestion rates averaging approximately 60 mg/day. Age-specific distributions of soil and dust intake rates for the four partition scenarios are shown in Table 5-16. The 95th percentile soil and dust intake rates ranged from 120 mg/day to 493 mg/day. The 55/45 partition scenario consistently produced higher 95th percentile soil and dust intake rates compared to the other scenarios. These age specific soil/dust intake rates were input to the IEUBK model to compare predicted and observed blood lead levels (von Lindern et al., 2016). Linear regression analyses indicated that the 50/25/10/15 and the 40/30/30 average intake rates were the partition scenarios that best fit the blood lead levels predicted by the IEUBK model to the observed blood lead levels. The data from these two

partition scenarios were used in developing the recommended soil and dust ingestion values shown in Tables 5-1 and 5-34.

This study provides soil and dust intake rates for various age groups including very young children. Blood lead data were collected for a number of consecutive years. The strengths of this study are that the soil and dust ingestion estimates are based on a large number of samples, and that the estimates represent long-term exposures. One of the limitations of this study is that partition coefficients that were derived may not be representative of all age groups, all neighborhoods in the study, or other populations. Partition of soil and dust materials contributing to an individual child's lead uptake can be expected to vary strongly among residences and among children. The authors also acknowledged that education and intervention programs may have resulted in children's temporary reduction in soil/dust ingestion rates at this site (von Lindern et al., 2016). Increased knowledge and concern about lead exposure may lead to residents taking steps to reduce their child's lead exposure through more frequent hand washing, more household vacuuming, and changing the areas where children play. This is evidenced by a decline in the estimated average ingestion rates from 1988 to 2002 when the analysis was performed for the different partition scenarios by year. Other uncertainties include not accounting for the variability in the children's blood lead levels with time, a limited number of soil and dust measurements, the representativeness of the soil and dust measurements of the children's play areas, and measurement error. In addition, the equations derived by von Lindern et al. (2016) for the analysis would be highly sensitive to low lead media concentrations and less sensitive to higher lead concentrations.

5.3.4. Relevant Studies of Primary Analysis

The following studies are classified as relevant rather than key. They either do not provide a quantitative estimate of soil ingestion, or they are estimates generated for a population that may not be representative of the U.S. general population. Studies that provide data for special populations such as those engaging in wilderness lifestyles in Canada (Doyle et al., 2012; Irvine et al., 2014) are presented in this section. Data from these studies may be appropriate for high soil contact scenarios. The general population tracer element studies described in this section are not designated as key because the methodology to account for nonsoil

tracer exposures (e.g., food, medicine) was not as well developed as the methodology in the U.S. tracer element studies described in Sections 5.3.2 and 5.3.3. However, the method of Clausen et al. (1987) and data of van Wijnen et al. (1990) were used in developing biokinetic model default soil and dust ingestion rates (U.S. EPA, 1994a) used in the Hogan et al. (1998) study and von Lindern et al. (2016), which were designated as key. In most cases, the survey response studies were of a nonrandomized design, provided insufficient information to determine important details regarding study design, or provided no data to allow quantitative estimates of soil and/or dust ingestion rates.

5.3.4.1. *Dickins and Ford (1942)—Geophagy (Dirt Eating) among Mississippi Negro School Children*

Dickins and Ford (1942) conducted a survey response study of rural Black school children (4th grade and above) in Oktibbeha County, MS in September 1941. A total of 52 of 207 children (18 of 69 boys and 34 of 38 girls) studied gave positive responses to questions administered in a test-taking format regarding having eaten dirt in the previous 10 to 16 days. The authors stated that the study sample likely was more representative of the higher socioeconomic levels in the community because older children from lower socioeconomic levels sometimes left school in order to work and because children in the lower grades, who were more socioeconomically representative of the overall community, were excluded from the study. Clay was identified as the predominant type of soil eaten.

5.3.4.2. *Ferguson and Keaton (1950)—Studies of the Diets of Pregnant Women in Mississippi: II Diet Patterns*

Ferguson and Keaton (1950) conducted a survey response study of a group of 361 pregnant women receiving health care at the Mississippi State Board of Health, who were interviewed regarding their diet, including the consumption of clay or starch. All of the women were from the lowest economic and educational level in the area, and 92% were Black. Of the Black women, 27% reported eating clay and 41% eating starch. In the group of White women, 7 and 10% reporting clay- and starch-eating, respectively. The amount of starch eaten ranged from 2–3 small lumps to 3 boxes (24 ounces) per day. The amount of clay eaten ranged from one tablespoon to one cup per day.

5.3.4.3. Cooper (1957)—*Pica: A Survey of the Historical Literature as Well as Reports from the Fields of Veterinary Medicine and Anthropology, the Present Study of Pica in Young Children, and a Discussion of Its Pediatric and Psychological Implications*

Cooper (1957) conducted a nonrandomized survey response study in the 1950s of children age 7 months or older referred to a Baltimore, MD mental hygiene clinic. For 86 out of 784 children studied, parents or caretakers gave positive responses to the question, “Does your child have a habit, or did he ever have a habit, of eating dirt, plaster, ashes, etc.?” and identified dirt, or dirt combined with other substances, as the substance ingested. Cooper (1957) described a pattern of pica behavior, including ingesting substances other than soil, being most common between ages 2 and 4 or 5 years, with one of the 86 children ingesting clay at age 10 years and 9 months.

5.3.4.4. Barltrop (1966)—*The Prevalence of Pica*

Barltrop (1966) conducted a randomized survey response study of children born in Boston, MA between 1958 and 1962, inclusive, whose parents resided in Boston and who were neither illegitimate nor adopted. A stratified random subsample of 500 of these children was contacted for in-person caregiver interviews, in which a total of 186 families (37%) participated. A separate stratified subsample of 1,000 children was selected for a mailed survey in which 277 (28%) of the families participated. Interview-obtained data regarding caregiver reports of pica (in this study is defined as placing nonfood items in the mouth and swallowing them) behavior in all children ages 1 to 6 years in the 186 families ($N = 439$) indicated 19 had ingested dirt (defined as yard dirt, house dust, plant-pot soil, pebbles, ashes, cigarette ash, glass fragments, lint, and hair combings) in the preceding 14 days. These data do not appear to have been corrected for unequal selection probability in the stratified random sample, nor were they corrected for nonresponse bias. Interviews were conducted in the March/April time frame, presumably in 1964. Mail-survey obtained data regarding caregiver reports of pica in the preceding 14 days indicated that 39 of 277 children had ingested dirt, presumably using the same definition as above. Barltrop (1966) mentions several possible limitations of the study, including nonparticipation bias and respondents’ memory, or recall, effects.

5.3.4.5. Bruhn and Pangborn (1971)—*Reported Incidence of Pica among Migrant Families*

Bruhn and Pangborn (1971) conducted a survey among 91 low income families of migrant agricultural workers in California in May through August 1969. Families in two labor camps (Madison camp, 10 miles west of Woodland, and Davis camp, 10 miles east of Davis) were of Mexican descent, and families in one camp (Harney Lane camp 17 miles north of Stockton) were “Anglo.” Participation was 34 of 50 families at the Madison camp, 31 of 50 families at the Davis camp, and 26 of 26 families at the Harney Lane camp. Respondents for the studied families (primarily wives) gave positive responses to open-ended questions such as “Do you know of anyone who eats dirt or laundry starch?” Bruhn and Pangborn (1971) apparently asked a modified version of this question pertaining to the respondents’ own or relatives’ families. They reported 18% (12 of 65) of Mexican families’ respondents as giving positive responses for consumption of “dirt” among children within the Mexican respondents’ own or relatives’ families. They reported 42% (11 of 26) of “Anglo” families’ respondents as giving positive responses for consumption of “dirt” among children within the Anglo respondents’ own or relatives’ families.

5.3.4.6. Robischon (1971)—*Pica Practice and Other Hand-Mouth Behavior and Children’s Developmental Level*

A survey response sample of 19- to 24-month-old children examined at an urban well-child clinic in the late 1960s or 1970 in an unspecified location indicated that 48 of the 130 children whose caregivers were interviewed, exhibited pica behavior (defined as “ate nonedibles more than once a week”). The specific substances eaten were reported for 30 of the 48 children. All except 2 of the 30 children habitually ate more than one nonedible substance. The soil and dust-like substances reported as eaten by these 30 children were: ashes (17), “earth” (5), dust (3), fuzz from rugs (2), clay (1), and pebbles/stones (1). Caregivers for some of the study subjects (between 0 and 52 of the 130 subjects, exact number not specified) reported that the children “ate nonedibles less than once a week.”

5.3.4.7. Bronstein and Dollar (1974)—*Pica in Pregnancy*

The frequency and effects of pica behavior was investigated by Bronstein and Dollar (1974) in 410 pregnant, low-income women from both urban

($N = 201$) and rural ($N = 209$) areas in Georgia. The women selected were part of the Nutrition Demonstration Project, a study investigating the effect of nutrition on the outcome of the pregnancy, conducted at the Eugene Talmadge Memorial Hospital and University Hospital in Augusta, GA. During their initial prenatal visit, each patient was interviewed by a nutrition counselor who questioned her food frequency, social and dietary history, and the presence of pica. Patients were categorized by age, parity, and place of residence (rural or urban).

Of the 410 women interviewed, 65 (16%) stated that they practiced pica. A variety of substances were ingested, with laundry starch being the most common. There was no significant difference in the practice of pica between rural and urban women, although older rural women (20–35 years) showed a greater tendency to practice pica than younger rural or urban women (<20 years). The number of previous pregnancies did not influence the practice of pica. The authors noted that the frequency of pica among rural patients had declined from a previous study conducted 8 years earlier, and attributed the reduction to a program of intensified nutrition education and counseling provided in the area. No specific information on the amount of pica substances ingested was provided by this study, and the data are more than 30 years old.

5.3.4.8. *Hook (1978)—Dietary Cravings and Aversions during Pregnancy*

Hook (1978) conducted interviews of 250 women who had each delivered a live infant at two New York hospitals; the interviews took place in 1975. The mothers were first asked about any differences in consumption of seven beverages during their pregnancy, and the reasons for any changes. They were then asked, without mentioning specific items, about any cravings or aversions for other foods or nonfood items that may have developed at any time during their pregnancy.

Nonfood items reportedly ingested during pregnancy were ice, reported by three women, and chalk from a river clay bank, reported by one woman. In addition, one woman reported an aversion to nonfood items (specific nonfood item not reported). No quantity data were provided by this study.

5.3.4.9. *Binder et al. (1986)—Estimating Soil Ingestion: The Use of Tracer Elements in Estimating the Amount of Soil Ingested by Young Children*

Binder et al. (1986) used a tracer technique modified from a method previously used to measure soil ingestion among grazing animals to study the ingestion of soil among children 1 to 3 years of age who wore diapers. The children were studied during the summer of 1984 as part of a larger study of residents living near a lead smelter in East Helena, MT. Fecal samples from diapers were collected over a 3-day period from 65 children (42 males and 23 females), and composited samples of soil were obtained from the children's yards. Both excreta and soil samples were analyzed for aluminum, silicon, and titanium. These elements were found in soil but were thought to be poorly absorbed in the gut and to have been present in the diet only in limited quantities. Excreta measurements were obtained for 59 of the children. Soil ingestion by each child was estimated on the basis of each of the three tracer elements using a standard assumed fecal dry weight of 15 g/day, and the following Equation 5-7:

$$T_{i,e} = \frac{f_{i,e} \times F_i}{S_{i,e}} \quad (\text{Eqn. 5-7})$$

where:

- $T_{i,e}$ = estimated soil ingestion for child i based on element e (g/day)
- $f_{i,e}$ = concentration of element e in fecal sample of child i (mg/g)
- F_i = fecal dry weight (g/day)
- $S_{i,e}$ = concentration of element e in child i 's yard soil (mg/g)

The analysis assumed that (1) the tracer elements were neither lost nor introduced during sample processing, (2) the soil ingested by children originates primarily from their own yards, and (3) that absorption of the tracer elements by the children occurred in only small amounts. The study did not distinguish between ingestion of soil and house dust, nor did it account for the presence of the tracer elements in ingested foods or medicines.

The arithmetic mean quantity of soil ingested by the children in the Binder et al. (1986) study was estimated to be 181 mg/day (range 25 to 1,324) based on the aluminum tracer, 184 mg/day (range 31

to 799) based on the silicon tracer, and 1,834 mg/day (range 4 to 17,076) based on the titanium tracer (see Table 5-17). The overall mean soil ingestion estimate, based on the minimum of the three individual tracer estimates for each child, was 108 mg/day (range 4 to 708). The median values were 121 mg/day, 136 mg/day, and 618 mg/day for aluminum, silicon, and titanium, respectively. The 95th percentile values for aluminum, silicon, and titanium were 584 mg/day, 578 mg/day, and 9,590 mg/day, respectively. The 95th percentile value based on the minimum of the three individual tracer estimates for each child was 386 mg/day.

The authors were not able to explain the difference between the results for titanium and for the other two elements, but they speculated that unrecognized sources of titanium in the diet or in the laboratory processing of stool samples may have accounted for the increased levels. The frequency distribution graph of soil ingestion estimates based on titanium in the Binder et al. (1986) paper (not provided here) shows that a group of 21 children had particularly high titanium values (i.e., >1,000 mg/day). The remainder of the children showed titanium ingestion estimates at lower levels, with a distribution more comparable to that of the other elements.

5.3.4.10. Clausing et al. (1987)—A Method for Estimating Soil Ingestion by Children

Clausing et al. (1987) conducted a soil ingestion study with Dutch children using a tracer element methodology. The study measured aluminum, titanium, and acid-insoluble residue (AIR) contents of fecal samples from children aged 2 to 4 years attending a nursery school, and for samples of playground dirt at that school. Over a 5-day period, 27 daily fecal samples were obtained for 18 children. Soil samples from the direct surroundings of the nursery school were sieved through a 250 µm screen. Using the average soil concentrations present at the school, and assuming a standard fecal dry weight of 10 g/day, soil ingestion was estimated for each tracer. Six hospitalized, bedridden children served as a control group, representing children who had very limited access to soil; eight daily fecal samples were collected from the hospitalized children.

Recoveries from analytical analyses ranged from 54–89% for titanium and aluminum. Without correcting for the tracer element contribution from background sources, represented by the hospitalized children's soil ingestion estimates, the aluminum-based soil ingestion estimates for the school children in this study ranged from 23 to

979 mg/day, the AIR-based estimates ranged from 48 to 362 mg/day, and the titanium-based estimates ranged from 64 to 11,620 mg/day. As in the Binder et al. (1986) study, a fraction of the children (6/18) showed titanium values above 1,000 mg/day, with most of the remaining children showing substantially lower values. Calculating an arithmetic mean quantity of soil ingested based on each fecal sample yielded 232 mg/day for aluminum; 129 mg/day for AIR, and 1,431 mg/day for titanium (see Table 5-18). Based on the limiting tracer method (LTM) and averaging across each fecal sample, the arithmetic mean soil ingestion was estimated to be 105 mg/day with a population standard deviation of 67 mg/day (range 23 to 362 mg/day); geometric mean soil ingestion was estimated to be 90 mg/day. Use of the LTM assumed that "the maximum amount of soil ingested corresponded with the lowest estimate from the three tracers" (Clausing et al., 1987).

The hospitalized children's arithmetic mean aluminum-based soil ingestion estimate was 56 mg/day; titanium-based estimates included estimates for three of the six children that exceeded 1,000 mg/day, with the remaining three children in the range of 28 to 58 mg/day (see Table 5-19). AIR measurements were not reported for the hospitalized children. Using the LTM method, the mean soil ingestion rate was estimated to be 49 mg/day with a population standard deviation of 22 mg/day (range 26 to 84 mg/day). The geometric mean soil ingestion rate was 45 mg/day. The hospitalized children's data suggested a major nonsoil source of titanium for some children and a background nonsoil source of aluminum. However, conditions specific to hospitalization (e.g., medications) were not considered.

Clausing et al. (1987) estimated that the average soil ingestion of the nursery school children was 56 mg/day, after subtracting the mean LTM soil ingestion for the hospitalized children (49 mg/day) from the nursery school children's mean LTM soil ingestion (105 mg/day), to account for background tracer intake from dietary and other nonsoil sources.

5.3.4.11. Van Wijnen et al. (1990)—Estimated Soil Ingestion by Children

In a tracer element study by Van Wijnen et al. (1990), soil ingestion among Dutch children ranging in age from 1 to 5 years was evaluated using a tracer element methodology. Van Wijnen et al. (1990) measured three tracers (titanium, aluminum, and AIR) in soil and feces. The authors estimated soil ingestion based on the LTM, which assumed that soil

ingestion could not be higher than the lowest value of the three tracers. LTM values represented soil ingestion estimates that were not corrected for dietary intake. Recoveries for aluminum and titanium from soil materials mixed with fecal samples were 94 and 97%, respectively.

An average daily feces dry weight of 15 grams was assumed. A total of 292 children attending daycare centers were studied during the first of two sampling periods and 187 children were studied in the second sampling period; 162 of these children were studied during both periods (i.e., at the beginning and near the end of the summer of 1986). A total of 78 children were studied at campgrounds. Soil samples were sieved through a 2-mm mesh. The authors reported geometric mean LTM values because soil ingestion rates were found to be skewed and the log-transformed data were approximately normally distributed. Geometric mean LTM values were estimated to be 111 mg/day for children in daycare centers and 174 mg/day for children vacationing at campgrounds (see Table 5-20). For the 162 daycare center children studied during both sampling periods the arithmetic mean LTM was 162 mg/day, and the median was 114 mg/day. For the 78 children at the campgrounds, the overall arithmetic mean LTM was 213 mg/day and the median was 160 mg/day.

Fifteen hospitalized children were studied and used as a control group. These children's LTM soil ingestion estimates were 74 (geometric mean), 93 (mean), and 110 (median) mg/day. The authors assumed the hospitalized children's soil ingestion estimates represented dietary intake of tracer elements, and used rounded 95% confidence limits on the arithmetic mean, 70 to 120 mg/day (midpoint 95 mg/day), to correct the daycare and campground children's LTM estimates for dietary intake of tracers. Although the authors suggested that corrections should be made to the soil ingestion values obtained from the daycare and campground subjects by subtracting values obtained from the hospitalized children (i.e., background), they do not appear to have made these adjustments to the arithmetic means. These corrections would result in soil ingestion rates of 67 mg/day (162 mg/day minus 95 mg/day) for daycare children and 118 mg/day (213 mg/day minus 95 mg/day) for campers. Van Wijnen et al. (1990) showed corrected geometric mean soil ingestion to range from 0 to 90 mg/day, with a 90th percentile value of up to 190 mg/day for the various age categories within the daycare group and 30 to 200 mg/day, with a 90th percentile value of up to 300 mg/day for the various age categories within the camping group.

AIR was the limiting tracer in about 80% of the samples. Among children attending daycare centers, soil ingestion was also found to be higher when the weather was good (i.e., <2 days/week precipitation) than when the weather was bad (i.e., >4 days/week precipitation) (see Table 5-21).

5.3.4.12. Calabrese et al. (1990)—Preliminary Adult Soil Ingestion Estimates: Results of a Pilot Study

Calabrese et al. (1990) studied six adults to evaluate the extent to which they ingest soil. This adult study was originally part of the children soil ingestion study (Calabrese et al., 1989) and was used to validate part of the analytical methodology used in the children's study. The participants were six healthy adults, three males and three females, 25–41 years old. Each volunteer ingested one empty gelatin capsule at breakfast and one at dinner Monday, Tuesday, and Wednesday during the first week of the study. During the second week, they ingested 50 mg of sterilized soil within a gelatin capsule at breakfast and at dinner (a total of 100 mg of sterilized soil per day) for 3 days. For the third week, the participants ingested 250 mg of sterilized soil in a gelatin capsule at breakfast and at dinner (a total of 500 mg of soil per day) during the 3 days. Duplicate meal samples (food and beverage) were collected from the six adults. The sample included all foods ingested from breakfast Monday, through the evening meal Wednesday during each of the 3 weeks. In addition, all medications and vitamins ingested by the adults were collected. Total excretory output was collected from Monday noon through Friday midnight over three consecutive weeks.

Data obtained from the first week, when empty gelatin capsules were ingested, were used to estimate soil intake by adults. On the basis of recovery values, aluminum, silicon, yttrium, and zirconium were considered the most valid tracers. The mean values for these four tracers were: aluminum, 110 mg/day; silicon, 30 mg/day; yttrium, 63 mg/day; and zirconium, 134 mg/day. A limitation of this study is the small sample size. Thus, this study was classified as relevant.

5.3.4.13. Cooksey (1995)—Pica and Olfactory Craving of Pregnancy: How Deep Are the Secrets?

Postpartum interviews were conducted between 1992 and 1994 of 300 women at a mid-western hospital, to document their experiences of pica behavior. The majority of women were Black and low-income, and ranged in age from 13 to 42 years.

In addition to questions regarding nutrition, each woman was asked if during her pregnancy she experienced a craving to eat ice or other things that are not food.

Of the 300 women, 194 (65%) described ingesting one or more pica substances during their pregnancy, and the majority (78%) ate ice/freezer frost alone or in addition to other pica substances. Reported quantities of items ingested on a daily basis were three to four 8-pound bags of ice, two to three boxes of cornstarch, two cans of baking powder, one cereal bowl of dirt, five quarts of freezer frost, and one large can of powdered cleanser.

5.3.4.14. Smulian et al. (1995)—Pica in a Rural Obstetric Population

In 1992, Smulian et al. (1995) conducted a survey response study of pica in a convenience sample of 125 pregnant women in Muscogee County, GA, who ranged in age from 12 to 37 years. Of these, 73 were Black, 47 were White, 4 were Hispanic, and 1 was Asian. Interviews were conducted at the time of the first prenatal visit, using nondirective questionnaires to obtain information regarding substances ingested as well as patterns of pica behavior and influences on pica behavior. Only women ingesting nonfood items were considered to have pica. Ingestion of ice was included as a pica behavior only if the ice was reported to be ingested multiple times per day, if the ice was purchased solely for ingestion, or if the ice was obtained from an unusual source such as freezer frost.

The overall prevalence of pica behavior in this study was 14.4% (18 of 125 women), and was highest among Black women (17.8%). There was no significant difference between groups with respect to age, race, weight, or gestational age at the time of enrollment in the study. The most common form of pica was ice eating (pagophagia), reported by 44.4% of the patients. Nine of the women reported information on the frequency and amount of the substances they were ingesting. Of these women, 66.7% reported daily consumption and 33.3% reported pica behavior three times per week. Soap, paint chips, or burnt matches were reportedly ingested 3 days per week. One patient ate ice 60 times per week. Women who ate dirt or clay reported ingesting 0.5–1 pound per week. The largest amount of ice consumed was five pounds per day.

5.3.4.15. Grigsby et al. (1999)—Chalk Eating in Middle Georgia: A Culture-Bound Syndrome of Pica?

Grigsby et al. (1999) investigated the ingestion of kaolin, also known as white dirt, chalk, or white clay, in the central Georgia Piedmont area as a culture-bound syndrome. A total of 21 individuals who consumed kaolin at the time or had a history of consuming kaolin were interviewed, using a seven-item, one-page interview protocol. All of those interviewed were Black, ranging in age from 28 to 88 years (mean age of 46.5 years), and all were female except for one.

Reasons for eating kaolin included liking the taste, being pregnant, craving it, and to gain weight. Eight respondents indicated that they obtained the kaolin from others, five reported getting it directly from the earth, four purchased it from a store, and two obtained it from a kaolin pit mine. The majority of the respondents reported that they liked the taste and feel of the kaolin as they ate it. Only three individuals reported knowing either males or White persons who consumed kaolin. Most individuals were not forthcoming in discussing their ingestion of kaolin and recognized that their behavior was unusual.

The study suggests that kaolin-eating is primarily practiced by Black women who were introduced to the behavior by family members or friends, during childhood or pregnancy. The authors concluded that kaolin ingestion is a culturally transmitted form of pica, not associated with any other psychopathology. Although information on kaolin eating habits and attitudes were provided by this study, no quantitative information on consumption was included, and the sample population was small and nonrandom.

5.3.4.16. Ward and Kutner (1999)—Reported Pica Behavior in a Sample of Incident Dialysis Patients

Structured interviews were conducted with a sample of 226 dialysis patients in the metropolitan Atlanta, GA area from September 1996 to September 1997. Interviewers were trained in nutrition data collection methods, and patients also received a 3-day diet diary that they were asked to complete and return by mail. If a subject reported a strong past or current food or nonfood craving, a separate form was used to collect information to determine whether this was a pica behavior.

Pica behavior was reported by 37 of the dialysis patients studied (16%), and most of these patients (31 of 37) reported that they were currently practicing some form of pica behavior. The patients'

race and sex were significantly associated with pica behavior, with Black patients and women making up 86% and 84% of those reporting pica, respectively. Those reporting pica behavior were also younger than the remainder of the sample, and two patients described a persistent craving for ice. Other pica items reportedly consumed included starch, dirt, flour, or aspirin.

5.3.4.17. *Simpson et al. (2000)—Pica During Pregnancy in Low-Income Women Born in Mexico*

Simpson et al. (2000) interviewed 225 Mexican-born women, aged 18–42 years (mean age of 25 years), using a questionnaire administered in Spanish. Subjects were recruited by approaching women in medical facilities that served low-income populations in the cities of Ensenada, Mexico ($N = 75$), and Santa Ana, Bakersfield and East Los Angeles, CA ($N = 150$). Criteria for participation were that the women had to be Mexican-born, speak Spanish as their primary language, and be pregnant or have been pregnant within the past year. Only the data for the women in the United States are included in this handbook.

Pica behavior was reported in 31% of the women interviewed in the United States. Table 5-22 shows the items ingested and the number of women reporting the pica behavior. Of the items ingested, only ice was said to be routinely eaten outside of pregnancy, and was only reported by U.S. women, probably because none of the low-income women interviewed in Mexico owned a refrigerator. Removing the 12 women who reported eating only ice from the survey lowers the percentage of U.S. women who reported pica behavior to 23%. Women said they engaged in pica behavior because of the taste, smell, or texture of the items, for medicinal purposes, or because of advice from someone, and one woman reported eating clay for religious reasons. Magnesium carbonate, a pica item not found to be previously reported in the literature, was reportedly consumed by 17% of women. The amount of magnesium carbonate ingested ranged from a quarter of a block to five blocks per day; the blocks were approximately the size of a 35-mm film box. No specific quantity information on the amounts of pica substances ingested was provided in the study.

5.3.4.18. *Obialo et al. (2001)—Clay Pica Has No Hematologic or Metabolic Correlate to Chronic Hemodialysis Patients*

A total of 138 dialysis patients at the Morehouse School of Medicine, Atlanta, GA, were interviewed about their unusual cravings or food habits. The patients were Black and ranged in age from 37 to 78 years. Obialo et al. (2001) suggested that the stress caused by end-stage renal disease may provide a stimulus for pica, especially for those with cultural predispositions.

Thirty of the patients (22%) reported some form of pica behavior, while 13 patients (9.4%) reported clay pica. The patients with clay pica reported daily consumption of 225–450 g of clay.

5.3.4.19. *Klitzman et al. (2002)—Lead Poisoning among Pregnant Women in New York City: Risk Factors and Screening Practices*

Klitzman et al. (2002) interviewed 33 pregnant women whose blood lead levels were $>20 \mu\text{g/dL}$ as reported to the New York City Department of Health between 1996 and 1999. The median age of the women was 24 years (range of 15 to 43 years), and the majority were foreign born. The women were interviewed regarding their work, reproductive, and lead exposure history. A home visit was also conducted and included a visual inspection and a colorimetric swab test; consumable items suspected to contain lead were sent to a laboratory for analysis.

Thirteen women (39%) reported pica behavior during their current pregnancies. Of these, 10 reported eating soil, dirt, or clay; 2 reported pulverizing and eating pottery; and 1 reported eating soap. One of the women reported eating approximately one quart of dirt daily from her backyard for the past three months. No other quantity data were reported.

5.3.4.20. *Doyle et al. (2012)—A Soil Ingestion Pilot Study of a Population Following a Traditional Lifestyle Typical of Rural or Wilderness Areas*

Doyle et al. (2012) conducted a pilot study to estimate soil ingestion among a Canadian Aboriginal community living in a wilderness area. The study was conducted over a 3-week period during 2011 in the Nemiah Valley of British Columbia. The study was conducted on traditional lands in cooperation with the Xeni Gwet'in First Nation. Seven adults were recruited, and four of these adults were members of the Xeni Gwet'in community. During the study, the subjects participated in traditional

daily activities (e.g., fishing, clearing, scouting, hiking, cutting firewood, etc.). Soil ingestion was estimated using a mass balance tracer methodology. The tracers used for this study were aluminum, barium, cerium, lanthanum, manganese, silicon, thorium, titanium, uranium, vanadium, yttrium, and zirconium. Daily soil ingestion was calculated for each subject based on tracer concentrations in fecal and soil samples, assuming a 24-hour transit time. Soil ingestion rates were corrected for tracers ingested via the diet and in medications. Participants recorded their food and medicine intake in daily logs. Soil, food, water, and fecal samples were analyzed at a commercial laboratory.

Soil ingestion rates calculated for the four most reliable tracers (aluminum, cerium, lanthanum, silicon) are shown in Table 5-23. The most reliable tracers were considered those that are poorly absorbed in the gastrointestinal tract and those with the lowest food:soil ratios. For all four tracers combined, the mean, median, and 90th percentile soil ingestion rates were 75, 50, and 211 mg/day, respectively. This study provides quantitative soil ingestion estimates for an adult Canadian population following a traditional wilderness lifestyle. However, as a pilot study, the sample population was very small, and is not expected to be representative of the U.S. population.

5.3.4.21. Irvine et al. (2014)—Soil Ingestion Rate Determination in a Rural Population in Alberta, Canada Practicing a Wilderness Lifestyle

Irvine et al. (2014) estimated soil ingestion rates among a group of First Nations people inhabiting a wilderness area of Alberta, Canada using the mass balance tracer method. The study was conducted over a 3-week period in August 2012. Nine adults within the Cold Lake First Nations Reserve who practiced traditional activities (e.g., hunting, fishing, and gathering) participated in the study. The tracers used for this study were aluminum, barium, cerium, lanthanum, manganese, silicon, thorium, titanium, uranium, vanadium, yttrium, and zirconium. Soil were sieved into multiple particle size fractions to separate soil particles of <63 µm. Daily soil ingestion was calculated for each subject based on tracer concentrations in fecal and soil samples. A 24-hour transit time was assumed, and soil ingestion rates were corrected for tracers ingested via the diet. Four tracers were considered to be the most reliable (aluminum, cerium, lanthanum, and silicon) because of their low food:soil ratios, but aluminum and silicon had lower coefficients of variance. Table 5-24

provides the estimated soil ingestion rates based on aluminum and silicon, and on all four of the most reliable tracers (aluminum, cerium, lanthanum, and silicon combined). Mean soil ingestion rates for these tracers ranged from 32 to 68 mg/day for this adult population; 90th percentile values ranged from 152 to 231 mg/day. This study provides quantitative soil ingestion estimates for an adult Canadian population following a traditional wilderness lifestyle. However, as a pilot study, the sample population was very small, and is not expected to be representative of the U.S. population.

5.3.4.22. Lumish et al. (2014)—Gestational Iron Deficiency is Associated with Pica Behaviors in Adolescents

Lumish et al. (2014) examined pica behavior and iron status among 158 pregnant adolescents (<18 years of age) receiving prenatal care at a health clinic in Rochester, NY in 2006–2009. The women were mostly African-American (two-thirds) and about 25% were Hispanic. At each visit, the women were asked whether they craved any nonfood items, and were asked to provide detailed information on the items that they craved or ate. A total of 18 different items were reported to have been ingested, including: ice; raw starches (flour and cornstarch); powder (dust, vacuum powder from vacuum cleaner bags, and baby powder); soap (soap, bar soap, laundry soap, and powdered cleansers); plastic/foam (stuffing from pillows/sofas and sponges); paper (writing paper, toilet paper, and tissues); baking soda/powder; and other (dirt and chalk). Overall, 46% of the teens reported ingesting one or more of these items. Ice was the nonfood item most often consumed (37% of all the pregnant adolescents), while only 1.3% of the teens reported ingestion of dirt/chalk. Lumish et al. (2014) also observed that a significantly larger proportion of African-American teens reported pica behavior than Caucasian teens. This study provides prevalence data for a population of pregnant adolescents. These data may not be entirely representative of the U.S. population as a whole or of pregnant women in general. Also, the study provides prevalence data only. No information on the quantity of substance ingested is provided.

5.3.4.23. Jang et al. (2014)—General Factors of the Korean Exposure Factors Handbook

Jang et al. (2014) reported on a soil ingestion study that was conducted in Seoul, South Korea. Feces samples were collected from 63 children, ages 0 to 7 years and analyzed for the following tracer elements: aluminum, barium, manganese, silicon,

titanium, vanadium, yttrium, and zirconium. Soil samples collected from the areas where the children spent most of their time were analyzed for the same tracer elements. Five children who spent no time outdoors were used as controls to account for exposures to tracer elements from sources other than soil (e.g., food, medicine). Using the LTM, aluminum was used to estimate soil ingestion rates. Jang et al. (2014) reported that, after adjusting for the environmental background levels based on the control group, the estimated arithmetic mean soil ingestion rate was 118 mg/day, and the geometric mean was 29 mg/day. The 90th percentile value was 286 mg/day and the 95th percentile value was 898 mg/day. This study provides quantitative data for a study population in South Korea. While it does not appear that tracer elements in food or medicines were accounted for, a control population was used to adjust for exposures from sources other than soil. A limitation of this study is that the study population may not be representative of children in the United States.

5.3.4.24. Chien et al. (2015)—Soil Ingestion Rates for Children under 3 Years Old in Taiwan

Chien et al. (2015) conducted a soil ingestion tracer study of 66 children (33 boys and 33 girls) under 3 years of age recruited from health centers from northern, central, southern, and eastern Taiwan from May 2011 to November 2012. Duplicate 24-hour food and liquid samples were collected for each child on Day one. All feces were collected beginning on Day 2 through Day 4 of the study. Diapers were collected for those children who wore diapers and feces were removed in the laboratory. Urine samples were not collected. Outdoor soil samples from the top 0–5 cm of soil were collected from typical play areas. Household dust samples were collected from the living room, bedroom, and kitchen floors using a handheld vacuum cleaner. Both soil and household dust samples were sieved using a 100-mesh (150 µm; ASTM, 2017) screen. Samples were analyzed for titanium and silicon. Soil ingestion rates were calculated using Equation 5-7 adapted from Davis and Mirick (2006).

$$S_{i,e} = \left(\frac{A_f - A_{food}}{E_{soil}} \right) \quad (\text{Eqn. 5-8})$$

where:

$S_{i,e}$ = amount of soil ingested (mg/day)

A_f = daily concentration of tracer element in the feces (µg/day)
 A_{food} = daily concentration of tracer element in the foods (µg/day)
 E_{soil} = concentration of tracer elements in soils (g/kg)

The following equation was used to adjust the daily fecal tracer concentration to account for missing fecal samples.

$$A_f = \left(C_{f,2} \times \frac{DW_{f,2}}{DW_{f,2} + DW_{f,3} + DW_{f,4}} + C_{f,3} \times \frac{DW_{f,3}}{DW_{f,2} + DW_{f,3} + DW_{f,4}} + C_{f,4} \times \frac{DW_{f,4}}{DW_{f,2} + DW_{f,3} + DW_{f,4}} \right) \times DW_{f,ave} \quad (\text{Eqn. 5-9})$$

where:

$C_{f,2}$ = concentration of tracer element in the feces on Day 2 (µg/day)
 $C_{f,3}$ = concentration of tracer element in the feces on Day 3 (µg/day)
 $C_{f,4}$ = concentration of tracer element in the feces on Day 4 (µg/day)
 $DW_{f,2}$ = dry weight of the feces on Day 2 (g)
 $DW_{f,3}$ = dry weight of the feces on Day 3 (g)
 $DW_{f,4}$ = dry weight of the feces on Day 4 (g)
 $DW_{f,ave}$ = average dry weight of the feces on Day 2 through Day 4 (g)

Activity pattern data were also collected by videotaping each child for 2 hours and by administering a questionnaire to parents or caregivers. Most of the children spent more than four times a week outdoors. About half of the children spent under one hour a day outdoors. Children washed their hands and took a bath or shower an average of 3.98 and 1.24 times a day, respectively.

Recoveries for the analyses were $100 \pm 20\%$. The soil intake rates ranged from 0–82.6 mg/day for silicon and 36.4–1,850 mg/day for titanium, with an average of 9.6 mg/day (SD = 19.2 mg/day) and 957.1 mg/day (SD = 477 mg/day) for silicon and titanium, respectively (Chien et al., 2015). These estimates excluded children with soil intake rates that were considered outliers. Negative soil intake rate values were replaced by 0 mg/day in the

estimation of the average soil intake rates. Soil intake rates based on silicon were positively correlated with the total hand-to-mouth frequency for both indoors and outdoors. Soil intake rates for children with hand-to-mouth contact ≥ 15 contacts/hr was estimated to be 15.9 mg/day compared to 5.46 mg/day for children with < 15 contacts/hour. Soil intake rates were also statistically significantly greater for children with higher hand washing frequency (≥ 4 events/day, mean = 17.4 mg/day) compared to children with less hand washing frequency (< 4 events/day, mean = 5.6 mg/day). While not suggested as an explanation for this observation by Chien et al. (2015), this may be due to re-loading of soil on hands and subsequent ingestion. Chien et al. (2015) found no significant difference between children's age and gender and the estimated soil intake rates. The authors stated that titanium may not be a suitable tracer for estimating soil intake rates in the study because other sources of titanium were not considered, including: peeling paint chips, toothpaste, and candy. They also noted that soil intake rates estimated in this study are lower than those in the United States. This may be due to several factors. The authors stated that dust loadings in the Taiwanese homes are lower than those in U.S. homes. As in most other Asian countries, the Taiwanese remove their shoes before entering the house, therefore, reducing the amount of household dust. The authors also found that the cleaning frequency in the study homes was higher than those found in studies performed in the United States. This study found correlations between soil intake rates and hand-to-mouth frequency behavior. The results, however, may not be representative of children's behavior in the United States. Another limitation is that the sources of tracer elements, other than food, were not accounted for in estimating of soil intake rates.

5.3.4.25. Wang et al. (2015)—Quantification of Soil/Dust (SD) on the Hands of Children from Hubei Province, China Using Hand Wipes

Wang et al. (2015) estimated soil and dust ingestion for three age ranges of children: kindergarten (ages 3 to < 7 years), primary school (7 to < 13 years), and middle school (13 to < 17 years) in Hubei Province in Central China. Hand wipe samples and background area soil samples were both analyzed for three tracer elements (cerium, vanadium, and yttrium). Age-specific estimates of soil/dust adhering to the hands (in mg) were calculated as the amount of tracer element on the

hand (in ng) divided by the amount of tracer element in the soil (in mg/kg). Based on the three tracer elements, the amount of soil/dust on the hands was estimated to range from 0.59–0.64 ng for kindergarten-aged children, 1.42–1.64 ng for primary school children, and 1.04–1.52 ng for middle school children. Wang et al. (2015) used these hand soil/dust estimates, along with assumptions about the number of hand-to-mouth contacts that occur over a 12-hour period, the proportion of the hand area that contacts the mouth, and the efficiency at which soil/dust is transferred from the hand to the mouth to estimate soil/dust ingestion rates. Hand-to-mouth contact was assumed to occur 15, 7, and 2 times per hour for kindergarten, primary, and middle school children, respectively. The proportion of the hand that contacts the mouth was assumed to be 0.1 (10%), and the transfer efficiency was assumed to be 0.159. The mean rates of hand soil/dust ingestion were estimated to be 1.79, 2.12, and 0.49 mg/day for kindergarten, primary, and middle school children, respectively. This study provides a novel method for estimating the amount of hand soil/dust ingested. However, these soil/dust ingestion estimates do not account for soil/dust ingested from other pathways (e.g., object-to-mouth contact, food-to-soil contact), and the population evaluated in this study may not be representative of the U.S. population. Additional limitations relate to the uncertainties associated with the input parameters for estimating soil/dust intake (e.g., transfer efficiency, proportion of the hand contacting the mouth).

5.3.4.26. Lin et al. (2015)—Pica during Pregnancy among Mexican-Born Women: A Formative Study

Lin et al. (2015) formed nine focus groups involving 76 Mexican-born pregnant or ≤ 2 -year postpartum women. Three of the focus groups were in central California ($N = 23$), and six were held in Mexico ($N = 53$). The aim of the focus group discussions was to obtain information on the frequency and types of pica behavior among the women. Pica was defined as “eating items that were not food.” Among the women in the California focus group, 10 (43%) indicated that they had engaged in pica, and 6 (60%) of these women reported pica behavior during pregnancy. Among the Mexican focus group, 18 (34%) reported engaging in pica, and 16 (80%) of these women reported engaging in pica during pregnancy. Commonly eaten items were earth, bean stones, and adobe. Among the California group, 5 (22%) had eaten earth. Among the Mexican

group, 6 (11%) had eaten earth. Some women discussed their pica behavior in the context of micronutrient deficiencies, or perceived health consequences of unfulfilled cravings. This study provides information on the pica behavior for Mexican-born women living in the United States and Mexico. However, this population may not be representative of the general population of the United States. Also, the study provides prevalence data only. Data on the quantity of pica substances ingested are not provided.

5.3.4.27. *Ma et al. (2016)—Estimation of the Daily Soil/Dust (SD) Ingestion Rate of Children from Gansu Province, China via Hand-to-Mouth Contact Using Tracer Elements*

Ma et al. (2016) estimated soil and dust ingestion among 60 children between the ages of 3 and 12 years in the Gansu Province of China. An activity pattern modeling approach was used to estimate the soil and dust ingestion from hand-to-mouth contact using the following equation:

$$IR_{handSD} = TA_{handSD} \times TE \times SAC \times EF \quad (\text{Eqn. 5-10})$$

where:

IR_{handSD} = daily ingestion of soil and dust from hands (mg/day)

TA_{handSD} = theoretical amount of hand soil and dust (mg)

TE = transfer efficiency at each contact

SAC = proportion of the hand surface area contacting the mouth at each event

EF = frequency of contact in a day (day^{-1})

The amount of soil on the hands was estimated by collecting two hand wipes from each child (one in the morning and one in the afternoon), and analyzing them for three tracer elements (cerium, yttrium, and vanadium). Background levels of these tracers were also measured in soil samples from the Gansu Province. Using these data, the amount of soil and dust on the children's hands (TA_{SD}) was estimated as follows:

$$TA_{SD} = C_{tracer-hands} / C_{tracer-soil} \quad (\text{Eqn. 5-11})$$

where:

$C_{tracer-hands}$ = the amount of tracer on the hands (ng)

$C_{tracer-soil}$ = the amount of tracer in background soil (mg/kg)

Transfer efficiency (TE) was assumed to be 0.159, based on a study by Kissel et al. (1998b), the proportion of the hand surface contacting the mouth per event was assumed to be 0.1, and the frequency of contact (EF) was assumed to be 15 and 7 contacts/hour, for kindergarten and primary school children, respectively, over a 12-hour exposure period. The estimated mean soil and dust ingestion rates from hand-to-mouth contact ranged from 6 to 10 mg/day and 95th percentile rates ranged from 12 to 18 mg/day.

The estimates provided by Ma et al. (2016) are based on various assumptions related to hand-to-mouth exposure (i.e., surface areas of the hand contacted, transfer efficiency, the number of contacts per day), which introduce a certain degree of uncertainty. The amount of soil on the hands was based on measurements of three tracers (i.e., cerium, yttrium, and vanadium) from hand wipe samples, which the authors believed to “more accurately estimate the amounts of [soil and dust] on the hands” than simply weighing the hand wipes before and after wiping the children's hands because other substances such as grease and other organic ingredients are eliminated. The estimates account for soil and dust ingestion from hand-to-mouth contact only, and the population of children studied may not be representative of children in the United States.

5.3.5. **Relevant Studies of Secondary Analysis and Other Relevant Information**

The following studies are classified as relevant rather than key. This section includes studies of secondary analysis using the three methodologies discussed in Section 5.3.1, and data on the prevalence of the soil ingestion behavior. The secondary analysis literature on soil and dust ingestion rates also gives important insights into methodological strengths and limitations of the studies. These methodological issues include attempts to determine the origins of apparent positive and negative bias in the methodologies, including: food input/fecal output misalignment; missed fecal samples; assumptions about the weight of children's feces; particle sizes of, and relative contributions of soils and dusts to total soil and dust ingestion; and attempts to identify a “best” tracer

element or combination of tracer elements. The secondary analysis literature also provides insights into the data needs for assessing soil and dust ingestion using activity pattern approaches. Potential error from using short-term-study estimates for long-term soil and dust ingestion behavior estimates is also discussed.

5.3.5.1. Wong (1988)—*The Role of Environmental and Host Behavioral Factors in Determining Exposure to Infection with Ascaris lumbricoides and Trichuris trichiura* Calabrese and Stanek (1993)—*Soil Pica: Not a Rare Event*

Calabrese and Stanek (1993) reviewed a tracer element study conducted by Wong (1988) to estimate the amount of soil ingested by two groups of children. Wong (1988) studied a total of 52 children in two government institutions in Jamaica. The younger group included 24 children with an average age of 3.1 years (range of 0.3 to 7.5 years). The older group included 28 children with an average age of 7.2 years (range of 1.8 to 14 years). One fecal sample was collected each month from each subject over the 4-month study period. The amount of silicon in dry feces was measured to estimate soil ingestion.

An unspecified number of daily fecal samples were collected from a hospital control group of 30 children with an average age of 4.8 years (range of 0.3 to 12 years). Dry feces were observed to contain 1.45% silicon, or 14.5 mg Si per gram of dry feces. This quantity was used to correct measured fecal silicon from dietary sources. Fecal silicon quantities greater than 1.45% in the 52 studied children were interpreted as originating from soil ingestion.

For the 28 children in the older group, soil ingestion was estimated to be 58 mg/day, based on the mean minus one outlier, and 1,520 mg/day, based on the mean of all the children. The outlier was a child with an estimated average soil ingestion rate of 41,000 mg/day (41 g/day) over the 4 months.

Estimates of soil ingestion were higher in the younger group of 24 children. The mean soil ingestion of all the children was 470 ± 370 mg/day. Due to some sample losses, of the 24 children studied, only 15 had samples for each of the 4 months of the study. Over the entire 4-month study period, 9 of 84 samples (or 10.5%) yielded soil ingestion estimates in excess of 1 g/day.

Of the 52 children studied, 6 had 1-day estimates of more than 1,000 mg/day. Table 5-25 shows the

estimated soil ingestion for these six children. The article describes 5 of 24 (or 20.8%) in the younger group of children as having a $>1,000$ mg/day estimate on at least one of the four study days; in the older group one child is described in this manner. A high degree of daily variability in soil ingestion was observed among these six children; three showed soil pica behavior on 2, 3, and 4 days, respectively, with the most consistent (4 out of 4 days) soil pica child having the highest estimated soil ingestion, 3.8 to 60.7 g/day.

5.3.5.2. Calabrese and Stanek (1992b)—*What Proportion of Household Dust is Derived from Outdoor Soil?*

Calabrese and Stanek (1992b) estimated the amount of outdoor soil in indoor dust using statistical modeling. The model used soil and dust data from the 60 households that participated in the Calabrese et al. (1989) study, by preparing scatter plots of each tracer's concentration in soil versus dust. Correlation analysis of the scatter plots was performed. The scatter plots showed little evidence of a consistent relationship between outdoor soil and indoor dust concentrations. The model estimated the proportion of outdoor soil in indoor dust using the simplifying assumption that the following variables were constants in all houses: the amount of dust produced every day from both indoor and outdoor sources, the proportion of indoor dust due to outdoor soil, and the concentration of the tracer element in dust produced from indoor sources. Using these assumptions, the model predicted that 31.3% by weight of indoor dust came from outdoor soil. This model was then used to adjust the soil ingestion estimates from Calabrese et al. (1989).

5.3.5.3. Stanek and Calabrese (1995b)—*Daily Estimates of Soil Ingestion in Children*

Stanek and Calabrese (1995b) presented a methodology that links the physical passage of food and fecal samples to construct daily soil ingestion estimates from daily food and fecal trace-element concentrations. Soil ingestion data for children obtained from the Amherst study (Calabrese et al., 1989) were reanalyzed by Stanek and Calabrese (1995b). A lag period of 28 hours between food intake and fecal output was assumed for all respondents. Day 1 for the food sample corresponded to the 24-hour period from midnight on Sunday to midnight on Monday of a study week; Day 1 of the fecal sample corresponded to the 24-hour period from noon on Monday to noon on Tuesday. Based on these definitions, the food soil

equivalent was subtracted from the fecal soil equivalent to obtain an estimate of soil ingestion for a trace element. A daily overall ingestion estimate was constructed for each child as the median of trace element values remaining after tracers falling outside of a defined range around the overall median were excluded.

Table 5-26 presents adjusted estimates, modified according to the input/output misalignment correction, of mean daily soil ingestion per child (mg/day) for the 64 study participants. The approach adopted in this paper led to changes in ingestion estimates from those presented in Calabrese et al. (1989).

Estimates of children's soil ingestion projected over a period of 365 days were derived by fitting log-normal distributions to the overall daily soil ingestion estimates using estimates modified according to the input/output misalignment correction (see Table 5-27). The estimated median value of the 64 respondents' daily soil ingestion averaged over a year was 75 mg/day, while the 95th percentile was 1,751 mg/day. In developing the 365-day soil ingestion estimates, data that were obtained over a short period of time (as is the case with all available soil ingestion studies) were extrapolated over a year. The 2-week study period may not reflect variability in tracer element ingestion over a year. This study was classified as relevant because, while Stanek and Calabrese (1995b) attempted to address the variability through modeling of the long-term ingestion, new uncertainties were introduced through the parametric modeling of the limited subject day data.

5.3.5.4. Calabrese et al. (1996)—Methodology to Estimate the Amount and Particle Size of Soil Ingested by Children: Implications for Exposure Assessment at Waste Sites

Calabrese et al. (1996) examined the hypothesis that one cause of the variation between tracers seen in soil ingestion studies could be related to differences in soil tracer concentrations by particle size. This study, published before the Calabrese et al. (1997a) primary analysis study results, used laboratory analytical results for the Anaconda, MT soil's tracer concentration after it had been sieved to a particle size of <250 μm in diameter (it was sieved to <2 mm soil particle size in Calabrese et al. [1997a]). The smaller particle size was examined based on the assumption that children principally ingest soil of small particle size adhering to fingertips and under fingernails. For five of the tracers used in the original study (aluminum, silicon,

titanium, yttrium, and zirconium), soil concentration was not changed by particle size. However, the soil concentrations of three tracers (lanthanum, cerium, and neodymium) were increased 2- to 4-fold at the smaller soil particle size. Soil ingestion estimates for these three tracers were decreased by approximately 60% at the 95th percentile compared to the Calabrese et al. (1997a) results.

5.3.5.5. Stanek et al. (1999)—Soil Ingestion Estimates for Children in Anaconda Using Trace Element Concentrations in Different Particle Size Fractions

Stanek et al. (1999) extended the findings from Calabrese et al. (1996) by quantifying trace element concentrations in soil based on sieving to particle sizes of 100–250 μm and to particle sizes of 53 to <100 μm . The earlier study (Calabrese et al., 1996) used particle sizes of 0–2 μm and 1–250 μm . This study used the data from soil concentrations from the Anaconda, MT site reported by Calabrese et al. (1997a). Results of the study indicated that soil concentrations of aluminum, silicon, and titanium did not increase at the two finer particle size ranges measured. However, soil concentrations of cerium, lanthanum, and neodymium increased by a factor of 2.5 to 4.0 in the 100–250 μm particle size range when compared with the 0–2 μm particle size range. There was not a significant increase in concentration in the 53–100 μm particle size range.

5.3.5.6. Stanek and Calabrese (2000)—Daily Soil Ingestion Estimates for Children at a Superfund Site

Stanek and Calabrese (2000) reanalyzed the soil ingestion data from the Anaconda study (Calabrese et al., 1997a) to provide estimates of variability between days and subjects, and daily soil ingestion rates over a longer period. Stanek and Calabrese (2000) attempted to address several sources of uncertainties in this reanalysis including identification of outliers and the estimation of soil ingestion rates based on particle size of <250 μm . Tracer-specific soil ingestion rates were estimated for 8 tracer elements for up to 7 subject days for each of the 64 children. The mean and median values were estimated for all tracers for each day, and median and mean estimates were generated over all subject days. Table 5-28 summarizes these soil ingestion estimates.

Assuming a log-normal distribution for the soil ingestion estimates in the Anaconda study, average long-term soil ingestion rates were predicted for children for each of the eight trace elements. Using

“best linear unbiased predictors,” the authors predicted 95th percentile soil ingestion values over time periods of 7 days, 30 days, 90 days, and 365 days. The 95th percentile soil ingestion values were predicted to be 133 mg/day over 7 days, 112 mg/day over 30 days, 108 mg/day over 90 days, and 106 mg/day over 365 days. Based on this analysis, estimates of the distribution of longer term average soil ingestion are expected to be narrower, with the 95th percentile estimates being as much as 25% lower (Stanek and Calabrese, 2000). This study was classified as relevant because, while Stanek and Calabrese (2000) attempted to characterize the variability between days for a given subject and between subjects, the derivation of usual (long term) intake based on limited short term subject day data introduces new uncertainties.

5.3.5.7. Stanek et al. (2001a)—Biasing Factors for Simple Soil Ingestion Estimates in Mass Balance Studies of Soil Ingestion

To identify and evaluate biasing factors for soil ingestion estimates, the authors developed a simulation model based on data from previous soil ingestion studies. The soil ingestion data used in this model were taken from Calabrese et al. (1989) (the Amherst study), Davis et al. (1990) (southeastern Washington State), Calabrese et al. (1997a) (the Anaconda study), and Calabrese et al. (1997b) (soil pica in Massachusetts), and relied only on the aluminum and silicon trace element estimates provided in these studies.

Of the biasing factors explored, the impact of study duration was the most striking, with a positive bias of more than 100% for 95th percentile estimates in a 4-day tracer element study. A smaller bias was observed for the impact of absorption of trace elements from food. Although the trace elements selected for use in these studies are believed to have low absorption, whatever amount is not accounted for will result in an underestimation of the soil ingestion distribution. In these simulations, the absorption of trace elements from food of up to 30% was shown to negatively bias the estimated soil ingestion distribution by less than 20 mg/day. No biasing effect was found for misidentifying play areas for soil sampling (i.e., ingested soil from a yard other than the subject's yard).

5.3.5.8. Stanek et al. (2001b)—Soil Ingestion Distributions for Monte Carlo Risk Assessment in Children

Stanek et al. (2001b) developed “best linear unbiased predictors” to reduce the biasing effect of

short-term soil ingestion estimates. This study estimated the long-term average soil ingestion distribution using daily soil ingestion estimates from children who participated in the Anaconda, MT study. Trace element specific estimates on a subject day were simulated assuming a normal distribution. In this long-term (annual) distribution, the soil ingestion estimates were: mean 31, median 24, 75th percentile 42, 90th percentile 75, and 95th percentile 91 mg/day. This study was classified as relevant because of the uncertainties introduced by the assumptions used to derive long-term average soil ingestion distribution. For example, the methodology assumes that the variance of the trace element estimates on a subject-day is identical for all subjects and days and that the variance between days in soil ingestion for a subject is the same for all subjects.

5.3.5.9. Von Lindern et al. (2003)—Assessing Remedial Effectiveness through the Blood Lead:Soil/Dust Lead Relationship at the Bunker Hill Superfund Site in the Silver Valley of Idaho

Similar to Hogan et al. (1998), Von Lindern et al. (2003) used the IEUBK model to predict blood lead levels in a nonrandom sample of several hundred children ages 0–9 years in an area of northern Idaho from 1989–1998 during community-wide soil remediation. Von Lindern et al. (2003) used the IEUBK default soil and dust ingestion rates together with observed house dust/soil lead levels (and imputed values based on community soil and dust lead levels, when observations were missing). The authors compared the predicted blood lead levels with observed blood lead levels and found that the default IEUBK soil and dust ingestion rates and lead bioavailability value over-predicted blood lead levels, with the over-prediction decreasing as the community soil remediation progressed. The authors stated that the over-prediction may have been caused either by a default soil and dust ingestion that was too high, a default bioavailability value for lead that was too high, or some combination of the two. They also noted under-predictions for some children, for whom follow up interviews revealed exposures to lead sources not accounted for in the model simulations (e.g., recreational exposures from outside the site). In addition, some of these children were socioeconomically disadvantaged, highly mobile, and cared for at multiple locations.

Von Lindern et al. (2003) developed a statistical model that apportioned the contributions of community soils, yard soils of the residence, and

house dust to lead intake; the models' results suggested that community soils contributed more (50%) than neighborhood soils (28%) or yard soils (22%) to soil found in house dust of the studied children.

5.3.5.10. Layton and Beamer (2009)—Migration of Contaminated Soil and Airborne Particulates to Indoor Dust

Layton and Beamer (2009) developed a modeling and measurement framework to assess the transport of contaminated soils and airborne particulates indoors at a residence from outdoor sources. The model accounted for the resuspension and deposition processes, and the removal of particles by cleaning and exhalation. The model consisted of a two-compartment model (i.e., air and floor) that simulated the dust fall, accumulation, and loss of particles on floor surfaces using the concentration of an inorganic tracer in those two media. Monitoring data from the National Human Exposure Assessment Survey (NHEXAS) in six Midwestern states and a city in The Netherlands were used to characterize the transport parameters of the model. The analysis assumed a lognormal distribution of soil track-in indoors with a geometric mean of 0.1 g/day (GSD = 3) based on data from the published literature. Results of the model indicated that 60% of the arsenic indoors originated from ambient air, while 40% was a result of soil tracked-in.

5.3.5.11. Gavrelis et al. (2011)—An Analysis of the Proportion of the U.S. Population That Ingests Soil or Other Non-Food Substances

Gavrelis et al. (2011) evaluated the prevalence of the U.S. population that ingests nonfood substances such as soil, clay, starch, paint, or plaster. Data were compiled from the National Health and Nutrition Examination Survey (NHANES) collected from 1971 to 1975 (NHANES I) and 1976 to 1980 (NHANES II), which represent a complex, stratified, multistage, probability-cluster design, and include nationwide probability samples of approximately 21,000 and 25,000 study participants, respectively. NHANES I surveyed people aged 1 to 74 years and NHANES II surveyed those 6 months to 74 years. The study population included women of childbearing age, people with low income status, the elderly, and preschool children, who represented an oversampling of specific groups in the population that were believed to have high risks for malnutrition.

The survey questions were demographic, socioeconomic, dietary, and health-related queries, and included specific questions regarding soil and nonfood substance ingestion. Survey questions for children under 12 years asked whether they consumed nonfood substances including dirt or clay, starch, paint or plaster, and other materials (NHANES I) or about consumption of clay, starch, paint or plaster, dirt, and other materials (NHANES II). For participants over 12 years of age, the survey questions asked only about consumption of dirt or clay, starch, and other materials (NHANES I) or about nonfood substances including clay, starch, and other materials (NHANES II).

Age groupings used in this analysis vary slightly from the age group categories established by EPA and described in *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). Other demographic parameters included sex (including pregnant and nonpregnant females), race (White, Black, and other), geography (urban and rural, with "urban" defined as populations >2,500), income level (ranging from \$0–\$9,999 up to >\$20,000, or not stated), and highest grade head of household (population under 18 years) or respondent (population >18 years) attended. For statistical analysis, frequency estimates were generated for the proportion of the total U.S. population that reported consumption of dirt, clay, starch, paint or plaster, or other materials "considered unusual" using the appropriate NCHS sampling weights and responses to the relevant questions in NHANES I and II. NHANES I and II were evaluated separately because the data sets did not provide components of the weight variable separately (i.e., probability of selection, nonresponse adjustment weight, and poststratification weight).

Although the overall prevalence estimates were higher in NHANES I compared with NHANES II, similar patterns were generally observed across substance types and demographic groups studied. For NHANES I, the estimated prevalence of all nonfood substance consumption in the United States for all ages combined was 2.5% (95% confidence interval [CI]: 2.2–2.9%), whereas for NHANES II, the estimated prevalence of all nonfood substance consumption in the United States for all ages combined was 1.1% (95% CI: 1.0–1.2%). Table 5-29 provides the prevalence estimates by type of substance consumed for all ages combined. By type of substance, the estimated prevalence was greatest for dirt and clay consumption and lowest for starch. Figures 5-1, 5-2, and 5-3, respectively, show the prevalence of nonfood substance consumption by

age, race, and income. The most notable differences were seen across age, race (Black vs. White), and income groups. For both NHANES I and II, prevalence for the ingestion of all nonfood substances decreased with increasing age, was higher among Blacks (5.7%; 95% CI: 4.4–7.0%) as compared to Whites (2.1%; 95% CI: 1.8–2.5%), and was inversely related to income level, with prevalence of nonfood consumption decreasing as household income increased. The estimated prevalence of all nonfood substances for the 1- to <3-year age category was at least twice that of the next oldest category (3 to <6 years). Prevalence estimates were 22.7% (95% CI: 20.1–25.3%) for the 1- to <3-year age group based on NHANES I and 12% based on NHANES II. In contrast, prevalence estimates for the >21-year age group was 0.7% (95% CI: 0.5–1.0%) and 0.4% (95% CI: 0.3–0.5%) for NHANES I and NHANES II, respectively. Other differences related to geography (i.e., urban and rural), highest grade level of the household head, and sex were less remarkable. For NHANES I, for example, the estimated prevalence of nonfood substance consumption was only slightly higher among females (2.9%; CI: 2.3–3.5%) compared to males (2.1%; CI: 1.8–2.5%) of all ages. For pregnant females, prevalence estimates (2.5%; 95% CI: 0.0–5.6%) for those 12 years and over were more than twice those for nonpregnant females (1.0%; 95% CI: 0.7–1.4%).

5.3.5.12. Stanek et al. (2012a)—Meta-Analysis of Mass-Balance Studies of Soil Ingestion in Children

Stanek et al. (2012a) conducted a meta-analysis of four major mass-balance soil ingestion studies in U.S. children between 1 and 7 years of age. The four studies included the Amherst study (Calabrese et al., 1989), the Washington State study (Davis et al., 1990), the Washington Family study (Davis and Mirick, 2006), and the Anaconda study (Calabrese et al., 1997a).

Data for only two trace elements were included (Al and Si). Excluded from the study were 10% of subjects identified as outliers. In addition, study subjects with high soil intake (soil pica) were excluded. Additional sources of variability and bias between the four studies included in the meta-analysis are discussed in Stanek et al. (2012b). Mean, median, and 95th percentile soil ingestion estimates based on 216 children were 25.5, 32.6, and 79.4 mg/day, respectively. Soil ingestion rates for males and females were similar. As shown in Table 5-30, soil ingestion appeared to increase with age

with the youngest age group (1 to <2 years) having the lowest soil ingestion rate.

This study provides age-specific soil ingestion estimates based on an analysis of four U.S. mass-balance soil ingestion studies for children. However, this study was classified as relevant because high-end values that were considered to be biased were excluded. In addition, data for a child with pica were also excluded. The study subjects were all from a limited study area (northern United States only) and data were collected only in the summer and early fall.

5.3.5.13. Wilson et al. (2015)—Estimation of Sediment Ingestion Rates Based on Hand-to-Mouth Contact and Incidental Surface Water Ingestion

Wilson et al. (2015) used a similar mechanistic approach to that of Wilson et al. (2013) to estimate sediment ingestion rates, except that greater adherence of sediment to the hands was assumed than for soil and dust. These sediment ingestion rates were intended for use in recreational exposure scenarios involving contact with sediments in aquatic areas. Sediment ingestion was assumed to occur as a result of direct contact with the sediment and subsequent hand-to-mouth contact, as well as incidental ingestion of surface water containing suspended sediments. Both deterministic and probabilistic methods were used to estimate sediment ingestion based on the following equations:

$$SDIR_{HM} = SL_{hands} \times SA_{hand} \times FSA_{fingers} \times FQ \times SE \quad (\text{Eqn. 5-12})$$

and

$$SDIR_{WC} = SS \times SWIR \quad (\text{Eqn. 5-13})$$

where:

- FQ = frequency of hand-to-mouth events (1/hour)
- $FSA_{fingers}$ = fractional surface area of the hands (unitless)
- SA_{hand} = surface area of the hand (cm²)
- $SDIR_{HM}$ = sediment ingestion rate from hand-to-mouth contact (mg/hr)
- $SDIR_{WC}$ = sediment ingestion from incidental water consumption (mg/hr)
- SE = saliva extraction factor (unitless)

SL_{hands} = sediment adherence on hands
(mg/cm²)
 SS = suspended sediment concentration
(mg/L)
 $SWIR$ = surface water ingestion rate (L/hr)

Table 5-31 presents the age-dependent input values used in these calculations. Both deterministic and probabilistic methods were used to estimate sediment ingestion rates. The results based on the probabilistic assessment are presented in Table 5-32. The estimated sediment ingestion rates based on hand-to-mouth contact using the probabilistic approach were 72 mg/hour for toddlers 7-months to 4 years old, 57 mg/hour for children 5 to 11 years old, 18 mg/hour for teens 12 to 19 years old, and 20 mg/hour for adults and seniors ages 20 to 60+ years. The sediment ingestion rate based on incidental surface water ingestion was 7.7 mg/hour for all age groups. Slightly lower values were observed using the deterministic approach.

This study provides sediment ingestion rates in units of mg/hour which can be used to estimate exposure to contaminants in sediment. Its limitations are based on the uncertainties associated with the input parameters used to model dust ingestion. Also, as indicated by the author, the age groups and receptor characteristics were intended to represent the Canadian population, which may or may not be representative of U.S. populations.

5.3.5.14. Wilson et al. (2016)—Estimation of Dust Ingestion Rates in Units of Surface Area per Day Using a Mechanistic Hand-to-Mouth Model

Wilson et al. (2016) estimated dust ingestion rates for various age groups of Canadian children on the basis of surface area (m²/day). These dust ingestion rates are intended to be used with measured contaminant loadings in surface dust (µg/m²) to estimate exposure from ingestion of surface dust. Wilson et al. (2016) used a similar approach and input parameters as used in Wilson et al. (2013). Dust ingestion was calculated using the following equation:

$$DIG = FTSS \times SA_{hand} \times FSA_{fingers} \times FQ \times SE \times ET$$

(Eqn. 5-14)

where:

DIG = dust ingestion rate (m²/d)

ET = exposure time (h/d)
 FQ = frequency of hand-to-mouth events
(events/hr)
 $FSA_{fingers}$ = fractional surface area of hand
mouthed
 $FTSS$ = fraction of dust transferred from
indoor surfaces to hands
 SA_{hand} = surface area of one hand (cm²)
 SE = saliva extraction factor (unitless)

The age-dependent parameters used were the same as those used in Wilson et al. (2013), as shown in Table 5-13. Age-specific exposure time (ET) values were estimated as 24 hours/day minus the time spent sleeping and the time spent outdoors. It was assumed that contact occurred with hard surfaces (e.g., carpets, countertops) 50% of the time and with soft surfaces (e.g., carpets, sofas) 50% of the time, except for infants for whom contact was assumed to occur with soft surfaces only (i.e., 100% of the time). Both deterministic and probabilistic methods were used to estimate dust ingestion rates. Results based on the probabilistic approach are presented in Table 5-33. Dust ingestion rates for children <11 years old were estimated to range from 0.025 m²/day for infants 0–6 months to 0.061 m²/day for toddlers 7 months to 4 years.

This study provides dust ingestion rates in units of m²/day which can be used with surface loadings of dust (and corresponding contaminant concentrations in the dust) in µg/m² to estimate exposure. Its limitations are based on the uncertainties associated with the input parameters used to model dust ingestion. The use of these dust ingestion rates assumes that the surface loading measurements are representative of the surfaces contacted.

5.3.5.15. Fawcett et al. (2016)—A Meta-Analysis of the Worldwide Prevalence of Pica during Pregnancy and the Postpartum Period

Fawcett et al. (2016) conducted a meta-analysis using information found in 70 studies published through February 2014 to develop worldwide pica prevalence estimates among pregnant and postpartum populations. Fawcett et al. (2016) also characterized variations in prevalence based on moderating variables (e.g., educational level, geographic region, and ethnicity). Of the studies evaluated, 33.8% were from North America, 5.6% were from South America, 33.8% were from Africa, 18.3% were from the Middle East, 4.2% were from

Asia, and 4.2% were from Europe. Fawcett et al. (2016) defined pica as “the purposeful consumption of nonfood or nonnutritive substances,” including “earth (geophagia), starch (amylophagia), ice (pagophagia), and a vast number of additional substances (e.g., baking soda).” Postpartum was defined as up to 12 months after delivery. The overall prevalence of pica was estimated to be 27.8%, but Fawcett et al. (2016) suggested that this is a poor indicator of pica prevalence among the general population of pregnant and postpartum because of the heterogeneity across studies. African women had the highest prevalence of pica at 44.8%, followed by North/South American at 23.0%, and Eurasia at 17.5%. Based on nine U.S. studies that included data on ethnicity, African-American women in the United States were also more likely to experience pica than non-African-American women. Based on a subset of 29 studies that reported the educational level of the women, education had a negative association with pica prevalence (i.e., higher educational level is associated with lower prevalence of pica). A subset of 31 studies reported on pica behavior among women with anemia. These women were one-and-a-half times more likely to report pica than nonanemic women.

This study estimated pica based on a wide range of studies, and provides information on the factors that may affect pica prevalence among pregnant and postpartum women. However, as stated by the author, the overall pica prevalence of 27.8% is not a good indicator of prevalence among the general population due to the wide range of values observed in the various studies evaluated. Also, pica was defined as ingestion of nonfood substances and did not represent soil/dust ingestion alone, but Fawcett et al. (2016) indicated that the moderating variables for geophagia did not differ from those of overall pica.

5.4. LIMITATIONS OF STUDY METHODOLOGIES

The three types of information needed to provide recommendations to exposure assessors on soil and dust ingestion rates among U.S. children include quantities of soil and dust ingested, frequency of high soil and dust ingestion episodes, and prevalence of high soil and dust ingesters. The methodologies provide different types of information: The tracer element, biokinetic model comparison, and activity pattern methodologies provide information on quantities of soil and dust ingested; the tracer element methodology provides limited evidence of the frequency of high soil ingestion episodes; and the

survey response methodology can shed light on prevalence of mouthing behavior and frequency of high soil ingestion episodes. The biokinetic model comparison methodology has the advantage of reflecting longer term exposures. However, the methodologies used to estimate soil and dust ingestion rates and prevalence of soil and dust ingestion behaviors have certain limitations when used for the purpose of developing recommended soil and dust ingestion rates. These limitations may not have excluded specific studies from use in the development of recommended ingestion rates, but have been noted throughout this handbook. This section describes some of the known limitations, presents an evaluation of the current state of the science for U.S. children’s soil and dust ingestion rates, and describes how the limitations affect the confidence ratings given to the recommendations.

5.4.1. Tracer Element Methodology

This section describes some previously identified limitations of the tracer element methodology as it has been implemented by U.S. researchers, as well as additional potential limitations that have not been explored. Some of these same limitations would also apply to the Dutch and Jamaican studies that used a control group of hospitalized children to account for dietary and pharmaceutical tracer intakes.

Binder et al. (1986) described some of the major and obvious limitations of the early U.S. tracer element methodology as follows:

[T]he algorithm assumes that children ingest predominantly soil from their own yards and that concentrations of elements in composite soil samples from front and back yards are representative of overall concentrations in the yards...children probably eat a combination of soil and dust; the algorithm used does not distinguish between soil and dust ingestion....fecal sample weights...were much lower than expected...the assumption that aluminum, silicon and titanium are not absorbed is not entirely true...dietary intake of aluminum, silicon and titanium is not negligible when compared with the potential intake of these elements from soil...Before accepting these estimates as true values of soil ingestion in toddlers, we need a better understanding of the metabolisms of aluminum, silicon and titanium in children, and the validity of the

assumptions we made in our calculations should be explored further.

The subsequent U.S. tracer element studies (Calabrese et al., 1997a, 1989; Barnes, 1990; Davis et al., 1990; Davis and Mirick, 2006) made some progress in addressing some of the Binder et al. (1986) study's stated limitations.

Regarding the issue of nonyard (community-wide) soil as a source of ingested soil, one study (Calabrese et al., 1989; Barnes, 1990) addressed this issue to some extent, by including samples of children's daycare center soil in the analysis. Calabrese et al. (1997a) attempted to address the issue by excluding children in daycare from the study sample frame. Homogeneity of community soils' tracer element content would play a role in whether this issue is an important biasing factor for the tracer element studies' estimates. Davis et al. (1990) evaluated community soils' aluminum, silicon, and titanium content and found little variation among 101 yards throughout the three-city area. Stanek et al. (2001a) concluded that there was "minimal impact" on estimates of soil ingestion due to mis-specifying a child's play area.

Regarding the issue of soil and dust both contributing to measured tracer element quantities in excreta samples, the key U.S. tracer element studies all attempted to address the issue by including samples of household dust in the analysis, and in some cases estimates are presented in the published articles that adjust soil ingestion estimates on the basis of the measured tracer elements found in the household dust. The relationship between soil ingestion rates and indoor settled dust ingestion rates has been evaluated in some of the secondary studies (Calabrese and Stanek, 1992b). An issue similar to the community-wide soil exposures in the previous paragraph could also exist with community-wide indoor dust exposures (such as dust found in schools and community buildings occupied by study subjects during or prior to the study period). A portion of the community-wide indoor dust exposures (due to occupying daycare facilities) was addressed in the Calabrese et al. (1989) and Barnes (1990) studies, but not in the other three key tracer element studies. In addition, if the key studies' vacuum cleaner collection method for household and daycare indoor settled dust samples influenced tracer element composition of indoor settled dust samples, the dust sample collection method would be another area of uncertainty with the key studies' indoor dust-related estimates. The survey response studies suggest that some young children may prefer ingesting dust to ingesting soil. The existing literature on soil versus

dust sources of children's lead exposure may provide useful information that has not yet been compiled for use in soil and dust ingestion recommendations.

Regarding the issue of fecal sample weights and the related issue of missing fecal and urine samples, the key tracer element studies have varying strengths and limitations. The Calabrese et al. (1989) article stated that wipes and toilet paper were not collected by the researchers, and thus fecal quantities, and soil and dust ingestion may have been underestimated. Calabrese et al. (1989) stated that cotton cloth diapers were supplied for use during the study; commodes apparently were used to collect both feces and urine for those children who were not using diapers. Barnes (1990) described cellulose and polyester disposable diapers with significant variability in silicon and titanium content and suggested that children's urine was not included in the analysis. Thus, it is unclear to what extent complete fecal and urine output was obtained for each study subject. The Calabrese et al. (1997a) study did not describe missing fecal samples and did not state whether urinary tracer element quantities were used in the soil and dust ingestion estimates, but stated that wipes and toilet paper were not collected. Missing fecal samples may have resulted in negative bias in the estimates from both of these studies. Davis et al. (1990) and Davis and Mirick (2006) were limited to children who no longer wore diapers. The authors made adjustments to the soil and dust ingestion estimates based on assumptions regarding the quantities of feces and urine in missed samples. These adjustments may have affected those studies' estimates, but the direction of the bias is uncertain. Adjustments for missing fecal and urine samples could introduce errors sufficient to cause negative estimates if missed samples were heavier than the collected samples used in the soil and dust ingestion estimate calculations.

Regarding the issue of dietary intake, the key U.S. tracer element studies have all addressed dietary (and nondietary, nonsoil) intake by subtracting calculated estimates of these sources of tracer elements from excreta tracer element quantities, or by providing study subjects with personal hygiene products that were low in tracer element content. Applying the food and nondietary, nonsoil corrections required subtracting the tracer element contributions from these nonsoil sources from the measured fecal/urine tracer element quantities. To perform this correction required assumptions to be made regarding the gastrointestinal transit time, or the time lag between inputs (food, nondietary nonsoil, and soil) and outputs (fecal and urine). The gastrointestinal transit

time assumption introduced a new potential source of bias that some authors (Stanek and Calabrese, 1995b) called input/output misalignment or transit time error. Stanek and Calabrese (1995a) attempted to correct for this transit time error by using the BTM and focusing estimates on those tracers that had low food:soil tracer concentration ratios. The lag time may also be a function of age. Davis et al. (1990) and Davis and Mirick (2006) assumed a 24-hour lag time in contrast to the 28-hour lag times used in Calabrese et al. (1989), Barnes (1990), and Calabrese et al. (1997a). ICRP (2002) suggested a lag time of 37 hours for 1-year-old children and 5- to 15-year-old children. Stanek and Calabrese (1995b) describe a method designed to reduce bias from this error source. Lag times that are shorter or longer than what is assumed may result in misalignment of the intake of tracers and their output. The direction of these biases is difficult to predict.

Regarding gastrointestinal absorption, the authors of three of the studies appeared to agree that the presence of silicon in urine represented evidence that silicon was being absorbed from the gastrointestinal tract (Davis et al., 1990; Calabrese et al., 1989; Barnes, 1990; Davis and Mirick, 2006). There was some evidence of aluminum absorption in Calabrese et al. (1989) and Barnes (1990); Davis and Mirick (2006) stated that aluminum and titanium did not appear to have been absorbed, based on low urinary levels. Davis et al. (1990) stated that silicon appears to have been absorbed to a greater degree than aluminum and titanium, based on urine concentrations. Absorption of these tracer elements would likely bias the estimated soil and dust ingestion rates low, because intake of the tracer elements would not be accounted for in the excreta if they had been absorbed. More research to better understand the uptake of these tracer elements may be warranted.

Aside from the gastrointestinal absorption, lag time, and missed fecal sample issues, Davis and Mirick (2006) offered another possible explanation for the negative soil and dust ingestion rates estimated for some study participants. Negative values result when the tracer amount in food and medicine is greater than that in urine/fecal matter. Given that some analytical error may occur, any overestimation of tracer amounts in the food samples would be greater than an overestimation in urine/feces because the food samples were many times heavier than the urine and fecal samples. Overestimating the amount of tracers ingested via food and medicines would tend to negatively bias soil and dust ingestion estimates while underestimating the amount of tracers ingested via

foods and medicines would tend to positively bias soil and dust ingestion estimates. Interactions among elements in the gastrointestinal tract, in particular fluoride from ingested toothpaste, and how these may affect the absorption of tracer elements are not available based on the studies reviewed for this chapter.

Another limitation on the accuracy of tracer element-based estimates of soil and dust ingestion relates to inaccuracies inherent in environmental sampling and laboratory analytical techniques. The "percent recovery" of different tracer elements varies (according to validation of the study methodology performed with adults who swallowed gelatin capsules with known quantities of sterilized soil, as part of the Calabrese et al. [1989, 1997a] studies). Digestion/extraction efficiencies also vary by media type (e.g., food, soil, medicine). Estimates based on a particular tracer element with a lower or higher recovery than the expected 100% in any of the study samples would be influenced in either a positive or negative direction, depending on the recoveries in the various samples and their degree of deviation from 100% (Calabrese et al., 1989). Soil/dust size fractions, and digestion/extraction methods of sample analysis may be additional limitations.

Davis et al. (1990) offered an assessment of the impact of swallowed toothpaste on the tracer-based estimates by adjusting estimates for those children whose caregivers reported that they had swallowed toothpaste. Davis et al. (1990) had supplied study children with toothpaste that had been preanalyzed for its tracer element content, but it is not known to what extent the children actually used or swallowed the supplied toothpaste. Similarly, Calabrese et al. (1989, 1997a) supplied children in the Amherst, MA and Anaconda, MT studies with toothpaste containing low levels of most tracers, but it is unclear to what extent those children used or swallowed the supplied toothpaste. Not accounting for the consumption of toothpaste or other materials that contain the tracer elements would tend to bias soil and dust ingestion rates in the positive direction, but over-predicting the amount of tracers consumed in these materials would have the opposite effect.

Other research suggests additional possible limitations that have not yet been explored. First, lymph tissue structures in the gastrointestinal tract might serve as reservoirs for titanium dioxide food additives and soil particles, which could bias estimates either upward or downward depending on the tracers' entrapment within, or release from, these reservoirs during the study period (ICRP, 2002; Shepherd et al., 1987; Powell et al., 1996). Second,

gastrointestinal uptake of silicon may have occurred, which could bias those estimates downward. There is an increasing body of evidence that silicon is an essential nutrient and that it plays a role in the initiation of the mineralization process and bone formation (Chen et al., 2016; Nielsen, 2014; Price et al., 2012; Jugdaohsingh, 2007; Carlisle, 1980). However, absorption of silicon in the gastrointestinal tract is not well understood (Jugdaohsingh et al., 2002). Van Dyck et al. (2000) suggests a possible negative bias in the silicon-based soil ingestion estimates, depending on the quantities of silicon absorbed by growing children. Third, regarding the potential for swallowed toothpaste to bias soil ingestion estimates upward, commercially available toothpaste may contain quantities of titanium and perhaps silicon and aluminum in the range that could be expected to affect the soil and dust ingestion estimates. Fourth, for those children who drank bottled or tap water during the study period, and did not include those drinking water samples in their duplicate food samples, slight upward bias may exist in some of the estimates for those children because drinking water may contain small, but relevant, quantities of silicon and potentially other tracer elements. Fifth, the tracer element studies conducted to date have not explored the impact of soil properties' influence on toxicant uptake or excretion within the gastrointestinal tract. Nutrition researchers investigating influence of clay geophagy behavior on human nutrition have begun using in vitro models of human digestion (Dominy et al., 2003; Hooda et al., 2004). A recent review (Wilson, 2003) covers a wide range of geophagy research in humans and various hypotheses proposed to explain soil ingestion behaviors, with emphasis on the soil properties of geophagy materials.

5.4.2. Biokinetic Model Comparison Methodology

It is possible that the IEUBK biokinetic model comparison methodology contained sources of both positive and negative bias, like the tracer element studies, and that the net impact of the competing biases is not known. There may be several significant sources of bias with the biokinetic model comparison methodology. One source of potential bias was the possibility that the biokinetic model cannot account for sources of lead exposure that are important for certain children due to incomplete exposure characterizations. For these children, the model might under-predict blood lead levels compared to actual measured lead levels. However, this result may actually mean that the default

assumed lead intake rates via either soil and dust ingestion, or another lead source that is accounted for by the model, are too high. Another source of potential bias includes not accounting for the variability in the children's blood lead levels with time. There are also uncertainties with regard to the representativeness of the media concentrations in the children's play areas. For example, there is potential bias when predicting blood lead levels in children who have not spent a significant amount of time in the areas characterized as the main sources of environmental lead exposure. Modeling this population could result in either upward or downward biases in predicted blood lead levels. Comparing upward-biased predictions with actual measured blood lead levels and finding a relatively good match could lead to inferences that the model's default soil and dust ingestion rates are accurate, when in fact the children's soil and dust ingestion rates, or some other lead source, were actually higher than the default assumption. Von Lindern et al. (2016) attempted to address the issue of representativeness by assuming different partition models (i.e., percentage of time spent at various soil-contact locations).

Additionally, there is uncertainty with the assumption within the model itself regarding the biokinetics of absorbed lead, which could result in either positively or negatively biased predictions and the same kinds of incorrect inferences as the second source of potential bias. Another source of bias is the education and intervention programs implemented at contaminated sites which can potentially result in children's temporary reduction in soil/dust ingestion rates (see Section 5.4.4) (von Lindern et al., 2016).

In addition, there was no extensive sensitivity analysis. The calibration step used to fix model parameters limits the degree that most parameters can reasonably be varied. Second, the IEUBK model was not designed to predict blood lead levels greater than 25–30 µg/dL; there are few data to develop such predictions and less to validate them. If there are site-specific data that indicate soil ingestion rates (or other ingestion/intake rates) are higher than the defaults on average (not for specific children), the site-specific data should be considered. EPA considers the default IEUBK value of 30% bioavailability reasonable for most data sets/sites. Bioavailability has been assayed for soils similar to those in the calibration step and the empirical comparison data sets; 30% was used in the calibration step, and is therefore recommended for similar sites. The default provides a reasonable substitute when there are no specific data. Speciation of lead compounds for a particular exposure scenario

could support adjusting bioavailability if they are known to differ strongly from 30%. The use of the 30% bioavailability was further supported by von Lindern et al. (2016). In general, EPA supports using bioavailability rates determined for the particular soils of interest if available.

5.4.3. Activity Pattern Methodology

The limitations associated with the activity pattern methodology relate to the availability and quality of the underlying data used to model soil ingestion rates. Some examples where data are limited or lacking include: information on the activities and environments of very young children (e.g., hand-to-mouth, object-to-mouth, and pica behaviors), information on skin adherence and dust loadings on indoor objects and floors (bare and carpeted), as well as the transfer of dust from both bare floors and carpets to hands, soil loadings to hands while playing outdoors, and information to evaluate temporal variability. Soil properties that may also be important include: soil particle size, organic content, moisture content, and other properties that affect soil adherence to the skin.

Real-time hand recording, where observations are made by trained professionals (rather than parents), may offer the advantage of consistency in interpreting visible behaviors and may be less subjective than observations made by someone who maintains a care-giving relationship to the child. On the other hand, young children's behavior may be influenced by the presence of unfamiliar people (Davis et al., 1995). Groot et al. (1998) indicated that parent observers perceived that deviating from their usual care-giving behavior by observing and recording mouthing behavior appeared to have influenced the children's behavior. With video-transcription methodology, an assumption is made that the presence of the videographer or camera does not influence the child's behavior. This assumption may result in minimal biases introduced when filming newborns or when the camera and videographer are not visible to the child. However, if the children being studied are older than newborns and can see the camera or videographer, biases may be introduced. Ferguson et al. (2006) described apprehension caused by videotaping and described situations where a child's awareness of the videotaping crew caused "play-acting" to occur, or parents indicated that the child was behaving differently during the taping session. Another possible source of measurement error may be introduced when children's movements or positions cause their mouthing not to be captured by the

camera. Data transcription errors can bias results in either the negative or positive direction (i.e., underestimating mouthing behavior may bias results low while overestimating mouthing behavior may bias estimates high). Also, measurement error can occur if situations arise in which caregivers are absent during videotaping and researchers must stop videotaping and intervene to prevent risky behaviors (Zartarian et al., 1995). Finally, the videography studies have relatively small sample sizes, and the number of children studied and their method of selection may not be entirely representative of the population of the US.

Survey response studies rely on responses to questions about a child's mouthing behavior posed to parents or caregivers. Measurement errors from these studies could occur for a number of different reasons, including language/dialect differences between interviewers and respondents, question wording problems and lack of definitions for terms used in questions, differences in respondents' interpretation of questions, and recall/memory effects.

Other data collection methodologies (in-person interview, mailed questionnaire, or questions administered in "test" format in a school setting) may have had specific limitations. In-person interviews could result in either positive or negative response bias due to distractions posed by young children, especially when interview respondents simultaneously care for young children and answer questions. Other limitations include positive or negative response bias due to respondents' perceptions of a "correct" answer, question wording difficulties, lack of understanding of definitions of terms used, language and dialect differences between investigators and respondents, respondents' desires to avoid negative emotions associated with giving a particular type of answer, and respondent memory problems ("recall" effects) concerning past events. Positive biases would tend to occur when respondents overestimate behaviors that could result in soil and dust ingestion; negative biases would tend to occur when respondents underestimate behaviors that could result in soil and dust ingestion. Mailed questionnaires have many of the same limitations as in-person interviews, but may allow respondents to respond when they are not distracted by childcare duties. An in-school test format is more problematic than either interviews or mailed surveys because respondent bias related to teacher expectations could influence responses.

One approach to evaluating the degree of bias in survey response studies may be to make use of a surrogate biomarker indicator providing suggestive

evidence of ingestion of significant quantities of soil (although quantitative estimates would not be possible). The biomarker technique measures the presence of serum antibodies to *Toxocara* species, a parasitic roundworm from cat and dog feces. Two U.S. studies have found associations between reported soil ingestion and positive serum antibody tests for *Toxocara* infection (Marmor et al., 1987; Glickman et al., 1981); a third (Nelson et al., 1996) has not, but the authors stated that reliability of survey responses regarding soil ingestion may have been an issue. Further refinement of survey response methodologies, together with recent NHANES data on U.S. prevalence of positive serum antibody status regarding infection with *Toxocara* species, may be useful.

5.4.4. Environmental and Household Interventions

Some of the studies discussed in this chapter were conducted near hazardous waste sites where soil contamination was present (e.g., smelting and mining waste containing lead). Environmental and household educational interventions have occurred at many of these sites. Several studies have been published in the literature to evaluate the effectiveness of educational and environmental interventions for reducing blood lead levels in children. It may be reasonable to assume that environmental interventions (e.g., soil removal) would not have had an effect on soil and dust ingestion rates because blood lead levels may come down as a result of a reduction of lead concentrations and not a change in behavior. However, awareness of contamination and educational interventions may affect behaviors (e.g., increase in frequency of hand washing and household cleaning); thus, reducing soil ingestion rates. Researchers have studied the effectiveness of educational interventions alone in reducing blood lead levels in children (Brown et al., 2006; Jordan et al., 2003; Wasserman, 2002; Rhoads et al., 1999). These studies found a decline in blood lead levels in the intervention groups compared to the control groups. However, Rhoads et al. (1999) and Jordan et al. (2003) concluded that educational intervention was only partially effective in reducing or maintaining lower blood lead levels. Yeoh et al. (2014) conducted a meta-analysis of five studies of educational interventions (Lanphear et al., 1996; Lanphear et al., 1999; Brown et al., 2006; Jordan et al., 2003; and Wasserman, 2002). The meta-analysis of the log-transformed data from these five studies showed that there was no statistical significant reduction in blood lead levels (Yeoh et al., 2014).

However, another factor that may affect the results observed in these intervention studies is that bone turnover in children occurs at a higher rate than that of an adult, resulting in longer half-life of lead in blood (8 to 11 months for acute exposure and 20 to 38 months for chronic exposures), thus, providing a continuous source of lead in blood (Yeoh et al., 2014). With the exception of Jordan et al. (2003), who conducted quarterly booster sessions with participants for 2 years after the first year of educational intervention, the duration of these intervention studies was 12 months or less.

5.4.5. Key Studies: Representativeness of the U.S. Population

Limitations regarding the key studies performed in the United States for estimating soil and dust ingestion rates in the entire population of U.S. children ages 0 to <21 years fall into the broad categories of geographic range and demographics (age, sex, race/ethnicity, socioeconomic status).

Regarding geographic range, the two most obvious issues relate to soil types and climate. Soil properties might influence the soil ingestion estimates that are based on excreted tracer elements. The Davis et al. (1990), Calabrese et al. (1989), Barnes (1990), Calabrese et al. (1997a), and Davis and Mirick (2006) tracer element studies were conducted in locations with soils that had sand content ranging from 21–80%, silt content ranging from 16–71%, and clay content ranging from 3–20% by weight, based on data from USDA (2008). The location of children in the Calabrese et al. (1997b) study was not specified, but due to the original survey response study's occurrence in western Massachusetts, the soil types in the vicinity of the Calabrese et al. (1997b) study are likely to be similar to those in the Calabrese et al. (1989) and Barnes (1990) study.

The Hogan et al. (1998) study included locations in the central part of the United States (an area along the Kansas/Missouri border, and an area in western Illinois) and one in the eastern United States (Palmerton, PA). The Davis et al. (1990) study was conducted in Washington State, Von Lindern et al. (2016) was conducted in Idaho, and Wilson et al. (2013) was conducted in Canada. The only key study conducted in the southern part of the United States was Vermeer and Frate (1979).

Children might be outside and have access to soil in a very wide range of weather conditions (Wong et al., 2000). In the parts of the United States that experience moderate temperatures year-round, soil ingestion rates may be fairly evenly distributed

throughout the year. During conditions of deep snow cover, extreme cold, or extreme heat, children could be expected to have minimal contact with outside soil. All children, regardless of location, could ingest soils located indoors in plant containers, soil derived particulates transported into dwellings as ambient airborne particulates, or outdoor soil tracked inside buildings by human or animal building occupants. Davis et al. (1990) did not find a clear or consistent association between the number of hours spent indoors per day and soil ingestion, but reported a consistent association between spending a greater number of hours outdoors and high (defined as the uppermost tertile) soil ingestion levels across all three tracers used.

The key tracer element studies all took place in northern latitudes. The temperature and precipitation patterns that occurred during these four studies' data collection periods were difficult to discern due to no mention of specific data collection dates in the published articles. The Calabrese et al. (1989) and Barnes (1990) study apparently took place in mid to late September 1987 in and near Amherst, MA; Calabrese et al. (1997a) apparently took place in late September and early October 1992, in Anaconda, MT; Davis et al. (1990) took place in July, August, and September 1987, in Richland, Kennewick, and Pasco, WA; and Davis and Mirick (2006) took place in the same Washington state location in late July, August, and very early September 1988 (raw data). Inferring exact data collection dates, a wide range of temperatures may have occurred during the four studies' data collection periods (daily lows from 22–60°F and 25–48°F, and daily highs from 53–81°F and 55–88°F in Calabrese et al. [1989] and Calabrese et al. [1997a], respectively, and daily lows from 51–72°F and 51–67°F, and daily highs from 69–103°F and 80–102°F in Davis et al. [1990] and Davis and Mirick [2006], respectively) (NCDC, 2006). Significant amounts of precipitation occurred during Calabrese et al. (1989) (more than 0.1 inches per 24-hour period) on several days; somewhat less precipitation was observed during Calabrese et al. (1997a); precipitation in Kennewick and Richland during the data collection periods of Davis et al. (1990) was almost nonexistent; there was no recorded precipitation in Kennewick or Richland during the data collection period for Davis and Mirick (2006) (NCDC, 2006).

One key biokinetic model comparison study (Hogan et al., 1998) targeted three locations in more southerly latitudes (Pennsylvania, southern Illinois, and southern Kansas/Missouri) than the tracer element studies. The other key biokinetic model comparison study was conducted in Idaho. The

biokinetic model comparison methodology had an advantage over the tracer element studies in that the study represented long-term environmental exposures over periods up to several years that would include a range of seasons and climate conditions.

A brief review of the representativeness of the key studies' samples with respect to sex and age suggested that males and females were represented roughly equally in those studies for which study subjects' sex was stated. Children up to age 12 years were studied in the key studies with an emphasis on younger children.

A brief review of the representativeness of the key studies' samples with respect to socioeconomic status and racial/ethnic identity suggested that there were some discrepancies between the study subjects and the current U.S. population of children age 0 to <21 years. The single survey response study (Vermeer and Frate, 1979) was specifically targeted toward a predominantly rural Black population in a particular county in Mississippi. The tracer element studies are of predominantly White populations, apparently with limited representation from other racial and ethnic groups. The Amherst, MA study (Calabrese et al., 1989; Barnes, 1990) did not publish the study participants' socioeconomic status or racial and ethnic identities. The socioeconomic level of children studied by Davis et al. (1990) was reported to be primarily of middle to high income. Self-reported race and ethnicity of relatives of the children studied (in most cases, they were the parents of the children studied) in Davis et al. (1990) were White (86.5%), Asian (6.7%), Hispanic (4.8%), Native American (1.0%), and Other (1.0%), and the 91 married or living-as-married respondents identified their spouses as White (86.8%), Hispanic (7.7%), Asian (4.4%), and Other (1.1%). Davis and Mirick (2006) did not state the race and ethnicity of the follow-up study participants, who were a subset of the original study participants from Davis et al. (1990). For the Calabrese et al. (1997a) study in Anaconda, MT, population demographics were not presented in the published article. The study sample appeared to have been drawn from a door-to-door census of Anaconda residents that identified 642 toilet-trained children who were less than 72 months of age. Of the 414 children participating in a companion study (out of the 642 eligible children identified), 271 had complete study data for that companion study, and of these 271, 97.4% were identified as White and the remaining 2.6% were identified as Native American, Black, Asian, and Hispanic (Hwang et al., 1997). The 64 children in the Calabrese et al. (1997a) study apparently were a

stratified random sample (based on such factors as behavior during a previous study, the existence of a disability, or attendance in daycare) drawn from the 642 children identified in the door-to-door census. Presumably these children identified as similar races and ethnicities to the Hwang et al. (1997) study children. The Calabrese et al. (1997b) study indicated that 11 of the 12 children studied were White.

In summary, the geographic range of the key study populations was somewhat limited. Of those performed in North America, U.S. locations include Massachusetts, Kansas, Montana, Missouri, Illinois, Washington, Pennsylvania, and Idaho. Canada is also represented. The two most obvious issues regarding geographic range relate to soil types and climate. Soil types were not always described, so the representativeness of the key studies related to soil types and properties is unclear. The key tracer element studies all took place in northern latitudes. The only key study conducted in the southern part of the United States was Vermeer and Frate (1979).

In terms of sex and age, males and females were represented roughly equally in those studies for which study subjects' sex was stated, while the majority of children studied were under the age of eight. The tracer element studies are of predominantly White populations, with a single survey response study (Vermeer and Frate, 1979) targeted toward a rural Black population. Other racial and ethnic identities were not well reported among the key studies, nor was socioeconomic status.

5.5. DERIVATION OF RECOMMENDED SOIL AND DUST INGESTION VALUES

Table 5-34 summarizes the soil and dust ingestion estimates from the key studies for general population children, by age range, based on the tracer, biokinetic modeling, and activity patterns approaches. These three methods were given equal weight in deriving the recommendation because of the inherent limitations in all of the methods (see Section 5.4). Also, there is no supportive evidence to suggest that one method provides more reliable estimates than the other.

The mean and upper percentile recommendations were derived by averaging the values for each age group for each of the three study methodologies and then taking the average of the three study types, as follows:

$$IR_{soil + dust} = (IR_t + IR_b + IR_a) / 3 \quad (\text{Eqn 5-15})$$

Where:

$IR_{soil + dust}$ = age-specific mean (or 95th percentile) soil + dust ingestion rate (mg/day)

IR_t = average of the age-specific mean (or 95th percentile) soil + dust ingestion rates from the various tracer studies (mg/day);

IR_b = average of the age-specific mean (or 95th percentile) soil + dust ingestion rates from the various biokinetic modeling comparison studies (mg/day);

IR_a = average of the age-specific mean (or 95th percentile) soil + dust ingestion rates from the various activity pattern modeling studies.

For example, the mean soil + dust ingestion rate for children 1 to <6 years was estimated as follows (see Table 5-34 for additional details):

$$IR_{soil + dust} = (IR_t [99 \text{ mg/day}] + IR_b [90 \text{ mg/day}] + IR_a [65 \text{ mg/day}]) / 3$$

$$IR_{soil + dust} = 84 \text{ mg/day}$$

Where:

IR_t = average of 132, 69, 66, and 129 mg/day (means from 4 tracers studies that represent children 1 to <6 years of age) = 99 mg/day;

IR_b = average of 113 and 67 mg/day (means from 2 biokinetic modeling studies that represent children 1 to <6 years of age) = 90 mg/day;

IR_a = average of 68 and 61 mg/day (means from 2 activity pattern studies that represent children 1 to <6 years) = 65 mg/day.

Using the number of study participants in the various studies to weight the means and upper percentile estimates would not change the recommended values, when rounded to one significant figure. Also, although there might be alternatives to averaging upper percentile values to get an upper percentile value, it does not appear that other approaches would significantly change the upper percentile values for these data because the upper percentile values from all study types are similar when rounded to one significant figure.

As stated earlier in this chapter, the key studies were used as the basis for developing the soil and dust ingestion recommendations shown in Table 5-1. The following sections describe in more detail how the recommended soil and dust ingestion, soil pica, and geophagy values were derived. Appendix B

provides a comparison of data from the tracer studies conducted in Amherst, MA, Washington State, Anaconda, MT, and western MA. Appendix C provides a detailed summary of the key studies used in developing the recommended soil and dust ingestion rates. Appendix D provides a detailed summary of the studies on the prevalence of pica.

5.5.1. Central Tendency Soil and Dust Ingestion Recommendations

In general, “central tendency” recommendations in this chapter reflect an arithmetic mean (average) of measured values within a study, across studies within a methodology, and across the three methodologies. For some studies, arithmetic means were not available from the study, and some other central estimate was used. For example, for some of the tracer studies, the means represent the average of the median values for multiple tracers for each child. As noted, when describing how different estimates were averaged, there is uncertainty as to what is a central estimate consumption rate. Also, for some studies, the age groups evaluated did not match the age stratifications in EPA’s *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). However, for the purpose of providing recommended values for use in risk assessment, the ages were assumed to represent the age categories that they most closely matched.

For infants of 0 to <6 months in age, the recommended central tendency soil + dust ingestion estimate for use in risk assessments is 40 mg/day (36 mg/day rounded to one significant figure). This value is based on a single key activity pattern modeling study that provided data for infants 0 to <7 months (Wilson et al., 2013). Based on the assumption that 45% of the soil + dust ingestion can be attributed to soil and 55% can be attributed to dust, as in EPA’s IEUBK model for lead in older children (U.S. EPA, 1994a), the central tendency soil ingestion rate for infants 0 to <6 months of age is 18 mg/day and the dust ingestion rate is 22 mg/day. Rounded to one significant figure, both soil and dust mean ingestion estimates for infants 0 to <6 months of age are 20 mg/day. Because the Wilson et al. (2013) study did not include exposures from object-to-mouth contact, the recommended values provided here may underestimate soil + dust ingestion among this age group.

For infants, 6 months to <1 year, data from two key biokinetic modeling studies were used to estimate a central tendency soil + dust ingestion rate of 70 mg/day; no key tracer studies or activity

pattern modeling studies were available for this age group. This value is based on the average of the central estimate generated by von Lindern et al. (2016) and an EPA-adjusted central estimate from Hogan et al. (1998). Using the IEUBK model, Hogan et al. (1998) reported a predicted geometric mean blood lead level that was 1.4-fold higher than the geometric mean blood lead levels observed for 31 children 6- to 12-months old from a site in Illinois. The default soil and dust intakes for the 6- to 12-month old infants in the model (U.S. EPA, 1994b) are 38 mg soil/day and 47 mg house dust/day, for a total soil + dust intake of 85 mg/day for this life stage (U.S. EPA, 1994a). Assuming all other model input parameters are roughly accurate, EPA adjusted the default ingestion rate of 85 mg/day by a factor of 1.4 to estimate a soil + dust ingestion rate of 61 mg/day. Also using the biokinetic modeling approach, von Lindern et al. (2016) reported a mean value of 81 mg/day for children 6 months to <1 year of age, based on the average of the two best-fit model runs, as described in Section 5.3.3.7. The average of the estimates from these two biokinetic modeling studies is 71 mg/day (rounded to 70 mg/day). Based on the assumption that 45% of the soil + dust ingestion can be attributed to soil and 55% can be attributed to dust, as in EPA’s IEUBK model for lead (U.S. EPA, 1994a), the central tendency soil ingestion rate for infants 6 months to <1 year of age is 32 mg/day and the dust ingestion rate is 38 mg/day. Rounded to one significant figure, the mean soil-only estimate is 30 mg/day and the mean dust-only estimate is 40 mg/day.

For children 1 to <2 years and children 2 to <6 years, the recommended central tendency soil + dust ingestion estimate for use in risk assessments are 90 mg/day (92 mg/day rounded to one significant figure) and 60 mg/day (62 mg/day rounded to one significant figure), respectively. These values are based on a single key biokinetic modeling study that provided data for these age groups (von Lindern et al., 2016). The averages of the two best-fit model runs were used for these age groups (see Section 5.3.3.7). Based on the assumption that 45% of the soil + dust ingestion can be attributed to soil and 55% can be attributed to dust, as in EPA’s IEUBK model (U.S. EPA, 1994a) for lead, the central tendency soil ingestion rate for children 1 to <2 years of age is 41 mg/day and the dust ingestion rate is 49 mg/day. Rounded to one significant figure, the soil ingestion rate is 40 mg/day and the dust ingestion rate is 50 mg/day for children 1 to <2 years old. For children 2 to <6 years, the soil-only estimate is 27 mg/day and the dust-only value is 33 mg/day. Rounded to one significant

figure, both soil and dust mean ingestion estimates for infants 2 to <6 years of age are 30 mg/day.

For children ages 1 to <6 years the recommended central tendency ingestion rate for use in risk assessment is 80 mg/day. This value is based on estimates provided by studies conducted using tracer, biokinetic modeling, and activity pattern modeling approaches. Four key tracer studies (Calabrese et al. [1989] as reanalyzed by Stanek and Calabrese [1995a]; Davis et al. [1990] as reanalyzed by Stanek and Calabrese [1995a]; Calabrese et al. [1997a,b]) estimated central tendency soil and dust ingestion rates for children ranging in age from 1 to <8 years ($N = 241$). The estimates ranged from 66 to 132 mg/day, with an average of 99 mg/day. For the Calabrese et al. (1989) study, as reanalyzed by Stanek and Calabrese et al. (1995a), the average of the median of the best four tracers for each child was used in developing the recommendations for children 1 to <6 years of age. Stanek and Calabrese et al. (1995a) suggest that this is the most reliable estimate for this data set. For the Davis et al. (1990) study, as reanalyzed by Stanek and Calabrese (1995a), data for only three tracers were available, and the average of the median of these three tracers was used. For the Calabrese et al. (1997a) study, the average based on the best tracer for each child was used. This estimate was assumed to be more reliable than the average of the best four tracers because the central tendency estimates for some of the four individual tracers were negative. For Calabrese et al. (1997b), data were available for aluminum, silicon, and titanium. However, only the data for aluminum and silicon were used, given the high degree of variability in the titanium estimates. The results of two biokinetic modeling studies were used (Hogan et al., 1998; von Lindern et al., 2016) in developing the recommendations for children 1 to <6 years of age. In the Hogan et al. (1998) study, blood levels for 471 children were similar to those predicted by the IEUBK model. The IEUBK default soil + dust ingestion values used in the Hogan et al. (1998) biokinetic modeling study were 135 mg/day for 1-, 2-, and 3-year-olds; 100 mg/day for 4-year-olds; 90 mg/day for 5-year-olds; and 85 mg/day for 6-year-olds (U.S. EPA 1994b, 2007). The time-averaged daily soil + dust ingestion rate for these 6 years of life was 113 mg/day. Also, using the biokinetic modeling approach, von Lindern et al. (2016) estimated a mean soil ingestion rate of 68 mg/day for children 1 to <6 years of age ($N = 1,075$), based on the average of the two best-fit model runs, as described in Section 5.3.3.6. The average based on these two biokinetic model studies is 91 mg/day. The two activity pattern modeling

studies provide somewhat lower soil + dust ingestion estimates for this life stage. Özkaynak et al. (2011) provided an estimate of 68 mg/day for 3- to <6-year-old children, and Wilson et al. (2013) provided an estimate of 61 mg/day for children aged 7 months to <5 years. The mean of these two estimates is 65 mg/day. Averaging the soil + dust ingestion estimates from the three approaches yields a soil + dust ingestion estimate of 84 mg/day which was rounded to 80 mg/day. Based on the assumption that 45% of the soil + dust ingestion can be attributed to soil and 55% can be attributed to dust, the central tendency estimates for soil and dust ingestion alone are both 40 mg/day, rounded to one significant figure (i.e., 36 mg/day soil and 44 mg/day dust) for children 1 to <6 years old. Although children 1 to <6 years old have been grouped together for the purposes of deriving this recommendation, it is important to note that children ages 1 to <2 years have been reported to have higher blood lead levels compared to other children (Hogan et al., 1998). This age group also presents higher mouthing behavior frequency (i.e., hand-to-mouth and object-to-mouth) than other age groups based on the available data (See Chapter 4 of this handbook). Default soil ingestion rates used in the IEUBK model are higher for this age group than for older aged children, and von Lindern et al. (2016) showed that soil ingestion rate for this age group was the highest among all of the age groups evaluated up to <10 years of age, with an estimated value of 93 mg/day. The recommended soil ingestion rate for 1- to <2-year-olds for use in risk assessment is 90 mg/day, based on the von Lindern et al. (2016) study, as discussed above.

For children 6 to <12 years old, the recommended central tendency soil + dust ingestion rate is based on data from one biokinetic modeling study (von Lindern et al., 2016) and one activity pattern modeling study (Wilson et al., 2013). Based on biokinetic modeling, soil + dust ingestion was estimated to be 56 mg/day for 6- to <10-year-olds, based on the average of two best-fit model runs conducted by von Lindern et al. (2016) (see Section 5.3.3.7). The estimate for 5- to <12-year-olds, predicted by Wilson et al. (2013) using the activity pattern modeling was also 55 mg/day. The average of these two estimates is 56 mg/day. Rounded to one significant figure, the central tendency soil + dust ingestion rate for this life stage is 60 mg/day. Again, assuming that 45% of the soil + dust ingestion can be attributed to soil and 55% can be attributed to dust, the central tendency estimates for soil and dust ingestion alone are both 30 mg/day, rounded to one significant figure, for 6- to <12-year-old children.

For older children (i.e., ages 12 to <19 years) and general population adults (i.e., ages ≥ 19 years), the recommended central tendency soil + dust ingestion rate is 30 mg/day. This is based on data from one key tracer study for adults (Davis and Mirick, 2006) and one activity pattern modeling study (Wilson et al., 2013). Davis and Mirick (2006) reported a mean soil + dust ingestion rate of 52 mg/day for 33 adults, based on average estimates using aluminum and silicon as tracers. Wilson et al. (2013) used an activity pattern modeling approach to estimate soil + dust ingestion among various age groups, including teens (ages 12 to <20 years), adults (ages 20 to 59 years), and senior (ages 60+ years). The estimated soil + dust ingestion rates were 3.7 mg/day for teens, 4.2 mg/day for adults, and 3.8 mg/day for seniors. Given the similarity in these estimates, the three ages group were combined into one category (i.e., 12 years through adults), with a central tendency soil + dust ingestion estimate of 4 mg/day. Averaging the estimates from the Davis and Mirick (2006) tracer study and the Wilson et al. (2013) activity pattern modeling study results in a central tendency soil + dust ingestion estimate of 28 mg/day. Rounded to one significant figure, this value is 30 mg/day. Assuming that 45% of the soil + dust ingestion can be attributed to soil and 55% can be attributed to dust, the central tendency estimate for soil is 13 mg/day and the estimate for dust is 17 mg/day. Rounded to one significant figure, the central tendency estimates are 10 mg/day and soil and 20 mg/day dust.

For rural populations following traditional rural or wilderness lifestyles as described by Doyle et al. (2012) and Irvine et al. (2014) adult soil ingestion rates may be somewhat higher than those of the general population (see Sections 5.3.4.20 and 5.3.4.21). Doyle et al. (2012) conducted a tracer study in Canada in which the estimated mean soil + dust was 42 mg/day based on the average values for aluminum and silicon tracers. Irvine et al. (2014) also conducted a tracer study in Canada and estimated a mean soil + dust ingestion rate of 52 mg/day, based on the aluminum and silicon tracers. The average of these two values is 47 mg/day. Rounded to one significant figure, the soil + dust ingestion estimate is 50 mg/day (20 mg/day soil and 30 mg/day dust).

5.5.2. Upper Percentile, Soil Pica, and Geophagy Recommendations

In general, there is considerably more uncertainty related to the upper percentile soil and dust ingestion rate estimates than for the average

estimates. Biases due to the errors (e.g., sampling errors, measurement errors, analytical errors, etc.) are more likely to affect the upper percentile estimates than the average estimates. The use of data obtained from short-term studies to represent long-term usual behavior also introduces biases that may have a more considerable effect on the upper percentile estimates.

The upper percentile soil + dust ingestion rate for infants 0 to <6 months of age was estimated to be 100 mg/day. This value is based on a single key activity pattern modeling study that provided a soil + dust ingestion rate of 140 mg/day for infants 0 to <7 months (Wilson et al., 2013). Rounded to one significant figure, this value is 100 mg/day. Based on the assumption that 45% of the soil + dust ingestion can be attributed to soil and 55% can be attributed to dust, as in EPA's IEUBK model for lead in older children (U.S. EPA, 1994a), the upper percentile soil ingestion rate for infants 0 to <6 months of age is 45 mg/day and the dust ingestion rate is 55 mg/day. Rounded to one significant figure, the soil ingestion rate is assumed to be 50 mg/day for soil and 60 mg/day for dust for infants 0 to <6 months of age. An uncertainty associated with this estimate is that the Wilson et al. (2013) study did not include exposures from object-to-mouth contact. Thus, the recommended values provided here may underestimate soil + dust ingestion among this age group.

The recommended upper percentile soil + dust ingestion rate for infants 6 months to <1 year is 200 mg/day. This value is based on data from one biokinetic modeling study. Von Lindern et al. (2016) provided a 95th percentile value of 208 mg/day, based on the average of two best-fit model runs (see Section 5.3.3.6), which has been rounded to 200 mg/day. It is assumed that 90 mg/day represents soil ingestion and 110 mg/day represents dust ingestion, based on the assumption that 55% of the 200 mg/day is soil and 45% is dust. Rounded to one significant figure the recommended upper percentile ingestion rates for infants 6 months to 1 year of age are 90 mg/day soil and 100 mg/day dust.

The von Lindern et al. (2016) biokinetic modeling study was also used as the basis for the upper percentile soil + dust ingestion rate for children 1 to <2 years of age and 2 to <6 years of age. For 1- to <2-year-olds, the upper percentile soil + dust ingestion rate was 240 mg/day, based on the average of two best-fit model runs (see Section 5.3.3.6). Rounded to one significant figure, the soil + dust ingestion recommendation for use in risk assessment is 200 mg/day (90 mg/day soil; 100 mg/day dust). For children ages 2 to <6 years, von

Lindern et al. (2016) reported an upper percentile soil + dust ingestion rate of 162 mg/day, based on the average of two best-fit model runs. Rounded to one significant figure, the soil + dust ingestion recommendation for use in risk assessment is also 200 mg/day (90 mg/day soil; 100 mg/day dust).

For children 1 to <6 years old, upper percentile soil + dust ingestion rates were derived from three tracer studies that used the BTM approach, one biokinetic study, and two activity pattern studies. The 95th percentile soil + dust ingestion estimates from the three tracer studies ranged from 154 to 282 mg/day, with a mean of 227 mg/day ($N = 229$) (Calabrese et al. [1989] as reanalyzed by Stanek and Calabrese [1995a]; Davis et al. [1990]; Calabrese et al. [1997a]). Von Lindern et al. (2016) estimated a 95th percentile rate of 178 mg/day. Özkaynak et al. (2011) and Wilson et al. (2013) reported similar estimates of the 95th percentile value (i.e., 224 mg/day and 204 mg/day for age groups 3 to <6 years and 7 months to <5 years, respectively). The average of these two values is 214 mg/day. Averaging the estimates from the three approaches gives an estimated 95th percentile soil + dust ingestion rate of 206 mg/day for children ages 1 to <6 years. Rounding to one significant figure, the recommended upper percentile estimate of soil + dust ingestion is 200 mg/day (90 mg/day soil; 100 mg/day dust).

Similar upper percentile estimates were provided for older children by von Lindern et al. (2016) and Wilson et al. (2013), and the recommended soil + dust ingestion rate for risk assessment purposes is also 200 mg/day. This upper percentile recommendation is the average of the von Lindern et al. (2016) estimate of 155 mg/day for children ages 6 to <10 years and the Wilson et al. (2013) estimate of 185 mg/day for children ages 5 to <12 years. The average of these two values is 170 mg/day. Rounded to one significant figure the soil + dust ingestion recommendation for use in risk assessment is 200 mg/day (90 mg/day soil; 100 mg/day dust).

Data that could be used to develop an upper percentile soil + dust ingestion rate for ages 12 years through adult were limited. For example, an upper percentile rate was not provided in the only adult tracer study. The only data available were from a single activity pattern study that provided an upper percentile rate (i.e., 14 mg/day) for teens, adults, and seniors that is inconsistent with the recommended central tendency rate of 30 mg/day. Therefore, an upper percentile recommendation for 12 years of age through adults was developed by assuming that the ratio of the 95th percentile value to the mean value for adults is the same as the average of the ratios of

95th percentiles to means for all other age groups (i.e., average ratio of the 95th percentile recommendations to the mean recommendation for all ages groups <12 years = 3.2). It should be noted that this assumes that the variance is the same for children and adults. Because estimates for adults are lower than those of children, they are likelier to have a lower variance. Applying this ratio to the central tendency estimate of 30 mg/day for the 12 years through adult age group gives an estimated upper percentile value of 100 mg/day (i.e., $30 \text{ mg/day} \times 3.2 = 94 \text{ mg/day}$, rounded to one significant figure). If upper percentile soil- or dust-only values are needed, the recommended rates are 50 mg/day soil and 60 mg/day dust. These values are rounded to one significant figure from 45 mg/day and 55 mg/day, assuming that 45% of the soil + dust estimate is soil and 55% is dust.

For rural populations following traditional rural or wilderness lifestyles the data from tracer studies conducted in rural Canadian locations and reported in Doyle et al. (2012) and Irvine et al. (2014) (see Section 5.3.4.20 and 5.3.4.21) may be used to estimate an upper percentile soil + dust ingestion rate for this population. Doyle et al. (2012) reported a 90th percentile soil + dust ingestion rate of 124 mg/day, based on the average of the results using aluminum and silicon as tracers. Irvine et al. (2014) reported a 90th percentile value of 220 mg/day based on the average of these same two tracers. Averaging the results from these two studies gives an upper percentile estimate of 172 mg/day. Rounded to one significant figure, the upper percentile soil + dust ingestion rate for these populations would be 200 mg/day (90 mg/day soil and 100 mg/day dust).

For the upper percentile soil pica and geophagy recommendations shown in Table 5-1, two primary lines of evidence suggest that at least some U.S. children exhibit soil pica behavior at least once during childhood. First, the survey response studies of reported soil ingestion behavior that were conducted in numerous U.S. locations and of different populations consistently yield a certain proportion of respondents who acknowledge soil ingestion by children. The surveys typically did not ask explicit and detailed questions about the soil ingestion incidents reported by the caregivers who acknowledged soil ingestion in children. Responses conceivably could fall into three categories: (1) responses in which caregivers interpret visible dirt on children's hands and subsequent hand-to-mouth behavior as soil ingestion; (2) responses in which caregivers interpret intentional ingestion of clay, "dirt," or soil as soil ingestion; and (3) responses in which caregivers

regard observations of hand-to-mouth behavior of visible quantities of soil as soil ingestion. Knowledge of soils' bulk density allows one to infer that these latter observed hand-to-mouth soil ingestion incidents are likely to represent a quantity of soil that meets the quantity part of the definition of soil pica used in this chapter, or 1,000 mg. Occasionally, what is not known from survey response studies is whether the latter type of survey responses include responses regarding repeated soil ingestion that meets the definition of soil pica used in this chapter. The second category probably does represent ingestion that would satisfy the definition of soil pica as well as geophagy. The first category may represent relatively small amounts that appear to be ingested by many children based on the biokinetic modeling studies and the tracer element studies. Second, the U.S. tracer studies report a wide range of soil ingestion values. Due to averaging procedures used, for 4-, 7-, or 8-day periods, the rounded range of these estimates of soil ingestion behavior that apparently met the definition of soil pica used in this chapter is from 1,000 to 6,000 mg/day averaged over the study period. Due to the short-term nature of these studies and the limited amount of data available for children exhibiting pica behavior, the lower end of this range of 1,000 mg/day is recommended for use in risk assessments involving soil pica for children 1 to <6 years old. However, it is important to note that soil ingestion for these children exhibiting soil pica behavior has been reported as high as 20 to 25 g/day on a given day (Calabrese et al., 1997b).

Although no tracer element studies or biokinetic model comparison studies have been performed for children 15- to <21-year-olds in which soil pica behavior has been investigated, EPA is aware of one study documenting pica behavior in a group that includes children in this age range (Hyman et al., 1990). The study was not specific regarding whether soil pica (vs. other pica substances) was observed, nor did it identify the specific ages of the children observed to practice pica. In the absence of data that can be used to develop specific soil pica ingestion recommendations for children aged 15 years and 16 to <21 years, EPA recommends that risk assessors who need to assess risks via soil and dust ingestion to children ages 15 to <21 years use the same soil ingestion rate as that recommended for younger children, in the 1 to <6, 6 to <11, and 11 to <16-year age categories.

Researchers who have studied human geophagy behavior around the world typically have studied populations in specific locations, and often include investigations of soil properties as part of the

research (Wilson, 2003; Aufreiter et al., 1997). Most studies of geophagy behavior in the United States were survey response studies of residents in specific locations who acknowledged eating clays. Typically, study subjects were from a relatively small area such as a county, or a group of counties within the same state. Although geophagy behavior may have been studied in only a single county in a given state, documentation of geophagy behavior by some residents in one or more counties of a given state may suggest that the same behavior also occurs elsewhere within that state.

A qualitative description of amounts of soil ingested by geophagy practitioners was provided by Vermeer and Frate (1979) with an estimated mean amount, 50 g/day that apparently was averaged over 32 adults and 18 children. The 18 children whose caregivers acknowledged geophagy (or more specifically, eating of clay) were ($N = 16$) ages 1 to 4 and ($N = 2$) ages 5 to 12 years. The definition of geophagy used included consumption of clay "on a regular basis over a period of weeks." EPA is recommending this 50 g/day value for geophagy. This mean quantity is roughly consistent with a median quantity reported by Geissler et al. (1998) in a survey response study of geophagy in primary school children in Nyanza Province, Kenya (28 g/day, range 8 to 108 g/day; interquartile range 13 to 42 g/day).

Several studies are available that investigated pica behavior among pregnant women. Many of these studies focus on the prevalence of the behavior, and very few provide data on amounts ingested (Fawcett et al., 2016; Lin et al., 2015; Lumish et al., 2014; Klitzman et al., 2002; Simpson et al., 2000; Smulian et al., 1995; Cooksey, 1995; Bronstein and Dollar 1974; Ferguson and Keaton, 1950). Studies of pica among pregnant women in various U.S. locations (Rainville, 1998; Corbett et al., 2003; Smulian et al., 1995) suggest that clay geophagy among pregnant women may include those less than 21 years old (Smulian et al., 1995; Corbett et al., 2003). Smulian provides a quantitative estimate of clay consumption of approximately 200–500 g/week, for the very small number of geophagy practitioners ($N = 4$) in that study's sample ($N = 125$). If consumed on a daily basis, this quantity (approximately 30 to 70 g/day) is roughly consistent with the Vermeer and Frate (1979) estimated mean of 50 g/day.

Johns and Duquette (1991) describe use of clays in baking bread made from acorn flour, in a ratio of 1 part clay to 10 or 20 parts acorn flour, by volume, in a Native American population in California and in Sardinia (~12 grams clay suspended in water added

to 100 grams acorn). Either preparation method would add several grams of clay to the final prepared food; daily ingestion of the food would amount to several grams of clay.

Table 5-4. Amherst, MA Soil Pica Child's Daily Ingestion Estimates by Tracer and by Week (mg/day)		
Tracer Element	Estimated Soil Ingestion (mg/day)	
	Week 1	Week 2
Aluminum	74	13,600
Barium	458	12,088
Manganese	2,221	12,341
Silicon	142	10,955
Titanium	1,543	11,870
Vanadium	1,269	10,071
Yttrium	147	13,325
Zirconium	86	2,695
Source: Calabrese et al. (1991).		

Table 5-5. Estimated Soil Ingestion for Sample of Washington State Children (2–7 years; N = 101) ^a				
Element	Mean (mg/day)	Median (mg/day)	Standard Error of the Mean (mg/day)	Range (mg/day) ^b
Aluminum	38.9	25.3	14.4	279.0 to 904.5
Silicon	82.4	59.4	12.2	–404.0 to 534.6
Titanium	245.5	81.3	119.7	–5,820.8 to 6,182.2
Minimum	38.9	25.3	12.2	–5,820.8
Maximum	245.5	81.3	119.7	6,182.2
^a	Excludes three children who did not provide any samples.			
^b	Negative values occurred as a result of correction for nonsoil sources of the tracer elements. For aluminum, lower end of range published as 279.0 mg/day in article appears to be a typographical error that omitted the negative sign.			
Source: Adapted from Davis et al. (1990).

Table 5-9. Mean and Median Soil Ingestion (mg/day) by Family Members					
Participant	Tracer Element	Estimated Soil Ingestion ^a (mg/day)			
		Mean	Median	SD	Maximum
Children (ages 3–7 years) ^b	Aluminum	36.7	33.3	35.4	107.9
	Silicon	38.1	26.4	31.4	95.0
	Titanium	206.9	46.7	277.5	808.3
Mother ^c	Aluminum	92.1	0	218.3	813.6
	Silicon	23.2	5.2	37.0	138.1
	Titanium	359.0	259.5	421.5	1,394.3
Father ^d	Aluminum	68.4	23.2	129.9	537.4
	Silicon	26.1	0.2	49.0	196.8
	Titanium	624.9	198.7	835.0	2,899.1
^a For some study participants, estimated soil ingestion resulted in a negative value. These estimates have been set to 0 mg/day for tabulation and analysis. ^b Results based on 12 children with complete food, excreta, and soil data. ^c Results based on 16 mothers with complete food, excreta, and soil data. ^d Results based on 17 fathers with complete food, excreta, and soil data. SD = Standard deviation. Source: Davis and Mirick (2006).					

Table 5-10. Positive/Negative Error (Bias) in Soil Ingestion Estimates in Calabrese et al. (1989) Study: Effect on Mean Soil Ingestion Estimate (mg/day) ^a							
Tracer	Negative Error					Original Mean	Adjusted Mean
	Lack of Fecal Sample on Final Study Day	Other Cause ^b	Total Negative Error	Total Positive Error	Net Error		
Aluminum	14	11	25	43	+18	153	136
Silicon	15	6	21	41	+20	154	133
Titanium	82	187	269	282	+13	218	208
Vanadium	66	55	121	432	+311	459	148
Yttrium	8	26	34	22	−12	85	97
Zirconium	6	91	97	5	−92	21	113
^a	How to read table: for example, aluminum as a soil tracer displayed both negative and positive error. The cumulative total negative error is estimated to bias the mean estimate by 25 mg/day downward. However, aluminum has positive error biasing the original mean upward by 43 mg/day. The net bias in the original mean was 18 mg/day positive bias. Thus, the original 153 mg/day mean for aluminum should be corrected downward to 136 mg/day.						
^b	Values indicate impact on mean of 128 subject-weeks (64 children ages 1–4 years) in milligrams of soil ingested per day.						
Source: Calabrese and Stanek (1995).

95 th Percentile	208	254	518	17,374	224	279	398	144	117
Maximum	7,703	4,692	17,991	17,374	4,975	12,055	845	8,976	208
^a For each child, estimates of soil ingestion were formed on days 4–8, and the mean of these estimates was then evaluated for each child. The values in the column “overall” correspond to percentiles of the distribution of these means over the 64 children. When specific trace elements were not excluded via the relative standard deviation criteria, estimates of soil ingestion based on the specific trace element were formed for 108 days for each subject. The mean soil ingestion estimate was again evaluated. The distribution of these means for specific trace elements is shown. Source: Stanek and Calabrese (1995b).									

Table 5-27. Estimated Distribution of Individual Mean Daily Soil Ingestion Based on Data for 64 Subjects (Ages 1 to <4 Years) Projected over 365 Days^a	
Range	1–2,268 mg/day ^b
50 th Percentile (median)	75 mg/day
90 th Percentile	1,190 mg/day
95 th Percentile	1,751 mg/day
^a Based on fitting a log-normal distribution to model daily soil ingestion values. ^b Subject with pica excluded.	
Source: Stanek and Calabrese (1995b).	

Table 5-28. Distribution of Daily Soil Ingestion (mg/day) Over 7 Days, 64 Children (Ages 1–4 years) from Anaconda, MT ^a									
Over days	Over elements within a day	Mean	SD	Percentile					Max

Mean	Mean ^c	36	72	–7	16	72	151	160	283
^a	Based on 7 of 8 tracer elements (excluding titanium), and 28-hour lag time.								
^b	Estimates correspond to the median from the 7 trace elements for each subject day.								
^c	Estimates correspond to the mean.								
Source:	Stanek and Calabrese (2000).								

Table 5-29. Prevalence of Nonfood Consumption by Substance from NHANES I and NHANES II						
Substance	NHANES I (age 1–74 years) <i>N</i> (sample size) = 20,724 (unweighted); 193,716,939 (weighted)			NHANES II (age 6 months–74 years) <i>N</i> (sample size) = 25,271 (unweighted); 203,432,944 (weighted)		
	<i>N</i> Unweighted (Weighted)	Prevalence ^a	95% Confidence Interval	<i>N</i> Unweighted (Weighted)	Prevalence ^a	95% Confidence Interval
Any nonfood substance	732 (4,900,370)	2.5%	2.2–2.9%	480 (2,237,993)	1.1%	1.0–1.2%
Clay				46 (223,361)	0.1%	0.1–0.2%
Starch	131 (582,101)	0.3%	0.2–0.4%	61 (450,915)	0.2%	0.1–0.3%
Paint and plaster	39 (195,764)	0.5% ^b	0.3–0.7%	55 (213,588)	0.6% ^c	0.4–0.8%
Dirt				216 (772,714)	2.1% ^d	1.7–2.5%
Dirt and clay	385 (2,466,210)	1.3%	1.1–1.5%			
Other	190 (1,488,327)	0.8%	0.6–0.9%	218 (1,008,476)	0.5%	0.4–0.6%
^a	Prevalence = Frequency (<i>n</i>) (weighted) ÷ Sample Size (<i>N</i>) (weighted).					
^b	NHANES I sample size (<12 years): 4,968 (unweighted); 40,463,951 (weighted).					
^c	NHANES II sample size (<12 years): 6,834 (unweighted); 37,697,059 (weighted).					
^d	For those aged <12 years only; question not prompted for those ≥12 years.					
Unweighted	= raw counts.					
Weighted	= adjusted to account for the unequal selection probabilities caused by the cluster design, item nonresponse, planned oversampling of certain subgroups, and adjustments to ensure data are representative of the civilian noninstitutionalized census population in the coterminous United States.					
Source:	Gavrelis et al. (2011).					

Table 5-30. Results of Meta-Analysis on Soil Ingestion (mg/day)									
Population Group	Number of Studies	Number of Subjects	Number of Subject-Weeks	Mean ^a	SE	95% UCL	50 th Percentile	95 th Percentile	Adjusted Mean ^b
Subjects	4	216	266	25.5	15.5	73.1	32.6	79.4	31.3
Male	4	114	137	27.7	15.5	74.7	27.1	88.8	31.2
Female	4	102	129	22.2	18.4	78.7	33.5	66.7	31.3
Age 1 to <2 years	2	39	58	3.8	11.8	154	9.2	18.1	6.8
Age 2 to <3 years	3	55	76	20.6	24.0	115	21.9	94.5	28.3
Age 3 to <4 years	4	47	57	32.2	22.3	104	57.0	71.3	46.3
Age 4 to <5 years	3	75	75	40.9	17.0	257	36.2	104	41.3
Excluding Anaconda data ^c	3	156	206	43.4	4.5	52.3	40.8	90.0	43.7
All subjects except pica child ^d	4	240	303	36.5	17.1	88.7	39.4	114	43.6
^a	Calculation of the mean includes negative values for some subjects.								
^b	Estimates of soil ingestion less than zero are set equal to zero.								
^c	Excludes data from the Anaconda study (Calabrese et al., 1997a) because the children lived near a Superfund site and it could be assumed that soil ingestion at that site could be different from at other sites because additional effort may be taken to limit soil ingestion at this site.								
^d	Excludes subject exhibiting pica behavior.

Table 5-34. Summary of Estimates of Soil and Dust Ingestion by General Population Children and Adults from Key Studies Using the Tracer Study, Biokinetic Modeling, and Activity Pattern Methodologies (mg/day)^a (Continued)

a	See Appendix B for additional details.
b	Estimates adjusted by Stanek and Calabrese (1995a) based on data from Calabrese et al. (1989) using BTM (average of the median of the four best tracers for each child).
c	Estimates from Davis et al. (1990) were adjusted by Stanek and Calabrese (1995a) using the BTM (average of the median of three tracers for each child).
d	Estimates based on BTM (average of the best tracer for each child).
e	Estimates based on aluminum and silicon.
f	Average of the means.
g	Average of the 95 th percentiles.
h	Adjusted from model default of 85 mg/day under the assumption that the geometric mean model predicted blood lead level was higher than the geometric mean blood lead by a factor of 1.4 due only to individual soil + dust ingestion rates.
i	Average of two best-fit models from Table 5-15.
j	Average of ages 1 to <2, 2 to <3, 3 to <4, 4 to <5, 5 to <6 years.
k	Average of 113 and 68 mg/day.
l	Simulations.
m	Wilson et al. (2013) data based on 200,000 trials.
n	Does not include object-to-mouth exposure to soil and dust.
o	Average of 68 and 61 mg/day.
p	Average of 224 and 204 mg/day.
q	Soil + dust ingestion rates may be higher for adults following a traditional rural or wilderness lifestyle (see Sections 5.3.4.20 and 5.3.4.21). Based on Doyle et al. (2012) and Irvine et al. (2014) the central tendency adult soil + dust ingestion rates is 50 mg/day (20 mg/day soil and 30 mg/day dust) and the upper percentile rate is 200 mg/day (90 mg/day soil and 100 mg/day dust).
r	Upper percentile value for adults estimated by multiplying the average of the ratios of 95 th percentiles to means for all other age groups times the adult central tendency estimate (i.e., 30 mg/day \times 3.2 = 100 mg/day).
NR	= Not reported.
P	= Percentile.

^a	Based on a reanalysis of the Calabrese et al. (1989) data using the BTM. Median of Al, Si, and Ti; median of best 4 of 8 tracers (i.e., 4 lowest F/S ratios); or best tracer (lowest F/S ratio) (see Table 6, Stanek and Calabrese, 1995a). The average of the best 4 tracers for each child was used in developing the recommended soil and dust ingestion rates.									
^b	Based on average (mean) daily soil ingestion estimates (mg/day) per child (Table 5, Stanek and Calabrese, 1995b).									
^c	Best Tracer Method; median of Al, Si, and Ti or best tracer (Table 9, Stanek and Calabrese, 1995a). The average of the 3 tracers for each child was used in developing the recommended soil and dust ingestion rates.									
^d	Best Tracer Method; median of best 4 of 5 tracers (i.e., lowest F/S ratios) or best tracer for a given subject-week (Table 12, Calabrese et al., 1997a). The average of the best tracer for each child was used in developing the recommended soil and dust ingestion rates.									
^e	Based on the mean of daily soil ingestion estimates based on the median values for 7 trace elements (Table 2, Stanek and Calabrese, 2000).									
^f	Average of mean soil ingestion values (Table 3, Calabrese et al., 1997b).									

APPENDIX C

Table C-1. Key Soil Ingestion Studies Used in Developing Soil + Dust Ingestion Recommendation for Use in Risk Assessment

Tracer Studies					
Reference	Location	Population	Tracers	Study Design	Results
Calabrese et al. (1989); Barnes (1990)	Amherst, MA	64 children (1 to <4 years)	aluminum, barium, manganese, silicon, titanium, vanadium, yttrium, zirconium	Duplicate samples of food, beverages, medicines, vitamins, excreta collected over 2-week period; soil/dust samples from children's homes/play areas; participants supplied with toothpaste, baby cornstarch, diaper rash cream, and soap with low levels of most tracer elements; fecal/urine samples collected.	<p>Mean soil + dust ingestion ranged from –496 mg/day based on manganese to 483 mg/day based on silicon. The 95th percentiles range from 159 for both yttrium and zirconium to 3,174 for manganese.</p> <p>Stanek and Calabrese (1995a) reanalyzed the data using the best tracer method (BTM) and the lowest four food:soil ratios for each child, calculated on a per-week (“subject-week”) basis. Based on the median of soil ingestion estimates from the best four tracers, the mean soil ingestion rate for children was 132 mg/day and the median was 33 mg/day. The 95th percentile value was 154 mg/day.</p>
Davis et al. (1990)	3-city area in southeastern Washington	101 children (2 to 7 years)	aluminum, silicon, titanium	Collected soil/house dust, duplicate food, dietary supplements/medications, and mouthwash samples over 7 days; urine/feces collected over 4 days; toothpaste with known tracer element content was supplied; information on dietary habits and demographics collected.	<p>Mean soil ingestion rates were 39 mg/day for aluminum, 82 mg/day for silicon, and 245 mg/day for titanium; median values were 25 mg/day for aluminum, 59 mg/day for silicon, and 81 mg/day for titanium. Adjusted mean soil + dust ingestion: 65 mg/day for aluminum, 160 mg/day for silicon, 268 mg/day for titanium; median values were: 52 mg/day for aluminum, 112 mg/day for silicon, 117 mg/day for titanium.</p> <p>Stanek and Calabrese (1995a) reanalyzed the data using the BTM and the lowest four food:soil ratios for each child, calculated on a per-week (“subject-week”) basis. The soil + dust ingestion values were 69 mg/day (mean), 44 mg/day (median), and 246 mg/day (95th percentile).</p>
Calabrese et al. (1997a)	Anaconda, MT	64 children (1 to 4 years) at a Superfund site	aluminum, cerium, lanthanum, neodymium, silicon, titanium, yttrium, zirconium	Duplicate samples of meals/beverages and over-the-counter medicines/vitamins collected; feces collected over 7 days; soil/and dust collected from the children's homes/play areas; toothpaste containing nondetectable tracer levels (except silica) provided; infants provided with baby cornstarch, diaper rash cream, and soap with low levels of tracers.	<p>Mean ranged from –544 mg/day based on titanium to 270 mg/day based on neodymium; 95th percentile estimates ranged from 69 mg/day based on silicon to 1,378 mg/day based on titanium. Using the BTM (average of best tracer for each child), the mean value for soil was 66 mg/day; the median was 20 mg/day; and the 95th percentile value was 282 mg/day.</p>

Table C-1. Key Soil Ingestion Studies Used in Developing Soil + Dust Ingestion Recommendation for Use in Risk Assessment (Continued)

Calabrese et al. (1997b)	Western Massachusetts	12 children 1 to 3 years old observed to have frequent soil ingestion in previous study.	aluminum, silicon, titanium	Mass balance tracer study with duplicate food sampling; both soil and dust samples collected.	Estimates calculated based on soil tracer element concentrations only for the 12 subjects ranged from –15 to +1,783 mg/day based on aluminum, –46 to +931 mg/day based on silicon, and –47 to +3,581 mg/day based on titanium. Mean soil estimates: 168 mg/day based on aluminum, 89 mg/day based on silicon, 448 mg/day based on titanium. Mean dust ingestion estimates: 260 mg/day based on aluminum, 297 mg/day based on silicon, 415 mg/day based on titanium. Based on the average of aluminum and silicon, the mean estimate is 129 mg/day. One child exhibited pica behavior.
Davis and Mirick (2006)	3-city area in southeastern Washington	Subset of Davis et al. (1990): 33 adults	aluminum, silicon, titanium	Duplicate samples of food/medications; feces collected for 11 consecutive days; urine samples collected; soil/house dust samples collected.	Mean for the three tracers ranged from 23 to 625 mg/day; calculated by setting negative estimates to zero. Based on the average of aluminum and silicon, the mean and median values are 52 mg/day and 7 mg/day respectively.
Biokinetic Modeling Comparison Studies					
Reference	Location	Population Studied	Study Design		Results
Hogan et al. (1998)	Historic lead smelting communities: Palmerton, PA; southeastern Kansas and southwestern Missouri; Madison Co., IL.	478 children ages 0.5 to <7 years Pennsylvania, Illinois, and Kansas/Missouri with blood lead measurements and related soil and dust lead levels; 31 of these children from the Illinois site were 0.5 to <1 year old	Compared IEUBK-predicted blood lead levels with observed blood lead levels using observed house dust/soil lead levels, and default soil and dust intake rates, and other model parameters.		The default IEUBK model mean soil + dust soil intake rates averaged over ages 1 to <7 years was approximately 135 mg/day. The geometric mean blood lead levels at one site were slightly over-predicted by the model; blood lead levels were slightly under-predicted at a second site, and the blood lead levels predicted by the model were roughly accurate at the third site. The default IEUBK model mean soil + dust soil intake rates averaged over ages 0.5 to <1 year was approximately 85 mg/day. For children 6 to 12 months old in the Illinois site only, Hogan et al. (1998) reported a predicted geometric mean blood lead level 1.4-fold higher than the geometric mean blood lead levels observed.

Table C-1. Key Soil Ingestion Studies Used in Developing Soil + Dust Ingestion Recommendation for Use in Risk Assessment (Continued)

Von Lindern et al. (2016)	Northern Idaho; site of community-wide soil remediation	3,203 children (ages 0 to <10 years) with blood lead measurements and related lead levels in yard, neighborhood and community soil, and house dust.	Compared IEUBK-predicted blood lead levels with observed blood lead levels; the soil and dust ingestion values used in the model were developed using a statistical model that apportioned the contributions of community soils, yard soils of the residence, and house dust to lead intake; soil + dust ingestion was estimated based on four partition scenarios that used different combinations of the proportions of dust + soil attributed to different sources (e.g., dust, yard soil, neighborhood soil).	All four partition scenarios produced similar central tendency intake rates. For children ages 0.5 to <10 years, the mean soil and dust ingestion rates ranged from 47 mg/day to 100 mg/day. Among the age groups evaluated, children ages 1 to <2 years had the highest mean soil and dust ingestion rates (i.e., 89–100 mg/day). The 95 th percentile soil and dust intake rates ranged from 120 mg/day to 493 mg/day for ages 0.5 to <10 years of age. Based on the average of all four scenarios, the mean soil + dust ingestion rates ranged from 50 mg/day for 7- to <8-year-olds to 93 mg/day for 1- to <2-year-olds.
Activity Pattern Modeling Studies				
Reference	Location	Population Studied	Study Design	Results
Özkaynak et al. (2011)	United States	Simulated population of children ages 3 to <6 years.	Used EPA's SHEDS-Multimedia model to estimate soil and dust ingestion rates using distributions of exposure factor values for hand-to-mouth activities; assumed soil and dust adhered to hands and remained until washed off or ingested by mouthing; object-to-mouth pathway for soil/dust ingestion was also addressed; outdoor matter was designated as "soil" and indoor matter as "dust."	Mean total soil and dust ingestion: 68 mg/day; approximately 60% originating from soil ingestion, 30% from dust on hands, and 10% from dust on objects; 95 th percentile: 224 mg/day. The predicted soil and dust ingestion values fit a log-normal distribution.
Wilson et al. (2013)	Canada	Simulated populations of infants aged 0 to <7 months; toddlers 7 months to <5 years; children 5 years to <12 years; teens 12 years to <20 years; adults 20 years to <60 years; seniors 60+ years.	Modeling approaches (deterministic and probabilistic) used to estimate soil + dust via hand-to-mouth contact; object-to-mouth exposures were not considered. The models used measures of particle loading to indoor surfaces, the fraction transferred to the hands, hand surface areas, the fraction of hand surface area that may be mouthed or contact food, the frequency of hand-to-mouth contacts, the amount dissolved in saliva, and the exposure time. Model parameters used were representative of the Canadian population. Contact was assumed to occur with hard surfaces 50% of the time and with soft surfaces 50% of the time, except for infants for whom contact was assumed to occur with soft surfaces only.	Mean soil + dust ingestion rates ranged from 4 mg/day for teens, adults, and seniors to 61 mg/day for toddlers (7 months to <5 years of age). The 95 th percentile soil + dust ingestion rates ranged from 14 mg/day for teens, adults, and seniors to 204 mg/day for toddlers (7 months to <5 years of age). Infants (0 to <7 months in age) were assumed to consume dust only at mean rate of 36 mg/day (95 th percentile: 140 mg/day).
Source: Adapted from Moya and Phillips (2014).				

APPENDIX D

Table D-1. Studies on the Prevalence of Ingesting Soil, Dust, or Other Nonfood Substances

Reference	Location	Population	Results
Dickins and Ford (1942)	Oktibbeha County, MS	207 rural Black school children ($\geq 4^{\text{th}}$ grade)	52 of the children ate dirt in the previous 10 to 16 days; clay was predominant type of soil eaten.
Ferguson and Keaton (1950)	Mississippi	361 pregnant women; primarily Black, low economic and educational level	27% of the Black women reported eating clay and 41% reported eating starch. 7% of the White women reported eating clay and 10% reported eating starch.
Cooper (1957)	Baltimore, MD	784 children (≥ 7 months) referred to a mental hygiene clinic	Parents/caretakers of 86 children responded positively to “Does your child have a habit, or did he ever have a habit, of eating dirt, plaster, ashes, etc.?”
Baltrop (1966)	Boston, MA	439 children (1–6 years): interview	19 children ingested dirt (defined as yard dirt, house dust, plant-pot soil, pebbles, ashes, cigarette ash, glass fragments, lint, and hair combings) in the preceding 14 days.
		277 children (1–6 years): mail survey	39 children ingested dirt in the 14 days prior to the survey.
Bruhn and Pangborn (1971)	California	91 Mexican and “Anglo” low-income families of migrant agricultural workers	12 of 65 Mexican and 11 of 26 “Anglo” respondents indicated consumption of “dirt” among their family members.
Robischon (1971)	Unspecified Location	130 children (19–24 months) from urban well-child clinic	48 “ate nonedibles more than once a week”; substances eaten for 30 of the children were: ashes (17), “earth” (5), dust (3), fuzz from rugs (2), clay (1), and pebbles/stones (1).
Bronstein and Dollar (1974)	Georgia	410 pregnant, low-income women: urban $N = 201$; rural $N = 209$	65 (16%) of the women practiced pica; a variety of substances were ingested, with laundry starch being the most common; there was no significant difference in the practice of pica between rural and urban women.
Hook (1978)	New York	250 who had delivered live infants	Nonfood items reportedly ingested during pregnancy were ice, reported by three women, and chalk from a river clay bank, reported by one woman.
Vermeer and Frate (1979)	Holmes County, MS	50 households (229 people; 140 children or adolescents)	Geophagy (regular consumption of clay over a period of weeks) in 16% of children under 13 years of age; average daily amount of clay consumed estimated at 50 g for both adults and children.
Cooksey (1995)	Midwest	350 postpartum women; majority Black, low income 13 to 42 years old	194 (65%) ingested one or more pica substances during their pregnancy, and the majority (78%) ate ice/freezer frost alone or in addition to other pica substances.
Smulian et al. (1995)	Muscogee County, GA	125 pregnant women ages 12 to 37 years; 73 Black, 47 White, 4 Hispanic, and 1 Asian.	14.4% (18 of 125 women) practiced pica; pica prevalence was highest among Black women (17.8%). The most common form of pica was ice eating (pagophagia), reported by 44.4% of the patients.
Stanek et al. (1998)	Western Massachusetts	528 children (ages 1–7 years) at well medical clinics	Daily mouthing or ingestion: 6% for sand and stones; 4% for soil and dirt; 1% for dust, lint, and dustballs. More than weekly mouthing or ingestion: 16% for sand and stones; 10% for soil and dirt; 3% for dust, lint, and dustballs. More than monthly mouthing or ingestion: 27% for sand and stones; 18% for soil and dirt; 6% for dust, lint, and dustballs.

Table D-1. Studies on the Prevalence of Ingesting Soil, Dust, or Other Nonfood Substances (Continued)

Reference	Location	Population	Results
Grigsby et al. (1999)	Middle Georgia	21 Black individuals (20 of whom were women) who had reported eating kaolin	Reasons for eating kaolin included liking the taste, being pregnant, craving it, and to gain weight.
Ward and Kutner (1999)	Metropolitan Atlanta, GA	226 dialysis patients	37 (16%) reported pica behavior; Black patients and women made up 86% and 84% of those reporting pica, respectively. Pica items reportedly consumed included ice, starch, dirt, flour, or aspirin.
Simpson et al. (2000)	Santa Ana, Bakersfield, and East Los Angeles, CA	150 Mexican-born, low-income, pregnant or postpartum women	46 (31%) of the women interviewed in the United States reported pica behavior; pica substances included dirt, bean stones, magnesium carbonate, ashes, clay, ice, and other substances; ice was the most consumed substance.
Obialo et al. (2001)	Atlanta, GA	138 Black dialysis patients; 37–78 years old	30 (22%) reported some form of pica behavior; 13 (9.4%) reported clay pica.
Klitzman et al. (2002)	New York City	33 pregnant women whose blood lead levels were >20 µg/dL; majority were foreign born; 15–43 years of age	13 women (39%) reported pica behavior during their current pregnancies; 10 reported eating soil, dirt or clay, 2 reported pulverizing and eating pottery, and 1 reported eating soap.
Gavrelis et al. (2011)	United States nationwide	~21,000 individuals (ages 1–74 years)	Prevalence of consuming nonfood substances was 22.7% for the 1- to <3-year age group based on NHANES I (1971–75) and 12% based on NHANES II (1976–80).
		~25,000 individuals, (ages 0.5–74 years)	Prevalence estimates for the >21-year age group was 0.7% and 0.4% for NHANES I (1971–75) and NHANES II (1976–80).
Lumish et al. (2014)	Rochester, NY	158 pregnant adolescents (<18 years of age); mostly African-American and ~25% Hispanic	46% reported ingesting one or more items, including raw starches (flour and cornstarch); powder (dust, vacuum powder from vacuum cleaner bags, and baby powder); soap (soap, bar soap, laundry soap, and powdered cleansers); plastic/foam (stuffing from pillows/sofas and sponges); paper (writing paper, toilet paper, and tissues); baking soda/powder; and other (dirt and chalk). Ice was the nonfood item most often consumed (37% of all the pregnant adolescents), while only 1.3% of the teens reported ingestion of dirt/chalk.
Lin et al. (2015)	Central California and Mexico	76 Mexican-born pregnant or ≤2-year postpartum women	In the California, 10 (43%) had engaged in pica; 6 during pregnancy. In the Mexican group, 18 (34%) had engaged in pica; 16 during pregnancy. Commonly eaten items were earth, bean stones, and adobe. In the California group, 5 (22%) had eaten earth; in the Mexican group, 6 (11%) had eaten earth.

Chapter 6—Inhalation Rates

6. INHALATION RATES**6.1. INTRODUCTION**

Ambient and indoor air are potential sources of exposure to toxic substances. Adults and children can be exposed to contaminated air during a variety of activities in different environments. They may be exposed to contaminants in ambient air and may also inhale chemicals from the indoor use of various sources (e.g., stoves, heaters, fireplaces, and consumer products) as well as from those that infiltrate from ambient air.

The Agency defines exposure as the chemical concentration at the boundary of the body (U.S. EPA, 1992). In the case of inhalation, the situation is complicated by the fact that oxygen exchange with carbon dioxide takes place in the distal portion of the lung. The anatomy and physiology of the respiratory system as well as the characteristics of the inhaled agent diminishes the pollutant concentration in inspired air (potential dose) such that the amount of a pollutant that actually enters the body through the upper respiratory tract (especially the nasal-pharyngeal and tracheo-bronchial regions) and lung (internal dose) is less than that measured at the boundary of the body. A detailed discussion of this concept can be found in *Guidelines for Exposure Assessment* (U.S. EPA, 1992). Suggestions for further reading on the anatomy and physiology of the respiratory system include Phalen et al. (1990), Bates (1989), Cherniack (1972), Forster et al. (1986), and West (2008a, b). When constructing risk assessments that concern the inhalation route of exposure, one must be aware of any adjustments that have been employed in the estimation of the pollutant concentration to account for this reduction in potential dose.

There are also a number of resources available in the literature describing various approaches and techniques related to inhalation rate estimates, including Ridley et al. (2008), Ridley and Olds (2008), Speakman and Selman (2003), Thompson et al. (2009), and Westerterp (2003).

Inclusion of this chapter in the *Exposure Factors Handbook* does not imply that assessors will always need to select and use inhalation rates when evaluating exposure to air contaminants. For example, it is unnecessary to calculate inhaled dose when using dose-response factors from the Integrated Risk Information System (IRIS) (U.S. EPA, 1994), because the IRIS methodology accounts for inhalation rates in the development of “dose-response” relationships. Information in this chapter may be used by toxicologists in their derivation of human equivalent concentrations (HECs), where adjustments are usually required to

account for differences in exposure scenarios or populations (U.S. EPA, 1994). Inhalation dosimetry and the factors affecting the disposition of particles and gases that may be deposited or taken up in the respiratory tract are discussed in more detail in the U.S. Environmental Protection Agency’s (EPA’s) report on *Methods for Derivation of Inhalation Reference Concentrations (RfCs) and Application of Inhalation Dosimetry* (U.S. EPA, 1994). When using IRIS for inhalation risk assessments, “dose-response” relationships require only an average air concentration to evaluate health concerns:

- For non-carcinogens, IRIS uses Reference Concentrations (RfCs), which are expressed in concentration units. Hazard is evaluated by comparing the inspired air concentration to the RfC.
- For carcinogens, IRIS uses unit risk values, which are expressed in inverse concentration units. Risk is evaluated by multiplying the unit risk by the inspired air concentration.

Detailed descriptions of the IRIS methodology for derivation of inhalation RfCs can be found in two methods manuals produced by the Agency (U.S. EPA, 1994, 1992).

The Superfund Program has also updated its approach for determining inhalation risk, eliminating the use of inhalation rates when evaluating exposure to air contaminants (U.S. EPA, 2009b). The current methodology recommends that risk assessors use the concentration of the chemical in air as the exposure metric (e.g., mg/m³), instead of the intake of a contaminant in air based on inhalation rate and body weight (e.g., mg/kg-day).

Due to their size, physiology, behavior, and activity level, the inhalation rates of children differ from those of adults. Infants and children have a higher resting metabolic rate and oxygen consumption rate per unit of body weight than adults because of their rapid growth and relatively larger lung surface area (SA) per unit of body weight. For example, the oxygen consumption rate for a resting infant between 1 week and 1 year of age is 7 milliliters per kilogram of body weight (mL/kg) per minute, while the rate for an adult under the same conditions is 3–5 mL/kg per minute (WHO, 1986). Thus, while greater amounts of air and pollutants are inhaled by adults than children over similar time periods on an absolute basis, the relative volume of air passing through the lungs of a resting infant is up to twice that of a resting adult on a body-weight basis. It should be noted that lung volume is correlated, among other factors, with a person’s

height. Also, people living in higher altitudes have larger lung capacity than those living at sea level.

Children's inhalation dosimetry and health effects were topics of discussion at a U.S. Environmental Protection Agency workshop held in June 2006 (Foos and Sonawane, 2008). Age-related differences in lung structure and function, breathing patterns, and how these affect the inhaled dose and the deposition of particles in the lung are important factors in assessing risks from inhalation exposures (Foos et al., 2008). Children more often than adults, breathe through their mouths and, therefore, may have a lesser nasal contribution to breathing during rest and while performing various activities. The uptake of particles in the nasal airways is also less efficient in children (Bennett et al., 2008). Thus, the deposition of particles in the lower respiratory tract may be greater in children (Foos et al., 2008). In addition, the rate of fine particle deposition has been significantly correlated with increased body mass index (BMI), an important point as childhood obesity becomes a greater issue (Bennett and Zeman, 2004).

Recommended inhalation rates (both long- and short-term) for adults and children are provided in Section 6.2, along with the confidence ratings for these recommendations, which are based on four key studies identified by U.S. EPA for this factor. Long-term inhalation is repeated exposure for more than 30 days, up to approximately 10% of the life span in humans (more than 30 days). Long-term inhalation rates for adults and children (including infants) are presented as daily rates (m^3/day). Short-term exposure is repeated exposure for more than 24 hours, up to 30 days. Short-term inhalation rates are reported for adults and children (including infants) performing various activities in m^3/minute . Following the recommendations, the available studies (both key and relevant studies) on inhalation rates are summarized.

6.2. RECOMMENDATIONS

The recommended inhalation rates for adults and children are based on three recent studies (U.S. EPA, 2009a; Stifelman, 2007; Brochu et al., 2006b), as well as an additional study of children (Arcus-Arth and Blaisdell, 2007). These studies represent an improvement upon those previously used for recommended inhalation rates in earlier versions of this handbook, because they use a large data set that is representative of the United States as a whole and consider the correlation between body weight and inhalation rate.

The selection of inhalation rates to be used for exposure assessments depends on the age of the exposed population and the specific activity levels of this population during various exposure scenarios. Table 6-1 presents the recommended long-term

values for adults and children (including infants) for use in various exposure scenarios. For children, the age groups included are from U.S. EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005a). Section 6.3.5 describes how key studies were combined to derive the mean and 95th percentile inhalation rate values and the concordance between the age groupings used for adults and children in this chapter and the original age groups in the key studies.

As shown in Table 6-1, the daily average inhalation rates for long-term exposures for children (males and females combined, unadjusted for body weight) range from 3.5 m^3/day for children from 1 to <3 months to 16.3 m^3/day for children aged 16 to <21 years. Mean values for adults range from 12.2 m^3/day (81 years and older) to 16.0 m^3/day (31 to <51 years). The 95th percentile values for children range from 5.8 m^3/day (1 to <3 months) to 24.6 m^3/day (16 to <21 years) and for adults range from 15.7 m^3/day (81 years and older) to 21.4 m^3/day (31 to <41 years). The mean and 95th percentile values shown in Table 6-1 represent averages of the inhalation rate data from the key studies for which data were available for selected age groups.

It should be noted that there may be a high degree of uncertainty associated with the upper percentiles. These values represent unusually high estimates of caloric intake per day and are not representative of the average adult or child. For example, using Layton's equation (Layton, 1993) for estimating metabolically consistent inhalation rates to calculate caloric equivalence (see Section 6.4.9), the 95th percentile value for 16 to <21-year-old children is greater than 4,000 kcal/day (Stifelman, 2003). All of the 95th percentile values listed in Table 6-1 represent unusually high inhalation rates for long-term exposures, even for the upper end of the distribution, but were included in this handbook to provide exposure assessors a sense of the possible range of inhalation rates for adults and children. These values should be used with caution when estimating long-term exposures.

Short-term mean and 95th percentile data in m^3/minute are provided in Table 6-2 for males and females combined for adults and children for whom activity patterns are known. These values represent averages of the activity level data from the one key study from which short-term inhalation rate data were available (U.S. EPA, 2009a).

Table 6-3 shows the confidence ratings for the inhalation rate recommendations. Table 6-4, Table 6-6 through Table 6-8, Table 6-10, Table 6-14, Table 6-15, and Table 6-17 through Table 6-20 provide multiple percentiles for long- and short-term inhalation rates for both males and females.

Table 6-1. Recommended Long-Term Exposure Values for Inhalation (males and females combined)

Age Group ^a	Mean (m ³ /day)	Sources Used for Means	95 th Percentile ^b (m ³ /day)	Sources Used for 95 th Percentiles	Multiple Percentiles
Birth to <1 month	3.6	c	7.1	c

51 to <61 years	15.7	d, e, f	21.3	d, e	
61 to <71 years	14.2	d, e, f	18.1	d, e	
71 to <81 years	12.9	d, e	16.6	d, e	
≥81 years	12.2	d, e	15.7	d, e	
^a When age groupings in the original reference did not match the U.S. EPA groupings used for this handbook, means from all age groupings in the original reference that overlapped U.S. EPA's age groupings by more than one year were averaged, weighted by the number of observations contributed from each age group. Similar calculations were performed for the 95 th percentiles. See Table 6-25 for concordance with U.S. EPA age groupings. ^b Some 95 th percentile values may be unrealistically high and not representative of the average person. ^c Arcus-Arth and Blaisdell (2007). ^d Brochu et al. (2006b). ^e U.S. EPA (2009a). ^f Stifelman (2007).

Chapter 6—Inhalation Rates

6.3. KEY INHALATION RATE STUDIES

6.3.1. Brochu et al. (2006b)—Physiological Daily Inhalation Rates for Free-Living Individuals Aged 1 Month to 96 Years, Using Data From Doubly Labeled Water Measurements: A Proposal for Air Quality Criteria, Standard Calculations, and Health Risk Assessment

Brochu et al. (2006b) calculated physiological daily inhalation rates (PDIRs) for 2,210 individuals aged 3 weeks to 96 years using the reported disappearance rates of oral doses of doubly labeled water (DLW) ($^2\text{H}_2\text{O}$ and H_2^{18}O) in urine, monitored by gas-isotope-ratio mass spectrometry for an aggregate period of more than 30,000 days. DLW data were complemented with indirect calorimetry and nutritional balance measurements.

In the DLW method, the disappearance of the stable isotopes deuterium (^2H) and heavy oxygen-18 (^{18}O) are monitored in urine, saliva, or blood samples over a long period of time (from 7 to 21 days) after subjects receive oral doses of $^2\text{H}_2\text{O}$ and H_2^{18}O . The disappearance rate of ^2H reflects water output and that of ^{18}O represents water output plus carbon dioxide (CO_2) production rates. The CO_2 production rate is then calculated by finding the difference between the two disappearance rates. Total daily energy expenditures (TDEEs) are determined from CO_2 production rates using classic respirometry formulas, in which values for the respiratory quotient ($\text{RQ} = \text{CO}_2 \text{ produced} / \text{O}_2 \text{ consumed}$) are derived from the composition of the diet during the period of time of each study. The DLW method also allows for measurement of the energy cost of growth (ECG). TDEE and ECG measurements can be converted into PDIR values using the following equation developed by Layton (1993):

$$\text{PDIR} = (\text{TDEE} + \text{ECG}) \times H \times VQ \times 10^{-3} \quad (\text{Eqn. 6-1})$$

where:

<i>PDIR</i>	=	physiological daily inhalation rates (m^3/day);
<i>TDEE</i>	=	total daily energy expenditure (kcal/day);
<i>ECG</i>	=	stored daily energy cost for growth (kcal/day);
<i>H</i>	=	oxygen uptake factor, volume of 0.21 L of oxygen (at standard temperature and pressure, dry air) consumed to produce 1 kcal of energy expended;

<i>VQ</i>	=	ventilatory equivalent (ratio of the minute volume [V_E] at body temperature pressure saturation to the oxygen uptake rate [VO_2] at standard temperature and pressure, dry air) $V_E/\text{VO}_2 = 27$; and
10^{-3}	=	conversion factor (L/m^3).

Brochu et al. (2006b) calculated daily inhalation rates (DIRs) (expressed in m^3/day and $\text{m}^3/\text{kg}\cdot\text{day}$) for the following age groups and physiological conditions: (1) healthy newborns aged 3 to 5 weeks old ($N = 33$), (2) healthy normal-weight males and females aged 2.6 months to 96 years ($N = 1,252$), (3) low-BMI subjects (underweight women, $N = 17$; adults from less affluent societies $N = 59$) and (4) overweight/obese individuals ($N = 679$), as well as (5) athletes, explorers, and soldiers when reaching very high energy expenditures ($N = 170$). Published data on BMI, body weight, basal metabolic rate (BMR), ECG, and TDEE measurements (based on DLW method and indirect calorimetry) for subjects aged 2.6 months to 96 years were used. Data for underweight, healthy normal-weight, and overweight/obese individuals were gathered and defined according to BMI cutoffs. Data for newborns were included regardless of BMI values because they were clinically evaluated as being healthy infants.

Table 6-4 to Table 6-8 present the distribution of daily inhalation rates for normal-weight and overweight/obese individuals by sex and age groups. Table 6-9 presents mean inhalation rates for newborns. Due to the insufficient number of subjects, no distributions were derived for this group.

An advantage of this study is that data are provided for age groups of less than 1 year. A limitation of this study is that data for individuals with pre-existing medical conditions were lacking.

6.3.2. Arcus-Arth and Blaisdell (2007)—Statistical Distributions of Daily Breathing Rates for Narrow Age Groups of Infants and Children

Arcus-Arth and Blaisdell (2007) derived daily breathing rates for narrow age ranges of children using the metabolic conversion method of Layton (1993) and energy intake (EI) data adjusted to represent the U.S. population from the Continuing Survey of Food Intake for Individuals (CSFII) 1994–1996, 1998. Normalized ($\text{m}^3/\text{kg}\cdot\text{day}$) and non-normalized (m^3/day) breathing rates for children 0–18 years of age were derived using the general

equation developed by Layton (1993) to calculate energy-dependent inhalation rates:

$$V_E = H \times VQ \times EE \quad (\text{Eqn. 6-2})$$

where:

- V_E = volume of air breathed per day (m^3/day),
- H = volume of oxygen consumed to produce 1 kcal of energy (m^3/kcal),
- VQ = ratio of the volume of air to the volume of oxygen breathed per unit time (unitless), and
- EE = energy (kcal) expended per day.

Arcus-Arth and Blaisdell (2007) calculated H values of 0.22 and 0.21 for infants and non-infant children, respectively, using the 1977–1978 Nationwide Food Consumption Survey (NFCS) and CSFII data sets. Ventilatory equivalent (VQ) data, including those for infants, were obtained from 13 studies that reported VQ data for children aged 4–8 years. Separate preadolescent (4–8 years) and adolescent (9–18 years) VQ values were calculated in addition to separate VQ values for adolescent boys and girls. Two-day-averaged daily EI values reported in the CSFII data set were used as a surrogate for EE. CSFII records that did not report body weight and those for children who consumed breast milk or were breast-fed were excluded from their analyses. The EIs of children 9 years of age and older were multiplied by 1.2, the value calculated by Layton (1993) to adjust for potential bias related to under-reporting of dietary intakes by older children. For infants, EI values were adjusted by subtracting the amount of energy put into storage by infants as estimated by Scrimshaw et al. (1996). Self-reported body weights for each individual from the CSFII data set were used to calculate non-normalized (m^3/day) and normalized ($\text{m}^3/\text{kg-day}$) breathing rates, which decreased the variability in the resulting breathing rate data. Daily breathing rates were grouped into three 1-month groups for infants, 1-year age groups for children 1 to 18 years of age, and the age groups recommended by U.S. EPA *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* (U.S. EPA, 2005b) to receive greater weighting for mutagenic carcinogens (0 to <2 years of age, and 2 to <16 years of age). Data were also presented for adolescent boys and girls, aged 9 to 18 years (see Table 6-10). For each age and age-sex group, Arcus-Arth and Blaisdell (2007) calculated the

arithmetic mean, standard error of the mean, percentiles (50th, 90th, and 95th), geometric mean, standard deviation, and best-fit parametric models of the breathing rate distributions. Overall, the CSFII-derived non-normalized breathing rates progressively increased with age from infancy through 18 years of age, while normalized breathing rates progressively decreased. The data are presented in Table 6-11 in units of m^3/day . There were statistical differences between boys and girls 9 to 18 years of age, both for these years combined ($p < 0.00$) and for each year of age separately ($p < 0.05$). The authors reasoned that since the fat-free mass (basically muscle mass) of boys typically increases during adolescence, and because fat-free mass is highly correlated to basal metabolism which accounts for the majority of EE, non-normalized breathing rates for adolescent boys may be expected to increase with increasing age. Table 6-11 presents the mean and 95th percentile values for males and females combined, averaged to fit within the standard U.S. EPA age groups.

The CSFII-derived mean breathing rates derived by Arcus-Arth and Blaisdell (2007) were compared to the mean breathing rates estimated in studies that utilized DLW technique EE data that had been coupled with the Layton (1993) method. Infants' breathing rates estimated using the CSFII data were 15 to 27% greater than the comparison DLW EE breathing rates. In contrast, the children's CSFII breathing rates ranged from 23% less to 14% greater than comparison rates. Arcus-Arth and Blaisdell (2007) concluded that taking into account the differences in methods, data, and some age definitions between the two sets of breathing rates, the CSFII and comparison rates were similar across age groups.

An advantage of this study is that it provides breathing rates specific to narrow age ranges, which can be useful for assessing inhalation dose during periods of greatest susceptibility. However, the study is limited by the potential for misreporting, underestimating, or overestimating of food intake data in the CSFII. In addition to underreporting of food intake by adolescents, EI values for younger children may be under- or overestimated. Overweight children (or their parents) may also under-report food intakes. In addition, adolescents who misreport food intake may have also misreported body weights.

Chapter 6—Inhalation Rates

6.3.3. Stifelman (2007)—Using Doubly Labeled Water Measurements of Human Energy Expenditure to Estimate Inhalation Rates

Stifelman (2007) estimated inhalation rates using DLW energy data. The DLW method administers two forms of stable isotopically labeled water: deuterium-labeled ($^2\text{H}_2\text{O}$) and ^{18}O -labeled (H_2^{18}O). The difference in disappearance rates between the two isotopes represents the energy expended over a period of 1–3 half-lives of the labeled water (Stifelman, 2007). The resulting duration of observation is typically 1–3 weeks, depending on the size and activity level.

The DLW database contains subjects from areas around the world and represents diversity in ethnicity, age, activity, body type, and fitness level. DLW data have been compiled by the Institute of Medicine (IOM) Panel on Macronutrients and the Food and Agriculture Organization of the United Nations. Stifelman (2007) used the equation of Layton (1993) to convert the recommended energy levels of IOM for the active to very-active people to their equivalent inhalation rates. The IOM reports recommend energy expenditure levels organized by sex, age, and body size (Stifelman, 2007).

The equivalent inhalation rates are shown in Table 6-12. Shown in Table 6-13 are the mean values for the IOM “active” energy level category, averaged to fit within the standard U.S. EPA age groups. Stifelman (2007) noted that the estimates based on the DLW are consistent with previous findings of Layton (1993) and the *Exposure Factors Handbook* (U.S. EPA, 1997) and that inhalation rates based on the IOM active classification are consistent with the mean inhalation rate in the handbook.

The advantages of this study are that the inhalation rates were estimated using the DLW data from a large data set. Stifelman (2007) noted that DLW methods are advantageous; the data are robust, measurements are direct and avoid errors associated with indirect measurements (heart rate [HR]), subjects are free-living, and the period of observation is longer than what is possible from staged activity measures. Observations over a longer period of time reduce the uncertainties associated with using short duration studies to infer long-term inhalation rates. A limitation with the study is that the inhalation rates that are presented are for active/very active persons only.

6.3.4. U.S. EPA (2009a)—Metabolically Derived Human Ventilation Rates: A Revised Approach Based Upon Oxygen Consumption Rates

U.S. EPA (2009a) conducted a study to ascertain inhalation rates for children and adults. Specifically, U.S. EPA sought to improve upon the methodology used by Layton (1993) and other studies that relied upon the VQ and a linear relationship between oxygen consumption and fitness rate. A revised approach, developed by U.S. EPA’s National Exposure Research Laboratory, was used, in which an individual’s inhalation rate was derived from his or her assumed oxygen consumption rate. U.S. EPA applied this revised approach using body-weight data from the 1999–2002 National Health and Nutrition Examination Survey (NHANES) and metabolic equivalents of work (METs) data from U.S. EPA’s Consolidated Human Activity Database (CHAD). In this database, metabolic cost is given in units of “METs” or “metabolic equivalents of work,” an energy expenditure metric used by exercise physiologists and clinical nutritionists to represent activity levels. An activity’s METs value represents a dimensionless ratio of its metabolic rate (energy expenditure) to a person’s resting, or BMR.

NHANES provided age, sex, and body-weight data for 19,022 individuals from throughout the United States. From these data, BMR was estimated using an age-specific linear equation used in the *Exposure Factors Handbook* (U.S. EPA, 1997), and in several other studies and reference works.

The CHAD database is a compilation of several databases of human activity patterns. U.S. EPA used one of these studies, the National Human Activity Pattern Survey (NHAPS), as its source for METs values because it was more representative of the entire U.S. population than the other studies in the database. The NHAPS data set included activity data for 9,196 individuals, each of which provided 24 hours of activity pattern data using a diary-based questionnaire. While NHAPS was identified as the best available data source for activity patterns, there were some shortcomings in the quality of the data. Study respondents did not provide body weights; instead, body weights were simulated using statistical sampling. Also, the NHAPS data extracted from CHAD could not be corrected to account for non-random sampling of study participants and survey days.

NHANES and NHAPS data were grouped according to the age categories presented elsewhere in this handbook, with the exception that children under the age of 1 year were placed into a single

category to preserve an adequate sample size within the category. For each NHANES participant, a “simulated” 24-hour activity pattern was generated by randomly sampling activity patterns from the set of NHAPS participants with the same sex and age category as the NHANES participant. Twenty such patterns were selected at random for each NHANES participant, resulting in 480 hours of simulated activity data for each NHANES participant. The data were then scaled down to a 24-hour time frame to yield an average 24-hour activity pattern for each of the 19,022 NHANES individuals.

Each activity was assigned a METS value based on statistical sampling of the distribution assigned by CHAD to each activity code. For most codes, these distributions were not age dependent, but age was a factor for some activities for which intensity level varies strongly with age. Using statistical software, equations for METS based on normal, lognormal, exponential, triangular, and uniform distributions were generated as needed for the various activity codes. The METS values were then translated into EE by multiplying the METS by the BMR, which was calculated as a linear function of body weight. The oxygen consumption rate (VO_2) was calculated by multiplying EE by H , the volume of oxygen consumed per unit of energy. VO_2 was calculated both as volume per time and as volume per time per unit of body weight.

The inhalation rate for each activity within the 24-hour simulated activity pattern for each individual was estimated as a function of VO_2 , body weight, age, and sex. Following this, the average inhalation rate was calculated for each individual for the entire 24-hour period, as well as for four separate classes of activities based on METS value (sedentary/passive [METS less than or equal to 1.5], light intensity [METS greater than 1.5 and less than or equal to 3.0], moderate intensity [METS greater than 3.0 and less than or equal to 6.0], and high intensity [METS greater than 6.0]). Data for individuals were then used to generate summary tables based on sex and age categories.

U.S. EPA (2009a) also conducted a validation exercise using the Air Pollutants Exposure Model to estimate ventilation rates (VRs) and compared results with recently published estimates of ventilation rates from Brochu et al. (2006b; 2006a) and Arcus-Arth and Blaisdell (2007). The results compared reasonably well when ventilation rates were normalized by BMI.

Table 6-14 through Table 6-22 present data from this study. Table 6-14 and Table 6-15 present, for male and female subjects, respectively, summary statistics for daily average inhalation rate by age

category on a volumetric (m^3/day) and body-weight adjusted ($\text{m}^3/\text{day}\cdot\text{kg}$) basis. Table 6-16 presents the mean and 95th percentile values for males, females, and males and females combined. Table 6-17 through Table 6-20 present, for male and female subjects, respectively, mean ventilation rates by age category on a volumetric (m^3/minute) and body-weight adjusted ($\text{m}^3/\text{minute}\cdot\text{kg}$) basis for the five different activity level ranges described above. Table 6-21 and Table 6-22 present the number of hours spent per day at each activity level by males and females.

An advantage of this study is the large sample size. In addition, the data sets used, NHAPS and NHANES, are representative of the U.S. general population. One limitation is that the NHAPS data are more than 15 years old. Also, day-to-day variability cannot be characterized because data were collected over a 24-hour period. There is also uncertainty in the METs randomization, all of which were noted by the authors. In addition, the approach does not take into consideration correlations that may exist between body weight and activity patterns. Therefore, high physical activity levels can be associated with individuals of high body weight, leading to unrealistically high inhalation rates at the upper percentile levels. The validation exercise presented in U.S. EPA (2009a) used normal-weight individuals. It is unclear if similar results would be obtained for overweight individuals.

6.3.5. Key Studies Combined

In order to provide the recommended long-term inhalation rates shown in Table 6-1, data from the four key studies were combined. Mean and 95th percentile inhalation rate values for the four key studies are shown in Table 6-23 and Table 6-24, respectively. The data from each study were averaged by sex and grouped according to the age groups selected for use in this handbook, when possible. Table 6-25 shows concordance between the age groupings used in this handbook and the original age groups in the key studies.

6.4. RELEVANT INHALATION RATE STUDIES

6.4.1. International Commission on Radiological Protection (ICRP) (1981)—Report of the Task Group on Reference Man

The International Commission on Radiological Protection (ICRP, 1981) estimated daily inhalation rates for reference adult males and females, children (10 years old), infants (1 year old), and newborn

Chapter 6—Inhalation Rates

babies by using a time-activity-ventilation approach. This approach for estimating an inhalation rate over a specified period of time was based on calculating a time weighted average of inhalation rates associated with physical activities of varying durations (see Table 6-26). ICRP (1981) compiled reference values (see Table 6-27) of minute volume/inhalation rates from various literature sources. ICRP (1981) assumed that the daily activities of a reference male, female, and child (10 years of age) consisted of 8 hours of rest and 16 hours of light activities. It was also assumed that for adults only, the 16 hours of light activities were divided evenly between occupational and non-occupational activities. It was assumed that a day consisted of 14 hours resting and 10 hours light activity for an infant (1 year). A newborn's daily activities consisted of 23 hours resting and 1-hour light activity. The estimated inhalation rates were 22.8 m³/day for adult males, 21.1 m³/day for adult females, 14.8 m³/day for children (age 10 years), 3.76 m³/day for infants (age 1 year), and 0.78 m³/day for newborns (see Table 6-26).

The advantages of this study are that they account fairly well for time and activity, and are sex specific. A limitation associated with this study is that it is almost 30 years old. In addition, the validity and accuracy of the inhalation rate data used in the compilation of reference values were not specified. This introduces some degree of uncertainty in the results obtained. Also, the approach used required that assumptions be made regarding the hours spent by various age/sex cohorts in specific activities. These assumptions may over-/under-estimate the inhalation rates obtained.

6.4.2. U.S. EPA (1985)—Development of Statistical Distributions or Ranges of Standard Factors Used in Exposure Assessment

The U.S. EPA (1985) compiled measured values of minute ventilation for various age/sex cohorts from early studies. The data compiled by the U.S. EPA (1985) for each of the age/sex cohorts were obtained at various activity levels (see Table 6-28). These levels were categorized as light, moderate, or heavy according to the criteria developed by the U.S. EPA Office of Environmental Criteria and Assessment for the Ozone Criteria Document. These criteria were developed for a reference male adult with a body weight of 70 kg (U.S. EPA, 1985). Table 6-29 details the estimated minute ventilation rates for adult males based on these activity level categories.

Table 6-28 presents a summary of inhalation rates by age and activity level. A description of activities included in each activity level is also presented in Table 6-28. Table 6-28 indicates that at rest, the average adult inhalation rate is 0.5 m³/hour. Table 6-28 indicates that at rest, the mean inhalation rate for children, ages 6 and 10 years, is 0.4 m³/hour. Table 6-30 presents activity pattern data aggregated for three microenvironments by activity level for all age groups. The total average hours spent indoors was 20.4, outdoors was 1.77, and in a transportation vehicle was 1.77. Based on the data presented in Table 6-28 and Table 6-30, a daily inhalation rate was calculated for adults and children by using a time-activity-ventilation approach. These data are presented for adults and children in Table 6-31. The calculated average daily inhalation rate is 16 m³/day for adults. The average daily inhalation rate for 6- and 10-year-old children is 16.74 and 21.02 m³/day, respectively.

Limitations associated with this study are its age and that many of the values used in the data compilation were from early studies. The accuracy and/or validity of the values used and data collection method were not presented in U.S. EPA (1985). This introduces uncertainty in the results obtained. An advantage of this study is that the data are actual measurement data for a large number of adults and children.

6.4.3. Shamoo et al. (1990)—Improved Quantitation of Air Pollution Dose Rates by Improved Estimation of Ventilation Rate

Shamoo et al. (1990) conducted a study to develop and validate new methods to accurately estimate ventilation rates for typical individuals during their normal activities. Two practical approaches were tested for estimating ventilation rates indirectly: (1) volunteers were trained to estimate their own VR at various controlled levels of exercise; and (2) individual VR and HR relationships were determined in another set of volunteers during supervised exercise sessions (Shamoo et al., 1990). In the first approach, the training session involved 9 volunteers (3 females and 6 males) from 21 to 37 years old. Initially the subjects were trained on a treadmill with regularly increasing speeds. VR measurements were recorded during the last minute of the 3-minute interval at each speed. VR was reported to the subjects as low (1.4 m³/hour), medium (1.5–2.3 m³/hour), heavy (2.4–3.8 m³/hour), and very heavy (3.8 m³/hour or higher) (Shamoo et al., 1990).

Following the initial test, treadmill training sessions were conducted on a different day in which 7 different speeds were presented, each for 3 minutes in arbitrary order. VR was measured, and the subjects were given feedback with the four ventilation ranges provided previously. After resting, a treadmill testing session was conducted in which seven speeds were presented in different arbitrary order from the training session. VR was measured, and each subject estimated their own ventilation level at each speed. The correct level was then revealed to each subject after his/her own estimate. Subsequently, two 3-hour outdoor supervised exercise sessions were conducted in the summer on 2 consecutive days. Each hour consisted of 15 minutes each of rest, slow walking, jogging, and fast walking. The subjects' ventilation level and VR were recorded; however, no feedback was given to the subjects. Electrocardiograms were recorded via direct connection or telemetry, and HR was measured concurrently with ventilation measurement for all treadmill sessions.

The second approach consisted of two protocol phases (indoor/outdoor exercise sessions and field testing). Twenty outdoor adult workers between 19 and 50 years old were recruited. Indoor and outdoor supervised exercises similar to the protocols in the first approach were conducted; however, there were no feedbacks. Also, in this approach, electrocardiograms were recorded, and HR was measured concurrently with VR. During the field testing phase, subjects were trained to record their activities during three different 24-hour periods during 1 week. These periods included their most active working and non-working days. HR was measured quasi-continuously during the 24-hour periods that activities were recorded. The subjects recorded in a diary all changes in physical activity, location, and exercise levels during waking hours. Self-estimated activities in supervised exercises and field studies were categorized as slow (resting, slow walking or equivalent), medium (fast walking or equivalent), and fast (jogging or equivalent).

Inhalation rates were not presented in this study. In the first approach, about 68% of all self-estimates were correct for the 9 subjects sampled (Shamoo et al., 1990). Inaccurate self-estimates occurred in the younger male population who were highly physically fit and were competitive aerobic trainers. This subset of the sample population tended to underestimate their own physical activity levels at higher VR ranges. Shamoo et al. (1990) attributed this to a "macho effect," in which these younger male subjects were reluctant to report "very heavy" exercise even when it was obvious to an observer, because they considered it an admission of poor physical

condition. In the second approach, a regression analysis was conducted that related the logarithm of VR to HR. The logarithm of VR correlated better with HR than VR itself (Shamoo et al., 1990).

Limitations associated with this study are its age and that the population sampled is not representative of the general U.S. population. Also, ventilation rates were not presented. Training individuals to estimate their VR may contribute to uncertainty in the results because the estimates are subjective. Another limitation is that calibration data were not obtained at extreme conditions; therefore, the VR/HR relationship obtained may be biased. An additional limitation is that training subjects may be too labor-intensive for widespread use in exposure assessment studies. An advantage of this study is that HR recordings are useful in predicting ventilation rates, which, in turn, are useful in estimating exposure.

6.4.4. Shamoo et al. (1991)—Activity Patterns in a Panel of Outdoor Workers Exposed to Oxidant Pollution

Shamoo et al. (1991) investigated summer activity patterns in 20 adult volunteers with potentially high exposure to ambient oxidant pollution. The selected volunteer subjects were 15 men and 5 women ages 19–50 years from the Los Angeles area. All volunteers worked outdoors at least 10 hours per week. The experimental approach involved two stages: (1) indirect objective estimation of VR from HR measurements, and (2) self-estimation of inhalation/ventilation rates recorded by subjects in diaries during their normal activities.

The approach consisted of calibrating the relationship between VR and HR for each test subject in controlled exercise; monitoring by subjects of their own normal activities with diaries and electronic HR recorders; and then relating VR with the activities described in the diaries (Shamoo et al., 1991). Calibration tests were conducted for indoor and outdoor supervised exercises to determine individual relationships between VR and HR. Indoors, each subject was tested on a treadmill at rest and at increasing speeds. HR and VR were measured at the third minute at each 3-minute interval speed. In addition, subjects were tested while walking a 90-meter course in a corridor at 3 self-selected speeds (normal, slower than normal, and faster than normal) for 3 minutes.

Two outdoor testing sessions (1 hour each) were conducted for each subject, 7 days apart. Subjects exercised on a 260-meter asphalt course. A session

Chapter 6—Inhalation Rates

involved 15 minutes each of rest, slow walking, jogging, and fast walking during the first hour. The sequence was also repeated during the second hour. HR and VR measurements were recorded starting at the 8th minute of each 15-minute segment. Following the calibration tests, a field study was conducted in which subjects self-monitored their activities by filling out activity diary booklets, self-estimated their breathing rates, and their HR. Breathing rates were defined as sleep; slow (slow or normal walking); medium (fast walking); and fast (running) (Shamoo et al., 1991). Changes in location, activity, or breathing rates during three 24-hour periods within a week were recorded. These periods included their most active working and non-working days. Each subject wore Heart Watches, which recorded their HR once per minute during the field study. Ventilation rates were estimated for the following categories: sleep, slow, medium, and fast.

Calibration data were fit to the equation $\log(\text{VR}) = \text{intercept} + (\text{slope} \times \text{HR})$, each individual's intercept and slope were determined separately to provide a specific equation that predicts each subject's VR from measured HR (Shamoo et al., 1991). The average measured VRs were 0.48, 0.90, 1.68, and 4.02 m³/hour for rest, slow walking or normal walking, fast walking, and jogging, respectively (Shamoo et al., 1991). Collectively, the diary recordings showed that sleep occupied about 33% of the subject's time; slow activity 59%; medium activity 7%; and fast activity 1%. The diary data covered an average of 69 hours per subject (Shamoo et al., 1991). Table 6-32 presents the distribution pattern of predicted ventilation rates and equivalent ventilation rates (EVR) obtained at the four activity levels. EVR was defined as the VR per square meter of body surface area, and also as a percentage of the subjects average VR over the entire field monitoring period (Shamoo et al., 1991). The overall mean predicted VR was 0.42 m³/hour for sleep; 0.71 m³/hour for slow activity; 0.84 m³/hour for medium activity; and 2.63 m³/hour for fast activity.

Table 6-33 presents the mean predicted VR and standard deviation, and the percentage of time spent in each combination of VR, activity type (essential and non-essential), and location (indoor and outdoor). Essential activities include income-related work, household chores, child care, study and other school activities, personal care, and destination-oriented travel. Non-essential activities include sports and active leisure, passive leisure, some travel, and social or civic activities (Shamoo et al., 1991). Table 6-33 shows that inhalation rates were higher outdoors than indoors at slow, medium, and fast activity levels.

Also, inhalation rates were higher for outdoor non-essential activities than for indoor non-essential activity levels at slow, medium, and fast self-reported breathing rates (see Table 6-33).

An advantage of this study is that subjective activity diary data can provide exposure modelers with useful rough estimates of VR for groups of generally healthy people. A limitation of this study is its age and that the results obtained show high within-person and between-person variability in VR at each diary-recorded level, indicating that VR estimates from diary reports could potentially be substantially misleading in individual cases. Another limitation of this study is that elevated HR data of slow activity at the second hour of the exercise session reflect persistent effects of exercise and/or heat stress. Therefore, predictions of VR from the VR/HR relationship may be biased.

6.4.5. Linn et al. (1992)—Documentation of Activity Patterns in “High-Risk” Groups Exposed to Ozone in the Los Angeles Area

Linn et al. (1992) conducted a study that estimated the inhalation rates for “high-risk” population groups exposed to ozone in their daily activities in the Los Angeles area. The population surveyed consisted of seven subject panels: Panel 1: 20 healthy outdoor workers (15 males, 5 females, ages 19–50 years); Panel 2: 17 healthy elementary school students (5 males, 12 females, ages 10–12 years); Panel 3: 19 healthy high school students (7 males, 12 females, ages 13–17 years); Panel 4: 49 asthmatic adults (clinically mild, moderate, and severe, 15 males, 34 females, ages 18–50 years); Panel 5: 24 asthmatic adults from 2 neighborhoods of contrasting O₃ air quality (10 males, 14 females, ages 19–46 years); Panel 6: 13 young asthmatics (7 males, 6 females, ages 11–16 years); and Panel 7: construction workers (7 males, ages 26–34 years). An initial calibration test was conducted, followed by a training session. Finally, a field study that involved the subjects collecting their own HRs and diary data was conducted. During the calibration tests, VR, breathing rate, and HR were measured simultaneously at each exercise level. From the calibration data, an equation was developed using linear regression analysis to predict VR from measured HR.

In the field study, each subject (except construction workers) recorded in diaries their daily activities, change in locations (indoors, outdoors, or in a vehicle), self-estimated breathing rates during

each activity/location, and time spent at each activity/location. Healthy subjects recorded their HR once every 60 seconds using a Heart Watch, an automated system consisting of a transmitter and receiver worn on the body. Asthmatic subjects recorded their diary information once every hour. Subjective breathing rates were defined as slow (walking at their normal pace), medium (faster than normal walking), and fast (running or similarly strenuous exercise). Table 6-34 presents the calibration and field protocols for self-monitoring of activities for each subject panel.

Table 6-35 presents the mean, 99th percentile, and mean VR at each subjective activity level (slow, medium, fast). The mean and 99th percentile VR were derived from all HR recordings that appeared to be valid, without considering the diary data. Each of the three activity levels was determined from both the concurrent diary data and HR recordings by direct calculation or regression. The mean VR for healthy adults was 0.78 m³/hour, while the mean VR for asthmatic adults was 1.02 m³/hour (see Table 6-35). The preliminary data for construction workers indicated that during a 10-hour work shift, their mean VR (1.50 m³/hour) exceeded the VRs of all other subject panels (see Table 6-35). The authors reported that the diary data showed that on a typical day, most individuals spent most of their time indoors at slow activity level. During slow activity, asthmatic subjects had higher VRs than healthy subjects (see Table 6-35). The authors also reported that in every panel, the predicted VR correlated significantly with the subjective estimates of activity levels.

A limitation of this study is that calibration data may overestimate the predictive power of HR during actual field monitoring. The wide variety of exercises in everyday activities may result in greater variation of the VR-HR relationship than was calibrated. Another limitation is the small sample size of each population surveyed. An advantage of this study is that diary data can provide rough estimates of ventilation patterns, which are useful in exposure assessments. Another advantage is that inhalation rates were presented for various populations (i.e., healthy outdoor adult workers, healthy children, asthmatics, and construction workers).

6.4.6. Shamoo et al. (1992)—Effectiveness of Training Subjects to Estimate Their Level of Ventilation

Shamoo et al. (1992) conducted a study where nine non-sedentary subjects in good health were trained on a treadmill to estimate their own ventilation rates at four activity levels: low, medium,

heavy, and very heavy. The purpose of the study was to train the subjects' self-estimation of ventilation in the field and to assess the effectiveness of the training (Shamoo et al., 1992). The subjects included 3 females and 6 males between 21 to 37 years of age. The tests were conducted in four stages. First, an initial treadmill pretest was conducted indoors at various speeds until the four ventilation levels were experienced by each subject; VR was measured and feedback was given to the subjects. Second, two treadmill training sessions, which involved seven 3-minute segments of varying speeds based on initial tests, were conducted; VR was measured and feedback was given to the subjects. Another similar session was conducted; however, the subjects estimated their own ventilation level during the last 20 seconds of each segment and VR was measured during the last minute of each segment. Immediate feedback was given to the subject's estimate; and the third and fourth stages involved 2 outdoor sessions of 3 hours each. Each hour comprised 15 minutes each of rest, slow walking, jogging, and fast walking. The subjects estimated their own ventilation level at the middle of each segment. The subject's estimate was verified by a respirometer, which measured VR in the middle of each 15-minute activity. No feedback was given to the subject. The overall percent correct score obtained for all ventilation levels was 68% (Shamoo et al., 1992). Therefore, Shamoo et al. (1992) concluded that this training protocol was effective in training subjects to correctly estimate their minute ventilation levels.

For this handbook, inhalation rates were analyzed from the raw data provided by Shamoo et al. (1992). Table 6-36 presents the mean inhalation rates obtained from this analysis at four ventilation levels in two microenvironments (i.e., indoors and outdoors) for all subjects. The mean inhalation rates for all subjects were 0.93, 1.92, 3.01, and 4.80 m³/hour for low, medium, heavy, and very heavy activities, respectively.

Limitations of this study are its age and the population sample size used in this study was small and was not selected to represent the general U.S. population. The training approach employed may not be cost effective because it was labor intensive; therefore, this approach may not be viable in field studies especially for field studies within large sample sizes.

Chapter 6—Inhalation Rates

6.4.7. Spier et al. (1992)—Activity Patterns in Elementary and High School Students Exposed to Oxidant Pollution

Spier et al. (1992) investigated the activity patterns of 17 elementary school students (10–12 years old) and 19 high school students (13–17 years old) in suburban Los Angeles from late September to October (oxidant pollution season). Calibration tests were conducted in supervised outdoor exercise sessions. The exercise sessions consisted of 5 minutes each of rest, slow walking, jogging, and fast walking. HR and VR were measured during the last 2 minutes of each exercise. Individual VR and HR relationships for each individual were determined by fitting a regression line to HR values and log VR values. Each subject recorded their daily activities, changes in location, and breathing rates in diaries for 3 consecutive days. Self-estimated breathing rates were recorded as slow (slow walking), medium (walking faster than normal), and fast (running). HR was recorded once per minute during the 3 days using a Heart Watch. VR values for each self-estimated breathing rate and activity type were estimated from the HR recordings by employing the VR and HR equation obtained from the calibration tests.

The data shown in Table 6-37 represent HR distribution patterns and corresponding predicted VR for each age group during hours spent awake. At the same self-reported activity levels for both age groups, inhalation rates were higher for outdoor activities than for indoor activities. The total number of hours spent indoors was higher for high school students (21.2 hours) than for elementary school students (19.6 hours). The converse was true for outdoor activities: 2.7 hours for high school students and 4.4 hours for elementary school students (see Table 6-38). Table 6-39 describes the distribution patterns of daily inhalation rates for elementary and high school students grouped by activity level.

A limitation of this study is the small sample size. The results may not be representative of all children in these age groups. Another limitation is that the accuracy of the self-estimated breathing rates reported by younger age groups is uncertain. This may affect the validity of the data set generated. An advantage of this study is that inhalation rates were determined for children and adolescents.

6.4.8. Adams (1993)—Measurement of Breathing Rate and Volume in Routinely Performed Daily Activities, Final Report

Adams (1993) conducted research to accomplish two main objectives: (1) identification of mean and

ranges of inhalation rates for various age/sex cohorts and specific activities, and (2) derivation of simple linear and multiple regression equations that could be used to predict inhalation rates through other measured variables: breathing frequency (f_B) and oxygen consumption. A total of 160 subjects participated in the primary study. There were four age-dependent groups: (1) children 6 to 12.9 years old, (2) adolescents between 13 and 18.9 years old, (3) adults between 19 and 59.9 years old, and (4) seniors >60 years old (Adams, 1993). An additional 40 children from 6 to 12.9 years old and 12 young children from 3 to 5.9 years old were identified as subjects for pilot testing purposes.

Resting protocols conducted in the laboratory for all age groups consisted of three phases (25 minutes each) of lying, sitting, and standing. The phases were categorized as resting and sedentary activities. Two active protocols—moderate (walking) and heavy (jogging/running) phases—were performed on a treadmill over a progressive continuum of intensity levels made up of 6-minute intervals at three speeds ranging from slow to moderately fast. All protocols involved measuring VR, HR, f_B , and VO_2 . Measurements were taken in the last 5 minutes of each phase of the resting protocol and the last 3 minutes of the 6-minute intervals at each speed designated in the active protocols.

In the field, all children completed spontaneous play protocols. The older adolescent population (16 to 18 years) completed car driving and riding, car maintenance (males), and housework (females) protocols. All adult females (19 to 60 years) and most of the senior (60 to 77 years) females completed housework, yardwork, and car driving and riding protocols. Adult and senior males completed car driving and riding, yardwork, and mowing protocols. HR, VR, and f_B were measured during each protocol. Most protocols were conducted for 30 minutes. All the active field protocols were conducted twice.

During all activities in either the laboratory or field protocols, VR for the children's group revealed no significant sex differences, but those for the adult groups demonstrated sex differences. Therefore, inhalation rate (IR) data presented in Table 6-40 and Table 6-41 were categorized as young children, children (no sex), and adult female, and adult male, and adult combined by activity type (lying, sitting, standing, walking, and running). These categorized data from Table 6-40 and Table 6-41 are summarized as inhalation rates in Table 6-42 and Table 6-43. Table 6-42 shows the laboratory protocols. Table 6-43 presents the mean inhalation rates by group and for moderate activity levels in field protocols. A comparison of the data shown in

Table 6-42 and Table 6-43 suggest that during light and sedentary activities in laboratory and field protocols, similar inhalation rates were obtained for adult females and adult males. Accurate predictions of inhalation rates across all population groups and activity types were obtained by including body SA, HR, and breathing frequency in multiple regression analysis (Adams, 1993). Adams (1993) calculated SA from measured height and body weight using the equation:

$$SA = \text{Height}^{(0.725)} \times \text{Weight}^{(0.425)} \times 71.84 \quad (\text{Eqn. 6-3})$$

A limitation associated with this study is that the population does not represent the general U.S. population. Also, the classification of activity types (i.e., laboratory and field protocols) into activity levels may bias the inhalation rates obtained for various age/sex cohorts. Age groups for which data are provided are limited and do not conform to U.S. EPA's recommended age groups for children. The estimated rates were based on short-term data and may not reflect long-term patterns.

6.4.9. Layton (1993)—Metabolically Consistent Breathing Rates for Use in Dose Assessments

Layton (1993) presented a method for estimating metabolically consistent inhalation rates for use in quantitative dose assessments of airborne radionuclides. Generally, the approach for estimating the breathing rate for a specified time frame was to calculate a time-weighted-average of ventilation rates associated with physical activities of varying durations. However, in this study, breathing rates were calculated on the basis of oxygen consumption associated with energy expenditures for short (hours) and long (weeks and months) periods of time, using the following general equation to calculate energy-dependent inhalation rates:

$$V_E = E \times H \times VQ \quad (\text{Eqn. 6-4})$$

where:

$$\begin{aligned} V_E &= \text{ventilation rate (m}^3/\text{minute or m}^3/\text{day);} \\ E &= \text{energy expenditure rate; [kilojoules/minute (KJ/minute) or megajoules/hour (MJ/hour)];} \\ H &= \text{volume of oxygen (at standard temperature and pressure, dry air} \end{aligned}$$

consumed in the production of 1 kilojoule [KJ] of energy expended [L/KJ or m³/MJ]); and

$$VQ = \text{ventilatory equivalent (ratio of minute volume [m}^3/\text{minute] to oxygen uptake [m}^3/\text{minute]) unitless.}$$

Layton (1993) used three approaches to estimate daily chronic (long term) inhalation rates for different age/sex cohorts of the U.S. population using this methodology.

First Approach

Inhalation rates were estimated by multiplying average daily food-energy intakes (EFDs) for different age/sex cohorts, H , and VQ , as shown in the equation above. The average food-energy intake data (see Table 6-44) are based on approximately 30,000 individuals and were obtained from the 1977–1978 USDA-NFCS. The food-energy intakes were adjusted upwards by a constant factor of 1.2 for all individuals 9 years and older. This factor compensated for a consistent bias in USDA-NFCS that was attributed to under-reporting of the foods consumed or the methods used to ascertain dietary intakes. Layton (1993) used a weighted average oxygen uptake of 0.05 L O₂/KJ, which was determined from data reported in the 1977–1978 USDA-NFCS and the second NHANES (NHANES II). The survey sample for NHANES II was approximately 20,000 participants. A VQ of 27 used in the calculations was calculated as the geometric mean of VQ data that were obtained from several studies.

The inhalation rate estimation techniques are shown in the footnotes in Table 6-45. Table 6-46 presents the daily inhalation rate for each age/sex cohort. As shown in Table 6-45, the highest daily inhalation rates were 10 m³/day for children between the ages of 6 and 8 years, 17 m³/day for males between 15 and 18 years, and 13 m³/day for females between 9 and 11 years. Estimated average lifetime inhalation rates for males and females are 14 m³/day and 10 m³/day, respectively (see Table 6-45). Inhalation rates were also calculated for active and inactive periods for the various age/sex cohorts.

The inhalation rate for inactive periods was estimated by multiplying the BMR times H times VQ . BMR was defined as “the minimum amount of energy required to support basic cellular respiration while at rest and not actively digesting food” (Layton, 1993). The inhalation rate for active periods was calculated by multiplying the inactive inhalation rate by the ratio of the rate of energy expenditure during active hours to the estimated BMR. This ratio

Chapter 6—Inhalation Rates

is presented as F in Table 6-45. Table 6-45 also presents these data for active and inactive inhalation rates. For children, inactive and active inhalation rates ranged from 2.35 to 5.95 m³/day and from 6.35 to 13.09 m³/day, respectively. For adult males (19 to 64 years old), the average inactive and active inhalation rates were approximately 10 and 19 m³/day, respectively. Also, the average inactive and active inhalation rates for adult females (19 to 64 years old) were approximately 8 and 12 m³/day, respectively.

Second Approach

Inhalation rates were calculated as the product of the BMR of the population cohorts, the ratio of total daily energy expenditure to daily BMR, H , and VQ. The BMR data obtained from the literature were statistically analyzed, and regression equations were developed to predict BMR from body weights of various age/sex cohorts. Table 6-46 presents the statistical data used to develop the regression equations. Table 6-47 presents the data obtained from the second approach. Inhalation rates for children (6 months–10 years) ranged from 7.3–9.3 m³/day for male and 5.6–8.6 m³/day for female children; for older children (10–18 years), inhalation rates were 15 m³/day for males and 12 m³/day for females. Adult females (18 years and older) ranged from 9.9–11 m³/day and adult males (18 years and older) ranged from 13–17 m³/day. These rates are similar to the daily inhalation rates obtained using the first approach. Also, the inactive inhalation rates obtained from the first approach are lower than the inhalation rates obtained using the second approach. This may be attributed to the BMR multiplier employed in the equation of the second approach to calculate inhalation rates.

Third Approach

Inhalation rates were calculated by multiplying estimated energy expenditures associated with different levels of physical activity engaged in over the course of an average day by VQ and H for each age/sex cohort. The energy expenditure associated with each level of activity was estimated by multiplying BMRs of each activity level by the MET and by the time spent per day performing each activity for each age/sex population. The time-activity data used in this approach were obtained from a survey conducted by Sallis et al. (1985) (Layton, 1993). In that survey, the physical-activity categories and associated MET values used were sleep, MET = 1; light-activity, MET = 1.5; moderate activity, MET = 4; hard activity, MET = 6; and very hard activity, MET = 10.

The physical activities were based on recall by the test subject (Layton, 1993). The survey sample was 2,126 individuals (1,120 women and 1,006 men) ages 20–74 years that were randomly selected from four communities in California. The body weights were obtained from a study conducted by Najjar and Rowland (1987) that randomly sampled individuals from the U.S. population (Layton, 1993). Table 6-48 presents the daily inhalation rates (V_E) in m³/day and m³/hour for adult males and females aged 20–74 years at five physical activity levels. The total daily inhalation rates ranged from 13–17 m³/day for adult males and 11–15 m³/day for adult females.

The rates for adult females were higher when compared with the other two approaches. Layton (1993) reported that the estimated inhalation rates obtained from the third approach were particularly sensitive to the MET value that represented the energy expenditures for light activities. Layton (1993) stated further that in the original time-activity survey [i.e., conducted by Sallis et al. (1985)], time spent performing light activities was not presented. Therefore, the time spent at light activities was estimated by subtracting the total time spent at sleep, moderate, heavy, and very heavy activities from 24 hours (Layton, 1993). The range of inhalation rates for adult females were 9.6–11 m³/day, 9.9–11 m³/day, and 11–15 m³/day, for the first, second, and third approaches, respectively. The inhalation rates for adult males ranged from 13–16 m³/day for the first approach, and 13–17 m³/day for the second and third approaches.

Inhalation rates were also obtained for short-term exposures for various age/sex cohorts and five energy-expenditure categories (rest, sedentary, light, moderate, and heavy). BMRs were multiplied by the product of MET, H , and VQ. Table 6-49 presents the inhalation-rate data obtained for short-term exposures.

The major strengths of the Layton (1993) study are that it obtains similar results using three different approaches to estimate inhalation rates in different age groups and that the populations are large, consisting of men, women, and children. Explanations for differences in results due to metabolic measurements, reported diet, or activity patterns are supported by observations reported by other investigators in other studies. Major limitations of this study are (1) the estimated activity pattern levels are somewhat subjective; (2) the explanation that activity pattern differences are responsible for the lower level obtained with the metabolic approach (25%) compared to the activity pattern approach is not well supported by the data; and (3) different

populations were used in each approach, which may have introduced error.

6.4.10. Linn et al. (1993)—Activity Patterns in Ozone Exposed Construction Workers

Linn et al. (1993) estimated the inhalation rates of 19 construction workers who perform heavy outdoor labor before and during a typical work shift. The workers (laborers, iron workers, and carpenters) were employed at a site on a hospital campus in suburban Los Angeles. The construction site included a new hospital building and a separate medical office complex. The study was conducted between mid-July and early November, 1991. During this period, ozone (O_3) levels were typically high. Initially, each subject was calibrated with a 25-minute exercise test that included slow walking, fast walking, jogging, lifting, and carrying. All calibration tests were conducted in the mornings. VR and HR were measured simultaneously during the test. The data were analyzed using least squares regression to derive an equation for predicting VR at a given HR. Following the calibration tests, each subject recorded the type of activities to be performed during their work shift (i.e., sitting/standing, walking, lifting/carrying, and “working at trade”—defined as tasks specific to the individual’s job classification). Location, and self-estimated breathing rates (“slow” similar to slow walking, “medium” similar to fast walking, and “fast” similar to running) were also recorded in the diary. During work, an investigator recorded the diary information dictated by the subjects. HR was recorded minute by minute for each subject before work and during the entire work shift. Thus, VR ranges for each breathing rate and activity category were estimated from the HR recordings by employing the relationship between VR and HR obtained from the calibration tests.

A total of 182 hours of HR recordings were obtained during the survey from the 19 volunteers; 144 hours reflected actual working time according to the diary records. The lowest actual working hours recorded was 6.6 hours, and the highest recorded for a complete work shift was 11.6 hours (Linn et al., 1993). Table 6-50 presents summary statistics for predicted VR distributions for outdoor workers, and for job- or site-defined subgroups. The data reflect all recordings before and during work, and at break times. For all subjects, the mean inhalation rate was $1.68 \text{ m}^3/\text{hour}$ with a standard deviation of ± 0.72 (see Table 6-50). Also, for most subjects, the 1st and 99th percentiles of HR were outside of the calibration range. Therefore, corresponding IR percentiles were

extrapolated using the calibration data (Linn et al., 1993).

The data shown in Table 6-51 represent distribution patterns of mean inhalation rate for each subject, total subjects, and job- or site-defined subgroups by self-estimated breathing rates (slow, medium, or fast) or by type of job activity. All data include working and non-working hours. The mean inhalation rates for most individuals showed statistically significant increases with higher self-estimated breathing rates or with increasingly strenuous job activity (Linn et al., 1993). Inhalation rates were higher in hospital site workers when compared with office site workers (see Table 6-51). In spite of their higher predicted VR workers at the hospital site reported a higher percentage of slow breathing time (31%) than workers at the office site (20%), and a lower percentage of fast breathing time, 3% and 5%, respectively (Linn et al., 1993). Therefore, individuals whose work was objectively heavier than average (from VR predictions) tended to describe their work as lighter than average (Linn et al., 1993). Linn et al. (1993) also concluded that during an O_3 pollution episode, construction workers should experience similar microenvironmental O_3 exposure concentrations as other healthy outdoor workers, but with approximately twice as high a VR. Therefore, the inhaled dose of O_3 should be almost two times higher for typical heavy-construction workers than for typical healthy adults performing less strenuous outdoor jobs.

Limitations associated with this study are its age and the small sample size. Another limitation of this study is that calibration data were not obtained at extreme conditions. Therefore, it was necessary to predict inhalation rate values that were outside the calibration range. This may introduce an unknown amount of uncertainty to the data set. Subjective self-estimated breathing rates may be another source of uncertainty in the inhalation rates estimated. An advantage is that this study provides empirical data useful in exposure assessments for a population thought to be the most highly exposed common occupational group (outdoor workers).

6.4.11. Rusconi et al. (1994)—Reference Values for Respiratory Rate in the First 3 Years of Life

Rusconi et al. (1994) examined a large number of infants and children in Milano, Italy, in order to determine the reference values for respiratory rate in children aged 15 days to 3 years. A total of 618 infants and children (336 males and 282 females), who did not have respiratory infections or any severe

Chapter 6—Inhalation Rates

disease, were included in the study. Of the 618, a total of 309 were in good health and were observed in daycare centers, while the remaining 309 were seen in hospitals or as outpatients.

Respiratory rates were recorded twice, 30 to 60 minutes apart, listening to breath sounds for 60 seconds with a stethoscope, when the child was awake and calm and when the child was sleeping quietly (sleep not associated with any spontaneous movement, including eye movements or vocalizations) (see Table 6-52). The children were assessed for 1 year in order to determine the repeatability of the recordings, to compare respiratory rate counts obtained by stethoscope and by observation, and to construct reference percentile curves by age in a large number of subjects.

The authors plotted the differences between respiratory rate counts determined by stethoscope at 30- to 60-minute intervals against their mean count in waking and sleeping subjects. The standard deviation of the differences between the two counts was 2.5 and 1.7 breaths/minute, respectively, for waking and sleeping children. This standard deviation yielded 95% repeatability coefficients of 4.9 breaths/minute when the infants and children were awake and 3.3 breaths/minute when they were asleep.

In both waking and sleeping states, the respiratory rate counts determined by stethoscope were found to be higher than those obtained by observation. The mean difference was 2.6 and 1.8 breaths per minute, respectively, in waking and sleeping states. The mean respiratory rate counts were significantly higher in infants and children at all ages when awake and calm than when asleep. A decrease in respiratory rate with increasing age was seen in waking and sleeping infants and children. A scatter diagram of respiratory rate counts by age in waking and sleeping subjects showed that the pattern of respiratory rate decline with age was similar in both states, but it was much faster in the first few months of life. The authors constructed centile curves by first log-transforming the data and then applying a second degree polynomial curve, which allowed excellent fitting to observed data. Figure 6-1 and Figure 6-2 show smoothed percentiles by age in waking and sleeping subjects, respectively. The variability of respiratory rate among subjects was higher in the first few months of life, which may be attributable to biological events that occur during these months, such as maturation of the neurologic control of breathing and changes in lung and chest wall compliance and lung volumes.

An advantage of this study is that it provides distribution data for respiratory rate for children from infancy (less than 2 months) to 36 months old. The

main limitation of this study is that data are provided in breaths/minute for awake and asleep subjects. Activity pattern data for the awake subjects are limited, which prevents characterization of breathing rates for various levels of exertion. These data are not U.S. data; U.S. distributions were not available. Although, there is no reason to believe that the respiratory rates for Italian children would be different from that of U.S. children, this study only provided data for a narrow range of activities.

6.4.12. Price et al. (2003)—Modeling Interindividual Variation in Physiological Factors Used in PBPK Models of Humans

Price et al. (2003) developed a database of values for physiological parameters often used in physiologically based pharmacokinetic (PBPK) models. The database consisted of approximately 31,000 records containing information on volumes and masses of selected organs and tissues, blood flows for the organ and tissues, and total resting cardiac output and average inhalation rates. Records were created based on data from the NHANES III survey.

The study authors note that the database provides a source of data for human physiological parameters where the parameter values for an individual are correlated with one another and capture interindividual variation in populations of a specific sex, race, and age range. A publicly available computer program, Physiological Parameters for PBPK Modeling, was also developed to randomly retrieve records from the database for groups of individuals of specified age ranges, sex, and ethnicities (Lifeline Group, 2006). Price et al. (2003) recommends that output sets be used as inputs to Monte Carlo-based PBPK models of interindividual variation in dose. A limitation of this study is that these data have not been validated against actual physiological data. Ideally, the database records would have been obtained from detailed physiological analyses of individuals, however, such a survey was not conducted for this study.

6.4.13. Brochu et al. (2006a)—Physiological Daily Inhalation Rates for Free-Living Pregnant and Lactating Adolescents and Women Aged 11 to 55 Years, Using Data From Doubly Labeled Water Measurements for Use in Health Risk Assessment

PDIRs were determined by Brochu et al. (2006a) for underweight, normal-weight, and overweight/obese pregnant and lactating females

aged 11 to 55 years using published data on total daily energy expenditures, and energy costs for growth, pregnancy and lactation (breast-energy output and maternal milk-energy synthesis) in free-living females. These data were obtained using the DLW methodology in which disappearance rates of predetermined doses of DLW ($^2\text{H}_2\text{O}$ and H_2^{18}O) in urine from non-pregnant and non-lactating females ($N = 357$) and normal-weight males ($N = 131$) as well as saliva from gravid and breast-feeding females ($N = 91$) were monitored by gas-isotope-ratio mass spectrometry.

PDIRs were calculated for underweight, normal-weight, and overweight/obese females aged 11 to 55 years in pre-pregnancy, at Weeks 9, 22, and 36 during pregnancy, and Weeks 6 and 27 postpartum. Weight groups were determined by BMI cutoffs settled by the Institute of Medicine for pre-pregnant females. Underweight, normal-weight, and overweight/obese individuals were defined as those having BMIs lower than 19.8 kg/m^2 , between 19.8 and 26 kg/m^2 , and greater than 26 kg/m^2 , respectively. Parameters used for breast-energy output and the extra energy cost for milk synthesis were $539.29 \pm 106.26 \text{ kcal/day}$ and $107.86 \pm 21.25 \text{ kcal/day}$, respectively. Monte Carlo simulations were necessary to integrate total daily energy requirements of non-pregnant and non-lactating females into energy costs and weight changes at the 9th, 22nd, and 36th weeks of pregnancy and at the 6th and 27th postpartum weeks. A total of 108 sets of 5,000 energetic data were run, resulting in a simulation of 540,000 data, pertaining to 45,000 simulated subjects. Means, standard deviations, and percentiles of energetic values in kcal/day and kcal/kg-day for males and females were converted into PDIRs in m^3/day and $\text{m}^3/\text{kg-day}$ by using the equation developed by Layton (1993).

Table 6-53, Table 6-54, and Table 6-55 present the distribution of physiological daily inhalation rate percentiles in m^3/day for underweight, normal-weight, and overweight/obese females, respectively, during pregnancy and postpartum weeks. Table 6-56, Table 6-57, and Table 6-58 present physiological daily inhalation rate percentiles in $\text{m}^3/\text{kg-day}$ for the same categories. PDIRs for under-, normal-, and overweight/obese pregnant and lactating females were higher than those for males reported in Brochu et al. (2006b). In normal-weight subjects, inhalation rates are higher by 18 to 41% throughout pregnancy and 23 to 39% during postpartum weeks: actual values were higher in females by 1.13 to $2.01 \text{ m}^3/\text{day}$ at the 9th week of pregnancy, 3.74 to $4.53 \text{ m}^3/\text{day}$ at the 22nd week, and 4.41 to $5.20 \text{ m}^3/\text{day}$ at the 36th week, and by 4.43 to

$5.30 \text{ m}^3/\text{day}$ at the 6th postpartum week and 4.22 to $5.11 \text{ m}^3/\text{day}$ at the 27th postpartum week. The highest 99th percentiles were found to be $0.622 \text{ m}^3/\text{kg-day}$ in pregnant females and $0.647 \text{ m}^3/\text{kg-day}$ in lactating females. By comparison, the highest 99th percentile value for individuals aged 2.6 months to 96 years was determined to be $0.725 \text{ m}^3/\text{kg-day}$ (Brochu et al., 2006b). The authors concluded that air quality criteria and standard calculations based on the latter value for non-carcinogenic toxic compounds should, therefore, be protective for virtually all pregnant and lactating females. Brochu et al. (2006a) also noted that the default assumption used by IRIS to derive HECs (total respiratory tract surface of an adult human male of 54.3 m^2 is exposed to a total daily air intake of 20 m^3) would underestimate exposures to pregnant or lactating females since approximately one pregnant or lactating female out of two is exposed to a total daily air intake of 20 m^3 up to the highest 99th percentile of 47.3 m^3 .

An advantage of this study is that it includes pregnant and lactating females, and that data are provided for adolescents aged 11 years and older. A limitation of this study is that the study population was partially drawn from Canada and may not represent the general U.S. population. Also, age groups for adolescents for which data are provided do not conform to U.S. EPA's recommended age groups for children.

6.4.14. Allan et al. (2009)—Inhalation Rates for Risk Assessments Involving Construction Workers in Canada

Allan et al. (2009) generated probability density distributions by performing a Monte Carlo simulation to describe inhalation rates for Canadian male and female construction workers. Construction workers in this study were those involved in the construction or physical maintenance of buildings, structures, or other facilities, and their ages ranged from 16 to 65 years. Information regarding activity patterns and/or inhalation rates was obtained from published literature and used to estimate male construction workers' hourly inhalation rates. Female construction worker inhalation rates were estimated using the ratio of general public female-to-male inhalation rates and male construction workers' hourly inhalation rates. Published energy expenditure and inhalation rates were compared by occupation within the construction industry, and these data were used to develop trade-specific scaling factors. All inhalation rates were developed as probability density functions through Monte Carlo simulation. Ten thousand iterations of random sampling were performed, and at

Chapter 6—Inhalation Rates

the end of the simulation, the results for all 10,000 iterations were summarized into frequency histograms. The mean, standard deviation, and percentiles were calculated based on the frequency counts.

Inhalation rates for male construction workers were represented by a log normal distribution, with a mean rate of 1.40 ± 0.51 m³/hour. Hourly inhalation rates for female construction workers were scaled down from those of their male counterparts, based on relative awake-time inhalation rates for men and women in the general public. Inhalation rates for female construction workers were also represented by a log normal distribution, with a mean rate of 1.25 ± 0.66 m³/hour. Construction trade-specific scaling factors were developed and ranged from 0.78 for electricians to 1.11 for ironworkers.

An advantage of this study is that it provides estimated inhalation rates for a population of construction workers. A limitation of this study is that the construction workers in this study were solely male construction workers; no females were among the cohorts monitored.

^a Measured body weight. Normal-weight individuals defined according to the BMI cut-offs.											
^b Physiological daily inhalation rates were calculated using the following equation: $(TDEE + ECG) \times H \times (V_E/VO_2) \times 10^{-3}$, where $H = 0.21$ L of O ₂ /Kcal, $V_E/VO_2 = 27$ (Layton, 1993) and ECG = stored daily energy cost for growth (kcal/day).											
^c Percentiles based on a normal distribution assumption for age groups.											
N = Number of individuals.											
SD = Standard deviation.											
Source: Brochu et al. (2006b).

32 days (~1 month)	10 ^{e,f}	4.7 ± 0.7	2.45 ± 0.59 ^g	0.53 ± 0.10 ^g
33 days (~1 month)	10 ^{b,f}	4.8 ± 0.3	2.99 ± 0.47 ^g	0.62 ± 0.09 ^g
^a	Physiological daily inhalation rates were calculated using the following equation: $(TDEE + ECG) \times H \times (V_E/VO_2) \times 10^{-3}$, where $H = 0.21$ L of O ₂ /Kcal, $V_E/VO_2 = 27$ (Layton, 1993), $TDEE$ = total daily energy expenditure (kcal/day) and ECG = stored daily energy cost for growth (kcal/day).			
^b	Formula-fed infants.			
^c	Healthy infants with very low birth weight.			
^d	TDEEs based on nutritional balance measurements during 3-day periods.			
^e	Breast-fed infants.			
^f	Infants evaluated as being clinically healthy and neither underweight or overweight.			
^g	TDEEs based on ² H ₂ O and H ₂ ¹⁸ O disappearance rates from urine.			
N	= Number of individuals.			
SD	= Standard deviation.

^a An individual's ventilation rate for the given activity category equals the weighted average of the individual's activity-specific ventilation rates for activities falling within the category, estimated using a multiple linear regression model, with weights corresponding to the number of minutes spent performing the activity. Numbers in these two columns represent averages, calculated across individuals in the specified age category, of these weighted averages. These are weighted averages, with the weights corresponding to the 4-year sampling weights assigned within NHANES 1999–2002.

N = Number of individuals.

MET = Metabolic equivalent.

Source: U.S. EPA (2009a).

^a An individual's ventilation rate for the given activity category equals the weighted average of the individual's activity-specific ventilation rates for activities falling within the category, estimated using a multiple linear regression model, with weights corresponding to the number of minutes spent performing the activity. Numbers in these two columns represent averages, calculated across individuals in the specified age category, of these weighted averages. These are weighted averages, with the weights corresponding to the 4-year sampling weights assigned within NHANES 1999–2002.

N = Number of individuals.

MET = Metabolic equivalent.

Source: U.S. EPA (2009a).

^a	An individual’s ventilation rate for the given activity category equals the weighted average of the individual’s activity-specific ventilation rates for activities falling within the category, estimated using a multiple linear regression model, with weights corresponding to the number of minutes spent performing the activity. Numbers in these two columns represent averages, calculated across individuals in the specified age category, of these weighted averages. These are weighted averages, with the weights corresponding to the 4-year sampling weights assigned within NHANES 1999–2002.									
N	= Number of individuals.									
MET	= Metabolic equivalent.									
Source: U.S. EPA (2009a).

^a	An individual's ventilation rate for the given activity category equals the weighted average of the individual's activity-specific ventilation rates for activities falling within the category, estimated using a multiple linear regression model, with weights corresponding to the number of minutes spent performing the activity. Numbers in these two columns represent averages, calculated across individuals in the specified age category, of these weighted averages. These are weighted averages, with the weights corresponding to the 4-year sampling weights assigned within NHANES 1999–2002.									
N	= Number of individuals.									
MET	= Metabolic equivalent.									
Source: U.S. EPA (2009a).

^a When age groupings in the original reference did not match the U.S. EPA groupings used for this handbook, means from all age groupings in the original reference that overlapped U.S. EPA's age groupings by more than 1 year were averaged, weighted by the number of observations contributed from each age group. See Table 6-25 for concordance with U.S. EPA age groupings. ^b Weighted (where possible) average of reported study means. ^c The total number of subjects for Stifelman (2007) was 3,007. ^d Unweighted average of means from key studies.

^a When age groups in the original reference did not match the U.S. EPA groupings used for this handbook, statistics were averaged from all age groupings in the original reference that overlapped U.S. EPA's age groupings by more than 1 year, weighted by the number of observations contributed from each age group. For example, Brochu et al. (2006b) contributes its 2 to <5-year age group data to both U.S. EPA's 2 to <3-year and 3 to <6-year age groups.				

Table 6-26. Time Weighted Average of Daily Inhalation Rates (DIRs) Estimated From Daily Activities^a

Subject	Inhalation Rate (m ³ /hour)		DIR ^b (m ³ /day)
	Resting	Light Activity	
Adult Man	0.45	1.2	22.8
Adult Woman	0.36	1.14	21.1
Child (10 years)	0.29	0.78	14.8
Infant (1 year)	0.09	0.25	3.76
Newborn	0.03	0.09	0.78

^a Assumptions made were based on 8 hr resting and 16 hr light activity for adults and children (10 years); 14 hr resting and 10 hr light activity for infants (1 year); 23 hr resting and 1 hr light activity for newborns.

^b

$$DIR = \frac{1}{T} \sum_{i=1}^K IR_i t_i$$

DIR = Daily Inhalation Rate,
IR_i = Corresponding inhalation rate at ith activity,
t_i = Hours spent during the ith activity,
k = Number of activity periods, and
T = Total time of the exposure period (i.e., a day).

Source: ICRP (1981).

Table 6-28. Summary of Human Inhalation Rates by Activity Level (m³/hour)^a

	<i>N</i> ^b	Resting ^c	<i>N</i> ^b	Light ^d	<i>N</i> ^b	Moderate ^e	<i>N</i> ^b	Heavy ^f
Child, 6 years	8	0.4	16	0.8	4	2.0	5	2.3
Child, 10 years	10	0.4	40	1.0	29	3.2	43	3.9
Adult male	454	0.7	102	0.8	102	2.5	267	4.8
Adult female	595	0.3	786	0.5	106	1.6	211	2.9
Average adult	1,049	0.5	888	0.6	208	2.1	478	3.9

^a Values of inhalation rates for children (male and female) presented in this table represent the mean of values reported for each activity level in 1985.

^b Number of observations at each activity level.

^c Includes watching television, reading, and sleeping.

^d Includes most domestic work, attending to personal needs and care, hobbies, and conducting minor indoor repairs and home improvements.

^e Includes heavy indoor cleanup, performance of major indoor repairs and alterations, and climbing stairs.

^f Includes vigorous physical exercise and climbing stairs carrying a load.

Source: Adapted from U.S. EPA (1985).

Table 6-29. Estimated Minute Ventilation Associated With Activity Level for Average Male Adult^a

Level of work	L/minute	Representative activities
Light	13	Level walking at 2 mph; washing clothes
Light	19	Level walking at 3 mph; bowling; scrubbing floors
Light	25	Dancing; pushing wheelbarrow with 15-kg load; simple construction; stacking firewood
Moderate	30	Easy cycling; pushing wheelbarrow with 75-kg load; using sledgehammer
Moderate	35	Climbing stairs; playing tennis; digging with spade
Moderate	40	Cycling at 13 mph; walking on snow; digging trenches
Heavy	55	Cross-country skiing; rock climbing; stair climbing
Heavy	63	with load; playing squash or handball; chopping
Very heavy	72	with axe
Very heavy	85	Level running at 10 mph; competitive cycling
Severe	100+	Competitive long distance running; cross-country skiing

^a Average adult assumed to weigh 70 kg.

Source: Adapted from U.S. EPA (1985).

Chapter 6—Inhalation Rates

Table 6-30. Activity Pattern Data Aggregated for Three Microenvironments by Activity Level for All Age Groups		
Microenvironment	Activity Level	Average Hours Per Day in Each Microenvironment at Each Activity Level
Indoors	Resting	9.82
	Light	9.82
	Moderate	0.71
	Heavy	0.10
	TOTAL	20.4
Outdoors	Resting	0.51
	Light	0.51
	Moderate	0.65
	Heavy	0.12
	TOTAL	1.77
In Transportation Vehicle	Resting	0.86
	Light	0.86
	Moderate	0.05
	Heavy	0.0012
	TOTAL	1.77

Source: Adapted from U.S. EPA (1985).

Table 6-31. Summary of Daily Inhalation Rates (DIRs) Grouped by Age and Activity Level					
Subject	Daily Inhalation Rate (m ³ /day) ^a				Total Daily IR ^b (m ³ /day)
	Resting	Light	Moderate	Heavy	
Child, 6 years	4.47	8.95	2.82	0.50	16.74
Child, 10 years	4.47	11.19	4.51	0.85	21.02
Adult Male	7.83	8.95	3.53	1.05	21.4
Adult Female	3.35	5.59	2.26	0.64	11.8
Adult Average	5.60	6.71	2.96	0.85	16

^a Daily inhalation rate was calculated using the following equation:

$$IR = \frac{1}{T} \sum_{i=1}^k IR t_i$$

IR_i = Inhalation rate at i^{th} activity,
 t_i = Hours spent per day during i^{th} activity,
 k = Number of activity periods, and
 T = Total time of the exposure period (e.g., a day).

^b Total daily inhalation rate was calculated by summing the specific activity (resting, light, moderate, heavy) and dividing them by the total amount of time spent on all activities.

Source: Generated using the data from U.S. EPA (1985) as shown in Table 6-28 and Table 6-30.

Table 6-32. Distribution Pattern of Predicted Ventilation Rate (VR) and Equivalent Ventilation Rate (EVR) for 20 Outdoor Workers

		VR (m ³ /hour) ^a		EVR ^b (m ³ /hour/m ² body surface)

		Medium	0.8	1.26 ± 0.60	213 ± 91
		Fast	0.7	2.82 ± 2.28	362 ± 275
^a	Essential activities include income-related work, household chores, child care, study and other school activities, personal care, and destination-oriented travel; Non-essential activities include sports and active leisure, passive leisure, some travel, and social or civic activities.				
^b	Data presented by Shamoo et al. (1991) in L/min were converted to m ³ /hour.				
^c	Statistic was calculated by converting each VR for a given subject to a percentage of her/his overall average.				
Source: Adapted from Shamoo et al. (1991).					

Table 6-34. Calibration and Field Protocols for Self-Monitoring of Activities Grouped by Subject Panels

Panel	Calibration Protocol	Field Protocol
Panel 1: Healthy Outdoor Workers—15 female, 5 male, age 19–50	Laboratory treadmill exercise tests, indoor hallway walking tests at different self-chosen speeds, 2 outdoor tests consisted of 1-hour cycles each of rest, walking, and jogging.	3 days in 1 typical summer week (included most active workday and most active day off); HR recordings and activity diary during waking hours.
Panel 2: Healthy Elementary School Students—5 male, 12 female, ages 10–12	Outdoor exercises each consisted of 20 minute rest, slow walking, jogging and fast walking.	Saturday, Sunday and Monday (school day) in early autumn; heart rate recordings and activity diary during waking hours and during sleep.
Panel 3: Healthy High School Students—7 male, 12 female, ages 13–17	Outdoor exercises each consisted of 20 minute rest, slow walking, jogging and fast walking.	Same as Panel 2, however, no heart rate recordings during sleep for most subjects.
Panel 4: Adult Asthmatics, clinically mild, moderate, and severe—15 male, 34 female, age 18–50	Treadmill and hallway exercise tests.	1 typical summer week, 1 typical winter week; hourly activity/health diary during waking hours; lung function tests 3 times daily; HR recordings during waking hours on at least 3 days (including most active work day and day off).
Panel 5: Adult Asthmatics from 2 neighborhoods of contrasting O ₃ air quality—10 male, 14 female, age 19–46	Treadmill and hallway exercise tests.	Similar to Panel 4, personal NO ₂ and acid exposure monitoring included. (Panels 4 and 5 were studied in different years, and had 10 subjects in common).
Panel 6: Young Asthmatics—7 male, 6 female, ages 11–16	Laboratory exercise tests on bicycles and treadmills.	Summer monitoring for 2 successive weeks, including 2 controlled exposure studies with few or no observable respiratory effects.
Panel 7: Construction Workers—7 male, age 26–34	Performed similar exercises as Panel 2 and 3, and also performed job-related tests including lifting and carrying a 9-kg pipe.	HR recordings and diary information during 1 typical summer work day.

^a	For this report, activity type presented in Table 6-37 and Table 6-38 was redefined as light activity for slow, moderate activity for medium, and heavy activity for fast.						
^b	Daily inhalation rate was calculated by multiplying the hours spent at each activity level (see Table 6-38) by the corresponding inhalation rate (see Table 6-37).						
^c	Number of elementary (EL) and high school students (HS).

Chapter 6—Inhalation Rates

Table 6-42. Summary of Average Inhalation Rates (m ³ /hour) by Age Group and Activity Levels for Laboratory Protocols					
Age Group	Activity Level				
	Resting ^a	Sedentary ^b	Light ^c	Moderate ^d	Heavy ^e
Young Children (3–5.9 years) Average inhalation rate (m ³ /hour) (<i>N</i> = 12, sex not specified)	0.37	0.40	0.65	DNP ^f	DNP
Children (6–12.9 years) Average inhalation rate (m ³ /hour) (<i>N</i> = 40, 20 male and 20 female)	0.45	0.47	0.95	1.74	2.23
Adults (females) (Adolescent, young to middle aged, and older adult females) (<i>N</i> = 37)	0.43	0.48	1.33	2.76	2.96 ^g
Adults (males) (Adolescent, young to middle aged, and older adult males) (<i>N</i> = 39)	0.54	0.60	1.45	1.93	3.63
Adults (combined) (<i>N</i> = 76)	0.49	0.54	1.38	2.35	3.30
^a	Resting defined as lying (see Table 6-40 for original data).				
^b	Sedentary defined as sitting and standing (see Table 6-40 for original data).				
^c	Light defined as walking at speed level 1.5–3.0 mph (see Table 6-40 for original data).				
^d	Moderate defined as fast walking (3.3–4.0 mph) and slow running (3.5–4.0 mph) (see Table 6-40 for original data).				
^e	Heavy defined as fast running (4.5–6.0 mph) (see Table 6-40 for original data).				
^f	Group did not perform (DNP) this protocol or <i>N</i> was too small for appropriate mean comparisons. All young children did not run.				
^g	Older adults not included in mean value since they did not perform running protocols at particular speeds.

≥75	1	9.6	8	1.4	1.6	6.90	11.04
Lifetime average ^g		10					

^a MET = Metabolic equivalent.^b L is the number of years for each age cohort.^c Daily inhalation rate was calculated by multiplying the EFD values (see Table 6-44) by $H \times VQ \times (\text{m}^3 \text{ 1,000 L}^{-1})$ for subjects under 9 years of age and by $1.2 \times H \times VQ \times (\text{m}^3 \text{ 1,000 L}^{-1})$ (for subjects 9 years of age and older (see text for explanation).

where:

 EFD = (Kcal/day) or (MJ/day), H = Oxygen uptake = 0.05 L O₂/KJ or 0.21 L O₂/Kcal, and VQ = Ventilation equivalent = 27 = geometric mean of VQs (unitless).^d For individuals 9 years of age and older, A was calculated by multiplying the ratio for EFD/BMR (unitless) (see Table 6-44) by the factor 1.2 (see text for explanation).^e $F = (24A - S)/(24 - S)$ (unitless), ratio of the rate of energy expenditure during active hours to the estimated BMR (unitless).

where:

 S = Number of hours spent sleeping each day (hours).^f Inhalation rate for inactive periods was calculated as $BMR \times H \times VQ \times (\text{d 1,440 minute}^{-1})$ and for active periods by multiplying inactive inactive inhalation rate by F (See footnote e); BMR values are from Table 6-44.

where:

 BMR = Basal metabolic rate (MJ/day) or (kg/hour).^g Lifetime average was calculated by multiplying individual inhalation rate by corresponding L values summing the products across cohorts and dividing the result by 75, the total of the cohort age spans.

^a Body weight was based on the average weights for age/sex cohorts in the U.S. population. ^b The BMRs are calculated using the respective body weights and BMR equations (see Table 6-46). ^c The values of the BMR multiplier (EFD/BMR) for those 18 years and older were derived from the Basiotis et al. (1989) study: male = 1.59, female = 1.38. For males and females under 10 years old, the mean BMR multiplier used was 1.6. For males and females aged 10 to <18 years, the mean values for A given in Table 6-45 for 12–14 years and 15–18 years, age brackets for males and females were used: male = 1.7 and female = 1.5. ^d Inhalation rate = $BMR \times A \times H \times VQ$; VQ = ventilation equivalent and H = oxygen uptake.

^a	Body weights were based on average weights for age/sex cohorts of the U.S. population.						
^b	The BMRs for the age/sex cohorts were calculated using the respective body weights and the BMR equations (see Table 6-46).						
^c	Range = 1.5–2.5.						
^d	Range = 3–5.						
^e	Range = >5–20.						
^f	The inhalation rate was calculated as $IR = BMR \text{ (MJ/day)} \times H \text{ (0.05 L/KJ)} \times MET \times VQ \text{ (27)} \times \text{(day/1,440 minutes)}$.						
^g	Original data were presented in L/minute. Conversion to m ³ /minute was obtained as follows: $\frac{m^3}{1000L} \times \frac{L}{min}$						
^h	The maximum possible MET sustainable for more than 5 minutes does not reach 10 for females and males until ages 13 and 12, respectively. Therefore, an MET of 10 is not possible for this age category.

Chapter 7—Dermal Exposure Factors

7. DERMAL EXPOSURE FACTORS**7.1. INTRODUCTION**

Dermal exposure can occur during a variety of activities in different environmental media and microenvironments [U.S. Environmental Protection Agency (U.S. EPA), (2004, 1992a, b)]. These include:

- water (e.g., bathing, washing, swimming);
- soil (e.g., outdoor recreation, gardening, construction);
- sediment (e.g., wading, fishing);
- other liquids (e.g., use of commercial products);
- vapors/fumes/gases (e.g., use of commercial products); and
- other solids or residues (e.g., soil/dust or chemical residues on carpets, floors, counter tops, outdoor surfaces, or clothing).

Exposure via the dermal route may be estimated in various ways, depending on the exposure media and scenario of interest. For example, dermal exposure to contaminants in soil, sediment, or dust may be evaluated using information on the concentration of contaminant in these materials in conjunction with information on the amount of material that adheres to the skin per unit surface area and the total area of skin surface exposed. An approach for estimating dermal exposure to contaminants in liquids uses information on the concentration of contaminant in the liquid in conjunction with information on the film thickness of liquid remaining on the skin after contact. When assessing dermal exposure to water (e.g., bathing or swimming) or to vapors and fumes, the concentration of chemical in water or vapor with the total exposed skin surface area may be considered. An approach for estimating exposure to surface residues is to use information on the rate of transfer of chemical residues to the skin as a result of contact with the surfaces. Dermal exposure also may result from leaching of chemicals that are impregnated in materials that come into contact with skin. For example, Snodgrass (1992) evaluated transfer of pesticides from treated clothing onto the skin. For information on various methods used to estimate dermal exposure, refer to *Guidelines for Exposure Assessment* (U.S. EPA, 1992b), *Dermal Exposure Assessment: Principles and Applications* (U.S. EPA, 1992a), and *Dermal Exposures Assessment: A Summary of EPA Approaches* (U.S. EPA, 2007a).

Additional scenario-specific information on dermal exposure assessment is available in *Risk Assessment Guidance for Superfund (RAGS) Part E* (U.S. EPA, 2004), *Standard Operating Procedures for Residential Pesticide Exposure Assessment, draft* (U.S. EPA, 2009), and *Methods for Assessing Exposure to Chemical Substances: Volume 7, Methods for Assessing Consumer Exposure to Chemical Substances* (U.S. EPA, 1987). In general, these methods for estimating dermal exposure require information on the surface area of the skin that is exposed. Some methods also require information on the adherence of solids to the skin or information on the film thickness of liquids on the skin. Others utilize information on the transfer of residues from contaminated surfaces to the skin surface and/or rate of contact with objects or surfaces. This chapter focuses on measurements of body surface area and non-chemical-specific factors related to dermal exposure (i.e., the deposition of contaminants onto the skin), such as adherence of solids to the skin, film thickness of liquids on the skin, and residue transfer from contaminated surfaces to the skin. However, this chapter only provides recommendations for surface area and solids adherence to skin. According to Riley et al. (2004), numerous factors may affect loading and retention of chemicals on the skin, including the form of the contaminant (particle, liquid, residue), surface characteristics (hard, plush, porous, surface loading, previous transfers), skin characteristics (moisture, age, loading), contact mechanics (pressure, duration, repetition), and environmental conditions (temperature, relative humidity, air exchange). These factors are discussed in this chapter, as reported by the various study authors. Information on other factors that may affect dermal exposure (e.g., contact frequency and duration, and skin thickness) also is provided in this chapter.

Factors that influence dermal uptake (i.e., absorption) and internal dose, including chemical-specific factors, are not provided in this handbook. These include factors such as the concentration of chemical in contact with the skin, weight fraction of chemicals in consumer products, and characteristics of the chemical (i.e., lipophilicity, polarity, volatility, solubility). Also, factors affecting the rate of absorption of the chemical through the skin at the site of application and the amount of chemical delivered to the target organ are not covered in this chapter. Absorption may be affected by the age and condition of the skin, including presence of perspiration (Williams et al., 2005; Williams et al., 2004). Also, the thickness of the stratum corneum (outer layer of the skin) varies over parts of the body and may affect absorption. While not the primary

Chapter 7—Dermal Exposure Factors

focus of this chapter, some limited information on skin thickness is presented in Section 7.7—Other Factors. For guidance on how to use information on factors needed to assess dermal dose, refer to *Dermal Exposure Assessment: Principles and Applications* (U.S. EPA, 1992a) and *Risk Assessment Guidelines for Superfund (RAGs) Part E* (U.S. EPA, 2004).

Frequency and duration of contact also may affect dermal exposure and dose. Data on dermal contact frequency and duration of hand contact with objects and surfaces are presented in Section 7.7.1 of this chapter. Additional information on consumer products use and activity factors that may affect dermal exposure is presented in Chapters 16 and 17.

Section 7.3 of this chapter provides data on surface area of the human skin. Section 7.4 provides data on adherence of solids to human skin. Information on the film thickness of liquids on the skin is limited. However, studies that estimated film thickness of liquids on the skin are presented in Section 7.5. Section 7.6 presents available information on the transfer of residues from contaminated surfaces to the skin. Section 7.7 provides information on other factors affecting dermal exposure (e.g., frequency and duration of dermal contact with objects and surfaces, and skin thickness).

Recommendations for skin surface area and dermal adherence of solids to skin are provided in the next section, along with a summary of the confidence ratings for these recommendations. The recommended values are based on key studies identified by U.S. EPA for these factors. Relevant data on these and other factors also are presented in this chapter to provide added perspective on the state-of-knowledge pertaining to dermal exposure factors.

7.2. RECOMMENDATIONS

7.2.1. Body Surface Area

Table 7-1 summarizes the recommended mean and 95th percentile total body surface area values. For children under 21 years of age, the recommendations for total body surface area are based on the U.S. EPA analysis of 1999–2006 data from the National Health and Nutrition Examination Survey (NHANES). These data are presented for the standard age groupings recommended by U.S. EPA (2005) for male and female children combined. For adults 21 years and over, the recommendations for total body surface area are based on the U.S. EPA analysis of NHANES (2005–2006) data. The U.S. EPA analysis of NHANES data uses correlations with body weight and height for deriving skin surface area

(see Section 7.3.1.3 and Appendix 7A). NHANES (1999–2006) used a statistically based survey design that should ensure that the data are reasonably representative of the general population for each 2-year interval (e.g., 1999 to 2000, 2001 to 2002). Multiple NHANES study years, supplying a larger sample size, were necessary for estimating surface area for children given the multiple stratifications by age. The advantage of using the NHANES data sets to derive the total surface area recommendations is that data are nationally representative and remain the principal source of body-weight and height data collected nationwide from a large number of subjects. Note that differences between the surface area recommendations presented here and those in the previous *Exposure Factors Handbook* (U.S. EPA, 1997) reflect changes in the body weights used in calculating these surface areas. If sex-specific data for children, sex-combined data for adults, or data for statistics other than the mean or 95th percentile are needed, refer to Table 7-9 through Table 7-13 of this chapter.

Table 7-2 presents the recommendations for the percentage of total body surface area represented by individual body parts for children based on data from U.S. EPA (1985) and Boniol et al. (2008) (see Section 7.3.1). The data from Boniol et al. (2008) are used for the recommendations for children greater than 2 years of age because they are based on a larger sample size than those in U.S. EPA (1985) for the same age groups. Because the Boniol et al. (2008) study does not include data for children less than 2 years of age, recommendations for this age group are based on the data from U.S. EPA (1985). It should be noted, however, that the sample size for the percentages of the total body represented by various body parts in this age group is very small. Table 7-2 also provides age-specific body part surface areas (m²) for children. These values were obtained by multiplying the age-specific mean body part percentages (for males and females combined) by the total body surface areas presented in Table 7-1. If sex-specific data are needed for children equal to or greater than 2 years of age, or if data for additional body parts not summarized in Table 7-2 are needed, refer to Table 7-8. The body part data in this table may be applied to data in Table 7-9 through Table 7-11 to calculate surface area for the various body parts.

The recommendations for surface area of adult body parts are based on the U.S. EPA Analysis of NHANES 2005–2006 data and algorithms from U.S. EPA (1985). The U.S. EPA Analysis of the NHANES data was used to develop recommendations for body parts because the data are

Chapter 7—Dermal Exposure Factors

nationally representative and based on a large number of subjects. Table 7-2 presents the data for adult males and adult females (21+ years of age). If sex-combined data for adults or data for statistics other than the mean and 95th percentile are needed, refer to Table 7-12 and Table 7-13. These tables present the surface area of body parts for males and females, respectively, 21 years of age and older. Table 7-3 presents the confidence ratings for the recommendations for body surface area.

For swimming and bathing scenarios, past exposure assessments have assumed that 75 to 100% of the skin surface is exposed (U.S. EPA, 1992a). More recent guidance recommends assuming 100% exposure for these scenarios (U.S. EPA, 2004). For other exposure scenarios, it is reasonable to assume that clothing reduces the contact area. However, while it is generally assumed that adherence of solids to skin only occurs to the areas of the body not covered by clothing, it is important to understand that soil and dust particles can get under clothing and be deposited on skin to varying degrees depending on the protective properties of the clothing. Likewise, liquids or chemical residues on surfaces may soak through clothing and contact covered areas of the skin. Assessors should consider these possibilities for the scenario of concern and select skin areas that are judged appropriate. Also, surface area of the body and body weight are highly correlated (Phillips et al., 1993). The relationship between these factors, therefore, should be considered when selecting body weights for use with the surface area data for estimating dermal exposure.

7.2.2. Adherence of Solids to Skin

The adherence factor (AF) describes the amount of solid material that adheres to the skin per unit of surface area. Although most research in this area has focused on soils, a variety of other solid residues can accumulate on skin, including household dust, sediments, and commercial powders. Studies on soil adherence have shown that (1) soil properties influence adherence, (2) soil adherence varies considerably across different parts of the body, and (3) soil adherence varies with activity (U.S. EPA, 2004). It is recommended that exposure assessors use adherence data derived from testing that matches the exposure scenario of concern in terms of solid type, exposed body parts, and activities as closely as possible. Refer to the activities described in Table 7-19 to select those that best represent the exposure scenarios of concern and use the corresponding adherence values from Table 7-20. Table 7-19 also lists the age ranges covered by each study. This may

be used as a general guide to the ages covered by these data.

Table 7-4 summarizes recommended mean AF values according to common activities. The key studies used to develop the recommendations for adherence of solids to skin are those based on field studies in which specific activities relevant to dermal exposure were evaluated (compared to relevant studies that evaluated adherence in controlled laboratory trials using sieved or standardized soil). Insufficient data were available to develop activity-specific distributions or probability functions for these studies. Also, the small number of subjects in these studies prevented the development of recommendations for the childhood specific age groups recommended by U.S. EPA (2005).

U.S. EPA (2004) recommends that scenario-specific adherence values be weighted according to the body parts exposed. Weighted adherence factors may be estimated according to the following equation:

$$AF_{wtd} = \frac{(AF_1)(SA_1) + (AF_2)(SA_2) + \dots + (AF_i)(SA_i)}{SA_1 + SA_2 + \dots + SA_i} \quad (\text{Eqn. 7-1})$$

where:

AF_{wtd} = weighted adherence factor,
 AF = adherence factor, and
 SA = surface area.

For the purposes of this calculation, the surface area of the face may be assumed to be 1/3 that of the head, forearms may be assumed to represent 45% of the arms, and lower legs may be assumed to represent 40% of the legs (U.S. EPA, 2004).

The recommended dermal AFs represent the amount of material on the skin at the time of measurement. U.S. EPA (1992a) recommends interpreting AFs as representative of contact events. Assuming that the amount of solids measured on the skin represents accumulation between washings, and that people wash at least once per day, these adherence values can be interpreted as daily contact rates (U.S. EPA, 1992a). The rate of solids accumulation on skin over time has not been well studied but probably occurs fairly quickly. Therefore, prorating the adherence values for exposure time periods of less than 1 day is not recommended.

Table 7-5 shows the confidence ratings for these AF recommendations. While the recommendations are based on the best available estimates of activity-

specific adherence, they are based on limited data from studies that have focused primarily on soil. Therefore, they have a high degree of uncertainty, and considerable judgment must be used when selecting them for an assessment. It also should be noted that the skin-adherence studies on which these recommendations are based have generally not considered the influence of skin moisture on adherence. Skin moisture varies depending on a number of factors, including activity level and ambient temperature/humidity. It is uncertain how well this variability has been captured in the dermal-adherence studies used for the recommendations.

7.2.3. Film Thickness of Liquids on Skin

The film thickness of liquids on skin represents the amount of material that remains on the skin after contact with a liquid (e.g., consumer product such as cleaning solution or soap). The data on film thickness of liquids on the hand are limited, and recommended values are not provided in this chapter. Refer to Section 7.5 for a description of the available data that may be used to assess dermal contact with liquid using the film thickness approach.

7.2.4. Residue Transfer

Several studies have developed methods for quantifying the rates of transfer of chemical residues to the skin of individuals performing activities on contaminated surfaces. These studies have been conducted primarily for the purpose of estimating exposure to pesticides. Section 7.6 describes studies that have estimated residue transfer to human skin. Because use of residue transfer depends on the specific conditions under which exposure occurs (e.g., activity, contact surfaces, age), general recommendations are not provided. Instead, refer to Section 7.6 for a description of the available data from which appropriate values may be selected.

Note:	Surface area values reported in m ² can be converted to cm ² by multiplying by 10,000 cm ² /m ² .						

Chapter 7—Dermal Exposure Factors

Table 7-3. Confidence in Recommendations for Body Surface Area

General Assessment Factors	Rationale	Rating
Soundness		Medium
<i>Adequacy of Approach</i>	Total surface area estimates were based on algorithms developed using direct measurements and data from NHANES surveys. The methods used for developing these algorithms were adequate. The NHANES data and the secondary data analyses to estimate total surface areas were appropriate. NHANES included large sample sizes; sample size varied with age. Body-part percentages for children <2 years of age were based on direct measurements from a very small number of subjects ($N = 4$). Percentages for children ≥ 2 years were based on 2,050 children; adult values were based on 89 adults.	
<i>Minimal (or Defined) Bias</i>	The data used to develop the algorithms for estimating surface area from height and weight data were limited. NHANES collected physical measurements of weight and height for a large sample of the population.	
Applicability and Utility		Medium
<i>Exposure Factor of Interest</i>	The key studies were directly relevant to surface area estimates.	
<i>Representativeness</i>	The direct measurement data used to develop the algorithms for estimating total body surface area from weight and height may not be representative of the U.S. population. However, NHANES height and weight data were collected using a complex, stratified, multi-stage probability cluster sampling design intended to be representative of the U.S. population. Body part percentages for children <2 years of age were based on direct measurements from a very small number of subjects ($N = 4$). Percentages for children ≥ 2 years were based on 2,050 children from various states in the United States and are assumed to be representative of U.S. children; adult values were based on 89 adults.	
<i>Currency</i>	The U.S. EPA analysis used the most current NHANES data to generate surface area data using algorithms based on older direct measurements. The data on body part percentages were dated. However, the age of the percentage data is not expected to affect its utility if the percentages are applied to total surface area data that has been updated based on the most recent NHANES body-weight and height data.	
<i>Data Collection Period</i>	The U.S. EPA analysis was based on four NHANES data sets covering 1999–2006 for children and one NHANES data set, 2005–2006, for adults.

Chapter 7—Dermal Exposure Factors

Table 7-5. Confidence in Recommendations for Solids Adherence to Skin		
General Assessment Factors	Rationale	Rating
Soundness		Medium
<i>Adequacy of Approach</i>	The approach was adequate; the skin-rinsing technique is widely employed for purposes similar to this. Small sample sizes were used in the studies; the key studies directly measured soil adherence to skin.	
<i>Minimal (or Defined) Bias</i>	The studies attempted to measure soil adherence for selected activities and conditions. The number of activities and study participants was limited.	
Applicability and Utility		Low
<i>Exposure Factor of Interest</i>	The studies were relevant to the factor of interest; the goal was to determine soil adherence to skin.	
<i>Representativeness</i>	The soil/dust studies were limited to the State of Washington, and the sediment study was limited to Rhode Island. The data may not be representative of other locales. All three studies were conducted by researchers from a laboratory where a similar methodology was used. This may limit the representativeness of the data in terms of a wider population.	
<i>Currency</i>	The studies were published between 1996 and 2005.	
<i>Data Collection Period</i>	Short-term data were collected. Seasonal factors may be important, but have not been studied adequately.	
Clarity and Completeness		Medium
<i>Accessibility</i>	Articles were published in widely circulated journals/reports.	
<i>Reproducibility</i>	The reports clearly describe the experimental methods, and enough information was provided to allow for the study to be reproduced.	
<i>Quality Assurance</i>	Quality control was not well described.	
Variability and Uncertainty		Low
<i>Variability in Population</i>	Variability in soil adherence is affected by many factors including soil properties, activity and individual behavior patterns. Not all age groups were represented in the sample.	
<i>Uncertainty</i>	The estimates are highly uncertain; the soil adherence values were derived from a small number of observations for a limited set of activities.

Chapter 7—Dermal Exposure Factors

7.3. SURFACE AREA

Surface area of the skin can be determined by using measurement or estimation techniques. Coating, triangulation, and surface integration are direct measurement techniques that have been used to measure total body surface area and the surface area of specific body parts. The coating method consists of coating either the whole body or specific body regions with a substance of known density and thickness. Triangulation consists of marking the area of the body into geometric figures, then calculating the figure areas from their linear dimensions. Surface integration is performed by using a planimeter and adding the areas. The results of studies conducted using these various techniques have been summarized in *Development of Statistical Distributions or Ranges of Standard Factors Used in Exposure Assessments* (U.S. EPA, 1985). Because of the difficulties associated with direct measurements of body surface area, the existing direct measurement data are limited and dated. However, several researchers have developed methods for estimating body surface area from measurements of other body dimensions (Du Bois and Du Bois, 1989; Gehan and George, 1970; Boyd, 1935). Generally, these formulas are based on the observation that body weight and height are correlated with surface area and are derived using multiple regression techniques. U.S. EPA (1985) evaluated the various formulas for estimating total body surface area. Appendix 7A presents a discussion and comparison of formulas. The key studies on body surface area that are presented in Section 7.3.1 are based on these formulas, as well as weight and height data from NHANES.

7.3.1. Key Body Surface Area Studies**7.3.1.1. U.S. EPA (1985)—*Development of Statistical Distributions or Ranges of Standard Factors Used in Exposure Assessments***

U.S. EPA (1985) summarized the direct measurements of the surface area of adults' and children's body parts provided by Boyd (1935) and USDA (1969) as a percentage of total surface area. Table 7-6 presents these percentages. A total of 21 children less than 18 years of age were included. Because of the small sample size, it is unclear how accurately these estimates represent averages for the age groups. A total of 89 adults, 18 years and older, were included in the analysis of body parts, providing greater accuracy for the adult estimates. Note that the proportion of total body surface area contributed by the head decreases from childhood to adulthood,

whereas the proportion contributed by the leg increases.

U.S. EPA (1985) analyzed the direct surface area measurement data of Gehan and George (1970) using the Statistical Processing System (SPS) software package of Buhyoff et al. (1982). Gehan and George (1970) selected 401 measurements made by Boyd (1935) that were complete for surface area, height, weight, and age for their analysis. Boyd (1935) had reported surface area estimates for 1,114 individuals using coating, triangulation, or surface integration methods (U.S. EPA, 1985).

U.S. EPA (1985) used SPS to generate equations to calculate surface area as a function of height and weight. These equations were subsequently used by U.S. EPA to calculate body surface area distributions of the U.S. population using the height and weight data obtained from the National Health and Nutrition Examination Survey, 1999–2006 [CDC (2006); see Section 7.3.1.3].

The equation proposed by Gehan and George (1970) was determined by U.S. EPA (1985) to be the best choice for estimating total body surface area. However, the paper by Gehan and George (1970) gave insufficient information to estimate the standard error about the regression. Therefore, U.S. EPA (1985) used the 401 direct measurements of children and adults and reanalyzed the data using the formula of Du Bois and Du Bois (1989) and SPS to obtain the standard error (U.S. EPA, 1985).

Regression equations were developed for specific body parts using the Du Bois and Du Bois (1989) formula and using the surface area of various body parts provided by Boyd (1935) and USDA (1969) in conjunction with SPS. Regression equations for adults were developed for the head, trunk (including the neck), upper extremities (arms and hands, upper arms, and forearms) and lower extremities (legs and feet, thighs, and lower legs) (U.S. EPA, 1985). Table 7-7 presents a summary of the equation parameters developed by U.S. EPA (1985) for calculating surface area of adult body parts. Equations to estimate the body part surface area of children were not developed because of insufficient data.

7.3.1.2. Boniol et al. (2008)—*Proportion of Skin Surface Area of Children and Young Adults from 2 to 18 Years Old*

Boniol et al. (2008) applied measurement data for 87 body parts to a computer model to estimate the surface area of body parts of children. The measurement data were collected in the late 1970s by Snyder et al. (1978) for the purpose of product safety design (e.g., toys and ergonomics) and represent

Chapter 7—Dermal Exposure Factors

1,075 boys and 975 girls from various states in the United States. A surface area module of the computer model MAN3D was used to construct models of the human body for children (ages 2, 4, 6, 8, 10, 12, 14, 16, and 18 years) to estimate surface area of 13 body parts for use in treating skin lesions. The body parts included head, neck, bosom, shoulders, abdomen, back, genitals and buttocks, thighs, legs, feet, upper arms, lower arms, and feet. The proportion of the skin surface area of these body parts relative to total surface area was computed. Table 7-8 presents these data for the various ages of male and female children. Except for the head, for which the percentages are much lower in this study than in U.S. EPA (1985), the body part proportions in this study appear to be similar to those presented in U.S. EPA (1985). For example, the proportions for hands range from 4.2 to 4.9% in this study and from 5.0 to 5.9% in U.S. EPA (1985). Because this study provides additional body parts that were not included in the U.S. EPA (1985) study, it is necessary to combine some body parts for the purpose of comparing their results. For example, upper arms and lower arms can be combined to represent total arms, and thighs plus legs can be combined to represent total legs. Upper arms plus lower arms for 4-year-olds from this study represent 14% of the total body surface, compared to 14.2% for arms for 3- to 6-year-olds from U.S. EPA (1985). Thighs plus legs for 2-year-olds from this study represent 25.3% of the total surface, compared to 23.2% for 2- to 3-year-olds from U.S. EPA (1985). Likewise, neck, bosom, shoulders, abdomen, back, and genitals/buttocks can be combined to represent the trunk.

The advantages of this study are that the data represent a larger sample size of children and are more recent than those used in U.S. EPA (1985). This study also provides data for more body parts than U.S. EPA (1985). However, the age groups presented in this study differ from those recommended in U.S. EPA (2005) and used elsewhere in this handbook, and no data are available for children 1 year of age and younger.

7.3.1.3. U.S. EPA Analysis of NHANES 2005–2006 and 1999–2006 Data

The U.S. EPA estimated total body surface areas by using the empirical relationship shown in Appendix 7A and U.S. EPA (1985), and body-weight and height data from the 1999–2006 NHANES for children and the 2005–2006 NHANES for adults. NHANES is conducted annually by the Centers for Disease Control (CDC) National Center of Health Statistics. The survey's target population is the

civilian, non-institutionalized U.S. population. The NHANES 1999–2006 survey was conducted on a nationwide probability sample of approximately 40,000 people for all ages, of which approximately 20,000 were children. The survey is designed to obtain nationally representative information on the health and nutritional status of the population of the United States through interviews and direct physical examinations. A number of anthropometrical measurements were taken for each participant in the study, including body weight and height. Unit non-response to the household interview was 19%, and an additional 4% did not participate in the physical examinations (including body-weight measurements).

The NHANES 1999–2006 survey includes oversampling of low-income persons, adolescents 12 to 19 years of age, persons 60+ years of age, African Americans, and Mexican Americans. Sample data were assigned weights to account both for the disparity in sample sizes for these groups and for other inadequacies in sampling, such as the presence of non-respondents. For children's estimates, the U.S. EPA utilized four NHANES data sets in its analysis (NHANES 1999–2000, 2001–2002, 2003–2004, and 2005–2006) to ensure adequate sample size for the age groupings of interest. Sample weights were developed for the combined data set in accordance with CDC guidance from the NHANES' Web site (http://www.cdc.gov/nchs/about/major/nhanes/nhanes20052006/faqs05_06.htm#question%2012). For adult estimates, the U.S. EPA utilized NHANES 2005–2006 in its estimates for currency and the same analytical methodology as in the earlier version of the *Exposure Factors Handbook* (U.S. EPA, 1997).

Table 7-9 presents the mean and percentile estimates of total body surface area by age category for males and females combined. Table 7-10 and Table 7-11 present the mean and percentiles of total body surface area by age category for males and females, respectively. Table 7-12 and Table 7-13 present the mean and percentile estimates of body surface area of specific body parts for males and females 21 years and older, respectively.

An advantage of using the NHANES data sets to derive total surface area estimates is that data are available for infants from birth and older. In addition, the NHANES data are nationally representative and remain the principal source of body-weight and height data collected nationwide from a large number of subjects. It should be noted that in the NHANES surveys, height measurements for children less than 2 years of age were based on recumbent length whereas standing height information was collected

Chapter 7—Dermal Exposure Factors

for children aged 2 years and older. Some studies have reported differences between recumbent length and standing height measurements for the same individual, ranging from 0.5 to 2 cm, with recumbent length being the larger of the two measurements (Buyken et al., 2005). The use of height data obtained from two different types of height measurements to estimate surface area of children may potentially introduce errors into the estimates.

7.3.2. Relevant Body Surface Area Studies**7.3.2.1. Murray and Burmaster (1992)—Estimated Distributions for Total Body Surface Area of Men and Women in the United States**

Murray and Burmaster (1992) generated distributions of total body surface area for men and women ages 18 to 74 years using Monte Carlo simulations based on height and weight distribution data. Four different formulae for estimating body surface area as a function of height and weight were employed: Du Bois and Du Bois (1989), Boyd (1935), U.S. EPA (1985), and Costeff (1966). The formulae of Du Bois and Du Bois (1989), Boyd (1935), and U.S. EPA (1985) are based on height and weight. The formula developed by Costeff (1966) is based on 220 observations that estimate body surface area based on weight only. Formulae were compared, and the effect of the correlation between height and weight on the body surface area distribution was analyzed.

Monte Carlo simulations were conducted to estimate body surface area distributions. They were based on the bivariate distributions estimated by Brainard and Burmaster (1992) for height and natural logarithm of weight and the formulae described previously. A total of 5,000 random samples each for men and women were selected from the two correlated bivariate distributions. Body surface area calculations were made for each sample, and for each formula, resulting in body surface area distributions. Murray and Burmaster (1992) found that the body surface area frequency distributions were similar for the four models (see Table 7-14). Using the U.S. EPA (1985) formula, the median surface area values were calculated to be 1.96 m² for men and 1.69 m² for women. The median value for women is identical to that generated by U.S. EPA (1985) but differs for men by approximately 1%. Body surface area was found to have lognormal distributions for both men and women (see Figure 7-1). It also was found that assuming correlation between height and weight influences the final distribution by less than 1%.

The advantages of this study are that it compared the various formulae for computing surface area and confirmed that the formula used by the U.S. EPA in its analysis—as described in Section 7.3.1.3—is appropriate. This study is considered relevant because the height and weight data used in this analysis predates the height and weight data used in the more recent U.S. EPA analysis (see Section 7.3.1.3).

7.3.2.2. Phillips et al. (1993)—Distributions of Total Skin Surface Area to Body-Weight Ratios

Phillips et al. (1993) observed a strong correlation (0.986) between body surface area and body weight and studied the effect of using these factors as independent variables in the lifetime average daily dose (LADD) equation (see Chapter 1). The authors suggested that, because of the correlation between these two variables, the use of body surface area-to-body-weight (SA/BW) ratios in human exposure assessments may be more appropriate than treating these factors as independent variables. Direct measurement data from the scientific literature were used to calculate SA/BW ratios for three age groups of the population (infants age 0 to 2 years, children age 2.1 to 17.9 years, and adults age 18 years and older). These ratios were calculated by dividing body surface areas by corresponding body weights for the 401 individuals analyzed by Gehan and George (1970) and summarized by U.S. EPA (1985). Distributions of SA/BW ratios were developed, and summary statistics were calculated for the three age groups and the combined data set.

Table 7-15 presents summary statistics for both adults and children. The shapes of these SA/BW distributions were determined using D'Agostino's test, as described in D'Agostino et al. (1990). The results indicate that the SA/BW ratios for infants were lognormally distributed. The SA/BW ratios for adults and all ages combined were normally distributed. SA/BW ratios for children were neither normally nor lognormally distributed. According to Phillips et al. (1993), SA/BW ratios may be used to calculate LADDs by replacing the body surface area factor in the numerator of the LADD equation with the SA/BW ratio and eliminating the body-weight factor in the denominator of the LADD equation.

The effect of sex and age on SA/BW distribution also was analyzed by classifying the 401 observations by sex and age. Statistical analyses indicated no significant differences between SA/BW ratios for males and females. SA/BW ratios were found to decrease with increasing age.

Chapter 7—Dermal Exposure Factors

The advantage of this study is that it studied correlations between surface area and body weight. However, data could not be broken out by finer age categories.

7.3.2.3. *Garlock et al. (1999)—Adult Responses to a Survey of Soil Contact Scenarios*

Garlock et al. (1999) reported on a survey conducted during the summer of 1996. The objective of the study was to evaluate behaviors relevant to dermal contact with soil and dust. Garlock et al. (1999) conducted computer-aided telephone interviews designed to be nationally representative of the U.S. population. The survey response rate was 61.4%, with a sample size of 450. Adult respondents were asked to provide information on what they usually wore while engaging in the following activities during warm or cold weather: gardening, outdoor team sports (e.g., soccer, softball, football), and home construction projects that include digging, as well as whether they washed or bathed following these activities. Information also was collected on frequency and duration of these activities (see Chapter 16). Similar information was collected for children's outdoor activities and is reported in Wong et al. (2000). Using the activity-specific clothing choices reported for each survey participant and body surface area data from U.S. EPA (1985), Garlock et al. (1999) estimated the percentages of adult total body surface areas that would be uncovered for each of the warm weather and cold weather activities (see Table 7-16). The median ranged from 28 to 33% for warm weather activities and 3 to 8% for cold weather activities.

The advantages of this study are that it provides information on the percentage of adult total surface area that may be exposed to soil during a variety of outdoor activities. These data represent outdoor activities only (no data are provided for exposure to indoor surface dusts).

7.3.2.4. *Wong et al. (2000)—Adult Proxy Responses to a Survey of Children's Dermal Soil Contact Activities*

Wong et al. (2000) reported on two national phone surveys that gathered information on activity patterns related to dermal contact with soil. The first [also reported on by Garlock et al. (1999)] was conducted in 1996 using random digit dialing. Information about 211 children was gathered from adults more than 18 years of age. For older children (those between the ages of 5 and 17 years), information was gathered on their participation in "gardening and yardwork," "outdoor sports," and

"outdoor play activities." For children less than 5 years of age, information was gathered on "outdoor play activities," including whether the activity occurred on a playground or yard with "bare dirt or mixed grass and dirt" surfaces. Information on the types of clothing worn while participating in these play activities during warm weather months (April through October) was obtained. The results of this survey indicated that most children wore short pants, a dress or skirt, short sleeve shirts, no socks, and leather or canvas shoes during the outdoor play activities of interest. Using the survey data on clothing and total body surface area data from U.S. EPA (1985), estimates were made of the skin area exposed (expressed as percentages of total body surface area) associated with various age ranges and activities. Table 7-17 provides these estimates.

The advantage of this study is that it provides information on the percentage of children's bodies exposed to soil. These data reflect exposed skin areas during warm weather for outdoor activities only.

7.3.2.5. *AuYeung et al. (2008)—The Fraction of Total Hand Surface Area Involved in Young Children's Outdoor Hand-to-Mouth Contacts*

AuYeung et al. (2008) videotaped a total of 38 children (20 girls and 18 boys) between the ages of 1 and 6 years while they engaged in unstructured play activities in outdoor residential locations. The data were reviewed, and contact information was recorded according to the objects contacted and the associated contact configurations (e.g., full palm press, closed hand grip, open hand grip, side hand contact, partial palm, fingers only). The fraction of the hand associated with each of the various configuration categories then was estimated for a convenience sample of children and adults using hand traces and handprints consistent with the various contact configurations. Statistical distributions of the fraction of children's total hand surface associated with outdoor contacts were estimated by combining the information on occurrence and configuration of contacts from the videotaped activity study with the data on the fraction of the hand associated with the various contact configurations. Table 7-18 provides the per-contact fractional surface areas for the various types of objects contacted and for all objects combined. For all objects contacted, fractional surface areas ranged from 0.13 to 0.27. AuYeung et al. (2008) suggested that "the majority of children's outdoor contacts with objects involve a relatively small fraction of the hand's total surface area."

Chapter 7—Dermal Exposure Factors

The advantage of this study is that it provides information on the fraction of the hand that contacts various surfaces and objects. However, the data are for a relatively small sample size of children (ages 1 to 6 years). Similar data for adults and older children were not provided.

7.4. ADHERENCE OF SOLIDS TO SKIN

Several field studies have been conducted to estimate the adherence of solids to skin. These field studies consider factors such as activity, sex, age, field conditions, and clothing worn. Section 7.4.1 provides information on key studies that measured adherence of solids to skin according to specific activities. Section 7.4.2 provides relevant information. Relevant studies provide additional perspective on adherence, including information on loading per contact event and the effects of soil/dust type, particle size, soil organic and moisture content, skin condition, and contact pressure and duration. This information may be useful for models based on individual contact events.

7.4.1. Key Adherence of Solids to Skin Studies**7.4.1.1. Kissel et al. (1996b)—Field Measurements of Dermal Soil Loading Attributable to Various Activities: Implications for Exposure Assessment**

Kissel et al. (1996b) collected direct measurements of soil loading on the surface of the skin of volunteers before and after activities expected to result in soil contact. Soil adherence associated with the following indoor and outdoor activities were estimated: greenhouse gardening, Tae Kwon Do, soccer, rugby, reed gathering, irrigation installation, truck farming, outdoor gardening and landscaping (groundskeepers), and playing in mud. Skin-surface areas monitored included hands, forearms, lower legs, faces, and feet (Kissel et al., 1996b).

Table 7-19 provides the activities, information on their duration, sample size, and clothing worn by participants. The subjects' body surfaces (forearms, hands, lower legs for all sample groups; faces and/or feet in some sample groups) were washed before and after the monitored activities. Paired samples were pooled into single ones. The mass recovered was converted to soil loading by using allometric models of surface area.

Table 7-20 presents geometric means for post-activity soil adherence by activity and body region for the four groups of volunteers evaluated. Children playing in the mud had the highest soil loadings among the groups evaluated. The results also indicate that, in general, the amount of soil adherence to the

hands is higher than for other parts of the body during the same activity.

An advantage of this study is that it provides information on soil adherence to various body parts resulting from unscripted activities. However, the study authors noted that because the activities were unstaged, "control of variables such as specific behaviors within each activity, clothing worn by participants, and duration of activity was limited." In addition, soil adherence values were estimated based on a small number of observations, and very young children and indoor activities were under represented.

7.4.1.2. Holmes et al. (1999)—Field Measurements of Dermal Loadings in Occupational and Recreational Activities

Holmes et al. (1999) collected pre- and post-activity soil loadings on various body parts of individuals within groups engaged in various occupational and recreational activities. These groups included children at a daycare center ("Daycare Kids"), children playing indoors in a residential setting ("Indoor Kids"), individuals removing historical artifacts from a site ("Archeologists"), individuals erecting a corrugated metal wall ("Construction Workers"), heavy equipment operators ("Equipment Operators"), individuals playing rugby ("Rugby Players"), utility workers jack-hammering and excavating trenches ("Utility Workers"), individuals conducting landscaping and rockery ("Landscape/Rockery"), and individuals performing gardening work ("Gardeners"). The study was conducted as a follow-up to previous field sampling of soil adherence on individuals participating in various activities (Kissel et al., 1996b). For this round of sampling, soil loading data were collected utilizing the same methods used and described in Kissel et al. (1996b). Table 7-19 presents information regarding the groups studied and their observed activities.

The daycare children studied were all at one location, and measurements were taken on three different days. The children freely played both indoors in the house and outdoors in the backyard. Table 7-19 describes the number of children within each day's group and the clothing worn. For the second observation day ("Daycare Kids No. 2"), post-activity data were collected for five children. All the activities on this day occurred indoors. For the third daycare group ("Daycare Kids No. 3"), four children were studied.

On two separate days, children playing indoors in a home environment were monitored. The first group ("Indoor Kids No. 1") had four children while the

Chapter 7—Dermal Exposure Factors

second group (“Indoor Kids No. 2”) had six. The play area was described by the authors as being primarily carpeted. Table 7-19 describes the clothing worn by the children within each day’s group.

Seven individuals (“Archeologists”) were monitored while excavating, screening, sorting, and cataloging historical artifacts from an ancient Native American site during a single event. Eight rugby players were monitored on two occasions after playing or practicing rugby. Eight volunteers from a construction company were monitored for 1 day while erecting corrugated metal walls. Four volunteers (“Landscape/Rockery”) were monitored while relocating a rock wall in a park. Four excavation workers (“Equipment Operators”) were monitored twice after operation of heavy equipment. Utility workers were monitored while cleaning and fixing water mains, jack-hammering, and excavating trenches (“Utility Workers”) on 2 days; five participated on the 1st day and four on the 2nd. Eight volunteers (“Gardeners”) ages 16 to 35 years were monitored while performing gardening activities (i.e., weeding, pruning, digging small irrigation trenches, picking and cleaning fruit). Table 7-19 describes the clothing worn by these groups.

Table 7-20 summarizes the geometric means and standard deviations (SDs) of the post-activity soil adherence for each group of individuals and for each body part. According to the authors, variations in the soil loading data from the daycare participants reflect differences in the weather and access to the outdoors.

An advantage of this study is that it provides a supplement to soil-loading data collected in a previous round of studies (Kissel et al., 1996b). Also, the data support the assumption that hand loading can be used as a conservative estimate of soil loading on other body surfaces for the same activity. The activities studied represent normal child play both indoors and outdoors, as well as different combinations of clothing. The small number of participants is a disadvantage of this study. Also, the children studied and the activity setting may not be representative of the U.S. population.

7.4.1.3. Shoaf et al. (2005b)—Child Dermal Sediment Loads Following Play in a Tide Flat

The purpose of the Shoaf et al. (2005b) study was to obtain sediment adherence data for children playing in a tidal flat (“Shoreline Play”). The study was conducted 1 day in late September 2003 at a tidal flat in Jamestown, RI. A total of nine subjects (three females and six males) ages 7 to 12 years participated in the study. Table 7-19 presents

information on activity duration, sample size, and clothing worn by participants. Participants’ parents completed questionnaires on their child’s typical activity patterns during tidal flat play, exposure frequency and duration, clothing choices, bathing practices, and clothes laundering.

This study reported direct measurements of sediment loadings on five body parts (face, forearms, hands, lower legs, and feet) after play in a tide flat. Each of nine subjects participated in two timed sessions, and pre- and post-activity sediment loading data were collected. Geometric mean (geometric standard deviations) dermal loadings (mg/cm²) on the face, forearm, hands, lower legs, and feet for the combined sessions, as shown in Table 7-20, were 0.04 (2.9), 0.17 (3.1), 0.49 (8.2), 0.70 (3.6), and 21 (1.9), respectively. Event duration did not appear to be associated with sediment loading on the skin.

The primary advantage of this study is that it provides adherence data specific to children and sediments, which previously had been largely unavailable. Results will be useful to risk assessors considering exposure scenarios involving child activities at a coastal shoreline or tidal flat. The limited number of participants (nine) and sampling during just 1 day and at one location, make extrapolation to other situations uncertain.

7.4.1.4. Shoaf et al. (2005a)—Adult Dermal Sediment Loads Following Clam Digging in Tide Flats

The purpose of this study was to obtain sediment adherence data for adults engaged in unscripted clam digging activities in a tidal flat. The study was conducted over three days in late August 2003 at a tide flat near Narragansett, RI. Eighteen subjects (nine females and nine males) ages 33 to 63 years old participated in the study. This study reports direct measurements of sediment loadings on five body parts (face, forearms, hands, lower legs and feet). Pre- and post-activity sediment loading data were collected using skin rinsing techniques. The data from this study are presented along with the other field studies in Table 7-19 (populations and field conditions) and Table 7-20 (soil adherence results). Activity time was found not to be a good indicator of skin loading.

The primary advantage of this study is that it provides adherence data for sediments which had previously been largely unavailable. Results will be useful to risk assessors considering exposure scenarios involving adult activities at a coastal shoreline or tide flat. The limited number of participants (18) and sampling over just 3 days and

Chapter 7—Dermal Exposure Factors

one location, make extrapolation to other situations uncertain.

7.4.2. Relevant Adherence of Solids to Skin Studies**7.4.2.1. Harger (1979)—A Model for the Determination of an Action Level for Removal of Creosote Contaminated Soil**

U.S. EPA (1992a, 1988, 1987) reported on experimental values for (soil-related) dust adherence as estimated by Harger (1979). According to U.S. EPA (1992a), “these estimates are based on unpublished experiments by Dr. Rolf Hartung (University of Michigan) as reported in a 1979 memorandum from J. Harger to P. Cole (both from Michigan Toxic Substance Control Commission in Lansing, MI). According to this memo, Dr. Hartung measured adherence using his own hands and found: 2.77 mg/cm² for kaolin with a SD of 0.66 and $N = 6$; 1.45 mg/cm² for potting soil with SD = 0.36 and $N = 6$; and 3.44 mg/cm² for sieved vacuum cleaner dust (mesh 80) with SD = 0.80 and $N = 6$. The details of the experimental procedures were not reported. Considering the informality of the study and lack of procedural details, the reliability of these estimates cannot be evaluated.” Accordingly, these data are not considered to be key for the purpose of developing recommendations for soil adherence to the skin.

7.4.2.2. Que Hee et al. (1985)—Evolution of Efficient Methods to Sample Lead Sources, Such as House Dust and Hand Dust, in the Homes of Children

Que Hee et al. (1985) used house dust having particle sizes ranging from 44 to 833 μm in diameter, fractionated into six size ranges, to estimate the amount that adhered to the palm of the hand of a small adult. The amount of dust that adhered to skin was determined by applying approximately 5 grams of dust for each size fraction, removing excess dust by shaking the hands, and then measuring the difference in weight before and after application. Que Hee et al. (1985) found no relationship between particle size and adherence for house dusts with particle sizes <246 μm . For all six particle sizes, an average of 63 ± 42 percent of applied dust adhered to the palm of the hand. This represents 31.2 ± 16.6 mg of soil. Excluding the two largest size fractions, $58 \pm 29\%$ of the applied dust adhered to the hand, representing 28.9 ± 1.9 mg.

The limitation of these data is that they were based on one adult hand and a single house dust sample. Also, the data are for hands only and are not linked to specific activities.

7.4.2.3. Driver et al. (1989)—Soil Adherence to Human Skin

Driver et al. (1989) conducted experiments to evaluate the conditions that may affect soil adherence to the skin of adult hands. Both top soils and subsoils of five soil types (Hyde, Chapanoke, Panorama, Jackland, and Montalto) were collected from sites in Virginia. The organic content, clay mineralogy, and particle size distribution of the soils were characterized, and the soils were dry sieved to obtain particle sizes of $\leq 250 \mu\text{m}$ and $\leq 150 \mu\text{m}$. For each soil type, the amount of soil adhering to adult male hands when using both sieved and unsieved soils was determined gravimetrically (i.e., measuring the difference in soil sample weight before and after soil application to the hands). An attempt was made to measure only the minimal or “monolayer” of soil adhering to the hands. This was done by mixing a preweighed amount of soil over the entire surface area of the hands for a period of approximately 30 seconds, followed by removing excess soil by gently rubbing the hands together after contact with the soil. Excess soil that was removed from the hands was collected, weighed, and compared to the original soil sample weight. Driver et al. (1989) measured average adherence of 1.40 mg/cm² for particle sizes less than 150 μm , 0.95 mg/cm² for particle sizes less than 250 μm , and 0.58 mg/cm² for unsieved soils. Analysis of variance statistics showed that the most important factor affecting adherence variability was particle size ($p < 0.001$). The next most important factor was soil type and subtype ($p < 0.001$), but the interaction of soil type and particle size also was significant ($p < 0.01$).

Driver et al. (1989) found statistically significant increases in soil adherence with decreasing particle size, whereas Que Hee et al. (1985) found that different size particles of house dust <246 μm adhered equally well to hands.

The advantages of this study are that it provides additional perspective on the effects of particle size on adherence and that it evaluated several different soil types. However, it is based on data for hands only for a limited number of experimental observations (i.e., one subject). Also, the data are not activity based.

Chapter 7—Dermal Exposure Factors

7.4.2.4. Sedman (1989)—The Development of Applied Action Levels for Soil Contact: A Scenario for the Exposure of Humans to Soil in a Residential Setting

Sedman (1989) used estimates from Lepow et al. (1975), Roels et al. (1980), and Que Hee et al. (1985) to develop a maximum soil load that could occur on the skin. Lepow et al. (1975) estimated that approximately 0.5 mg of soil adhered to 1 cm² of skin. Roels et al. (1980) estimated that 159 mg of soil adhered to the hand of an 11-year-old child. Assuming that approximately 60% (185 cm²) of the surface area of the hand was sampled, the amount of soil adhering per unit area of skin was estimated to be 0.9 mg/cm². Que Hee et al. (1985) estimated that approximately 31.2 mg of housedust adhered to the palm of a small adult. Assuming a hand surface area of 160 cm², Sedman (1989) estimated a soil loading of 0.2 mg/cm². A rounded arithmetic mean of 0.5 mg/cm² was calculated from these three studies. According to Sedman (1989), this was near the maximum load of soil that could occur on the skin, but it is unlikely that most skin surfaces would be covered with this amount of soil (Sedman, 1989).

This study is considered relevant and not key because it does not provide any new data, but uses data from other studies and various assumptions to estimate soil adherence.

7.4.2.5. Finley et al. (1994)—Development of a Standard Soil-to-Skin Adherence Probability Density Function for Use in Monte Carlo Analyses of Dermal Exposure

Using data from several existing studies, Finley et al. (1994) developed probability density functions of soil-to-skin adherence. Finley et al. (1994) reviewed studies that estimated adherence among adults and children based on various gravimetric and hand wiping/rinsing methods. Several of these studies were originally conducted for the purpose of estimating lead exposure from soil contact. By combining data from four studies [Charney et al. (1980); Roels et al. (1980); Gallacher et al. (1984); and Duggan et al. (1985)], Finley et al. (1994) estimated a mean \pm standard deviation soil adherence value for children of 0.65 ± 1.2 mg soil/cm²-skin. (50th percentile = 0.36 and 95th percentile = 2.4 mg soil/cm²-skin). Using data from three studies [Gallacher et al. (1984); Que Hee et al. (1985); and Driver et al. (1989)], Finley et al. (1994) estimated a mean \pm standard deviation soil adherence value for adults of 0.49 ± 0.54 mg soil/cm²-skin. (50th percentile = 0.06 and 95th percentile = 1.6 mg

soil/cm²-skin). Because the distributions of soil-to-skin adherence were similar for children and adults, Finley et al. (1994) developed a probability density function based on the combined data for children and adults. The probability density function is lognormally distributed with a mean \pm standard deviation of 0.52 ± 0.9 mg soil/cm²-skin (50th percentile = 0.25 and 95th percentile = 1.7 mg soil/cm²-skin).

The advantage of this study is that it provides distributions of soil adherence for children, adults, and children and adults combined. However, it is based on some older, relevant studies that are not activity- or body-part specific.

7.4.2.6. Kissel et al. (1996a)—Factors Affecting Soil Adherence to Skin in Hand-Press Trials: Investigation of Soil Contact and Skin Coverage

Kissel et al. (1996a) conducted soil adherence experiments to evaluate the effect of particle size and soil moisture content on adherence to the skin. Five soil types were obtained in the Seattle, WA, area (sand, two types of loamy sand, sandy loam, and silt loam) and were analyzed to determine composition. Clay content ranged from 0.5 to 7.0%, and organic carbon content ranged from 0.7 to 4.6%. Soils were dry-sieved to obtain particle size ranges of <150, 150–250, and >250 μ m. For each soil type, the amount of soil adhering to an adult female hand when using both sieved and unsieved soils was determined by measuring the soil sample weight before and after the hand was pressed into a pan containing the test soil. Loadings were estimated by dividing the recovered soil mass by the total surface area of one hand, although loading occurred primarily on only one side of the hand. Results showed that generally, soil adherence to hands was directly correlated with moisture content, inversely correlated with particle size, and independent of clay content or organic carbon content. For dry soil, mean adherence was the lowest for the largest particle sizes (i.e., >250 μ m) of dry soil (0.06 to 0.34 mg/cm²) and highest for the smallest particle sizes (0.42 to 0.76 mg/cm²). Adherence values based on moisture content ranged from 0.22 to 0.54 mg/cm² for soils with moisture contents of 9% or less, 0.39 to 3.09 mg/cm² for soils with moisture contents of 10 to 19%, and 1.64 to 14.8 mg/cm² for soils with moisture contents of 21 to 27%.

Chapter 7—Dermal Exposure Factors

The advantage of this study is that it provides information on how soil type can affect adherence to the skin. However, the soil adherence data are for a single subject, and the data are limited to five soil samples.

7.4.2.7. Holmes et al. (1996)—Investigation of the Influence of Oil on Soil Adherence to Skin

Holmes et al. (1996) conducted experiments to evaluate differences in adherence of soil to skin based on soil type, moisture content, and the presence of oil (i.e., petroleum contaminants) in the soil. Three soil types (loamy sand, silt loam, and sand) treated with three concentrations (0, 1, and 10%) of motor oil were used, and the experiments were conducted under wet and dry soil conditions. A single subject pressed the right hand, palm down, into a pan containing soil. The soil adhering to the hand was collected by washing and then weighed. For dry soil containing no oil, adherence values ranged from 0.29 mg/cm² for sandy soil to 0.59 mg/cm² for silt loam. For wet soil containing no oil (13 to 15% moisture), adherence values were 0.25 mg/cm² for silt loam, 1.6 mg/cm² for sand, and 3.7 mg/cm² for loamy sand. According to Holmes et al. (1996), “high concentrations of petroleum contaminants can increase the dermal adherence of soil, but the magnitude of the effect is likely to be modest.”

The advantage of this study is that it provides additional perspective on the factors that affect soil adherence to skin. However, it is based on limited observations (i.e., one subject) for only the hand under experimental conditions (i.e., not activity-based).

7.4.2.8. Kissel et al. (1998)—Investigation of Dermal Contact With Soil in Controlled Trials

Kissel et al. (1998) measured dermal exposure to soil from staged activities conducted in a greenhouse. A fluorescent marker was mixed in soil so that soil contact for a particular skin surface area could be identified. The subjects were video-imaged under a long-wave ultraviolet (UV) light before and after soil contact. In this manner, soil contact on hands, forearms, lower legs, and faces was assessed by presence of fluorescence. In addition to fluorometric data, gravimetric measurements for pre-activity and post-activity were obtained from the different body parts examined. The studied groups included adults transplanting 14 plants for 9 to 18 minutes, children playing for 20 minutes in a soil bed of varying moisture content representing wet and dry soils, and

adults laying plastic pipes for 15, 30, or 45 minutes. Table 7-21 summarizes the parameters describing each of these activities. Before each trial, each participant was washed to obtain a preactivity or background gravimetric measurement.

For wet soil, post-activity fluorescence results indicated that the hand had a much higher fractional coverage than other body surfaces (see Figure 7-2). As shown in Figure 7-3, post-activity gravimetric measurements for children playing and adults transplanting showed higher soil loading on hands and much lower soil loading on other body surfaces. This also was observed in adults laying pipe. The arithmetic mean percent of hand surface area fluorescing was 65% after 15 minutes laying pipe in wet soil and 85% after 30 and 45 minutes laying pipe in wet soil. The arithmetic mean percent of lower leg surface area fluorescing was ~20% after 15 minutes of laying pipe in wet soil, 25% after 30 minutes, and 40% after 45 minutes. According to Kissel et al. (1998), the relatively low loadings observed on non-hand body parts may be a result of a more limited area of contact for the body part rather than lower localized loadings. Kissel et al. (1998) observed geometric means of up to about 3 mg/cm² on adults' hands after the 30-minute pipelaying activity with wet soil. After children played and adults transplanted in wet soil, geometric mean soil loadings were 0.7 and 1.1 mg/cm², respectively. Mean loadings were lower on hands in the dry soil trial and on lower legs, forearms, and faces in both the wet and dry soil trials. Higher loadings were observed for all body surfaces with the higher moisture content soils.

This report is valuable in showing soil loadings from soils of different moisture content and providing evidence that dermal exposure to soil is not uniform for various body surfaces. This study also provides some evidence of the protective effect of clothing. Disadvantages of the study include the small number of study participants and the short activity duration.

7.4.2.9. Rodes et al. (2001)—Experimental Methodologies and Preliminary Transfer Factor Data for Estimation of Dermal Exposure to Particles

Rodes et al. (2001) conducted a study using the fluorescein-tagged Arizona Test Dust (ATD) as a surrogate for house dust and evaluated particle mass transfer from surfaces to the human skin of three test subjects (one female and two males). Transfers to wet and dry skin from stainless steel, vinyl, and carpeted surfaces that had been preloaded with tagged ATD were quantified. For carpets, experiments were

Chapter 7—Dermal Exposure Factors

conducted in which particles were either embedded in the carpet fibers or not embedded. Particles were embedded into carpet by dragging a steel cylinder across the carpet after loading. Controlled hand (palm) press experiments were conducted, and the amount of tagged ATD that had transferred to the skin of the palm was measured using fluorometry. Surface loadings that represented typical indoor conditions were used in the study. Rodes et al. (2001) used defined dust fractions ($<80\text{ }\mu\text{m}$) to evaluate the influence of particles size on transfer. For the experiments with wet hands, a surrogate saliva solution was used. The portion of the hand that contacted the material also was estimated.

Dermal transfer factors were calculated as the mass of particles on the hand (μg on hand/ cm^2 of dermal contact area) divided by the mass of particles on the surface contacts (μg on surface/ cm^2 of surface contact). Table 7-22 shows the dermal transfer factors (based on the mean of left and right hand presses) for the various surface types and hand moisture contents. The results indicate that for dry hands, transfer from smooth surfaces (i.e., stainless steel) was higher than for other materials (58.2 to 76.0%; mean = $69 \pm 9\%$). Skin moisture content was shown to be a critical factor in the proportion of particles to transfer (wet hands resulted in 100% transfer from stainless steel). As surface roughness increased, transfer tended to decrease, with carpet surfaces having the lowest transfer factors (3.4 to 16.9%). Embedding particles into the carpet significantly reduced particle transfer. Rodes et al. (2001) also observed that “only about $1/3^{\text{rd}}$ of the projected hand surface typically came in contact with the smooth test surfaces during a press....[and] consecutive presses decreased the particle transfer by a factor of three as the skin became loaded, requiring ~100 presses to reach an equilibrium transfer rate.”

The advantage of this study is that it evaluated particle transfer for a variety of surface types and skin conditions. However, a small number of subjects were involved in the study, and Rodes et al. (2001) suggested that when using these data, the similarities and differences in characteristics between ATD and real house dust should be considered.

7.4.2.10. Edwards and Lioy (2001)—Influence of Sebum and Stratum Corneum Hydration on Pesticide/Herbicide Collection Efficiencies of the Human Hand

Edwards and Lioy (2001) studied the effects of sebum/sweat and skin hydration on the transfer of pesticide residues in dust to the hands. Under normal conditions, the skin on the hand is covered by a layer

of sebum, a mixture of lipids secreted from the sebaceous glands, and sweat that is secreted from sweat ducts. Edwards and Lioy (2001) measured the levels of sebum and moisture on the palm of the hand of one subject prior to conducting hand press experiments using house dust treated with a mixture of four pesticides (atrazine, diazinon, malathion, and chlorpyrifos). The house dust sample was obtained from vacuum cleaner bags and was sieved to $<250\text{ }\mu\text{m}$. The dust was settled onto the sample surfaces and sprayed with the pesticide mixture, and the subject pressed one hand to the surface in a series of trials conducted approximately 1 week apart. The hand was rinsed with solvent to extract any transferred pesticide/dust, and the solution was analyzed for pesticide residues. Transfer efficiencies (percentage) were calculated as the concentration of residues measured in the hand rinse solution divided by the concentration of pesticide on the sampling surface times 100. The results of this study indicated that the transfer efficiencies of two pesticides in dust were negatively correlated with sebum levels (i.e., increased sebum levels resulted in a 13% reduction in atrazine transfer and an 8% reduction in malathion transfer) and transfer efficiencies of two pesticides in dust were negatively correlated with skin hydration [i.e., increased skin moisture resulted in a 7% reduction in diazinon transfer and 5% reduction in chlorpyrifos transfer; Edwards and Lioy (2001)].

The advantage of this study is that it provides additional perspective on factors that can affect adherence of solids to the skin. However, it is considered relevant and not key because the transfer of dust was studied for the hands only and used experimental conditions not based on exposure-related activities.

7.4.2.11. Choate et al. (2006)—Dermally Adhered Soil: Amount and Particle Size Distribution

Choate et al. (2006) investigated the soil characteristics that affect particle adherence to human skin. The factors considered included particle size, organic carbon content, and soil moisture. Day-to-day variability and differences based on whether or not hands were washed before contacting the soil also were examined. A total of 108 subjects ($1/3$ female) between 18 and 30 years of age participated in one or more of a series of soil adherence experiments. Some of the experiments were conducted using clay loam soil collected in Colorado, while others were conducted using silty-clay loam soil collected in Iowa. Soil moisture contents ranged from 1 to 10%. Choate et al. (2006) used either preweighed adhesive

Chapter 7—Dermal Exposure Factors

tape or hand washing with distilled water to remove and collect soil that had adhered to the palm of subjects' hands after contact with bulk soil under controlled experimental conditions. Removed soil was weighed, and the mass of soil per area of skin surface was calculated for each sample.

Based on the adhesive tape tests, an average of 0.7 mg/cm² of the Colorado soil adhered to the hand ($N = 6$ subjects each sampled using the right or left hand on 10–12 study days). There were no significant differences between the left and right hands, but there were “large average variabilities . . . both between subjects on a given day ($\pm 52\%$) and for an individual subject on different days ($\pm 50\%$).” Differences between soil adherence to hands that had or had not been washed prior to soil contact were observed, with hand washing resulting in a lower mean adherence value (0.51 mg/cm²; $N = 76$) than non-washing (1.1 mg/cm²; $N = 72$), when soil with a moisture content of 4.7% was used. The authors suggested that this is “probably due to the removal [during washing] of oils from the skin that aid in the adherence of soil particles.” Soil adherence for the two types of soils (i.e., from Colorado and Iowa) with low moisture content (i.e., <2%) averaged 0.64 and 0.69 mg/cm², compared to 1.47 and 1.36 mg/cm² for those with high moisture content (9% to 10%). Large particle fractions of the soils with higher moisture content adhered more readily than those in soils with low or medium moisture content. The “adhered fractions of dry or moderately moist soils with wide distribution of particle sizes generally consist[ed] of particles of diameters <63 μm .” The organic carbon content of the soils did not appear to be an important contributor to soil adherence.

The advantage of this study is that it provides additional perspective on factors that affect soil adherence to skin by using a larger number of subjects compared to some of the earlier studies. However, the data are based only on controlled experimental conditions and may not be representative of the specific types of activities in which dermal exposure may occur.

7.4.2.12. Yamamoto et al. (2006)—Size Distribution of Soil Particles Adhered to Children's Hands

Yamamoto et al. (2006) conducted both laboratory and field experiments that showed finer soil particles adhered more readily to children's hands than coarse particles. In the laboratory, one female subject pressed her hand into a tray containing reference soil. Her hand then was washed in ultrapure water that was analyzed to determine the

size distributions and the amount of soil that had adhered to the hand. Yamamoto et al. (2006) observed that the mode diameter of soil adhering to the hand ($22.8 \pm 0.0 \mu\text{m}$) was less than that of the reference soil ($36.9 \pm 4.9 \mu\text{m}$), indicating that finer particles adhered more efficiently to the hand. The effect of hand moisture was tested by moistening the hand prior to pressing it onto the tray of soil. Yamamoto et al. (2006) observed that while the amount of soil that adhered to the hand increased with hand moisture, the size distributions were not greatly changed.

A separate field experiment was conducted in which ten 4-year-old children (five males and five females) attending a nursery school in Japan participated. After playing in the playground and sandbox for a morning or afternoon, the children's hands were washed in bottles containing 500 mL ultrapure water, and aliquots of the water were analyzed to determine the size distributions and amounts of particles that had adhered to the hands. The particles sizes of soil samples collected from the children's playing area (i.e., playground, field, and sandbox) also were analyzed. The mean, median, and maximum amounts of soil adhering to the children's hands were 26.2, 15.2, and 162.5 mg/hand, respectively. Assuming a surface area of the hand of 210 cm², the amounts are equivalent to 0.125, 0.73, and 0.774 mg/cm², respectively. Compared to the soil in the children's play area, the soil adhering to the children's hands was composed primarily of the finer particles.

The advantage of this study is that both laboratory and field measurements were used to evaluate particle sizes of soil that adheres to the hands. However, only one subject participated in the laboratory study, and the children's activities in the field portion were not indexed to the amount of time spent performing soil contact activities.

7.4.2.13. Ferguson et al. (2009a; 2009c; 2009b; 2008)—Soil-Skin Adherence: Computer-Controlled Chamber Measurements

Ferguson et al. (2009a; 2009c; 2009b; 2008) conducted a series of soil adherence experiments by using a mechanical chamber designed to control and measure pressure and time of contact with surfaces loaded with soil. Adherence of play sand and lawn soil to human cadaver skin and cotton sheet samples was measured after contact with either loaded carpet or aluminum surfaces. Multiple pressure levels (20 to 50 kPa), durations of contact (10 to 50 seconds), and particle sizes (<139.7 μm and ≥ 139.7 to <381.0 μm)

were evaluated (Ferguson et al., 2009a; Ferguson et al., 2009b; Beamer et al., 2008). Also, both single- and multiple-contact experiments were conducted (Ferguson et al., 2009c). Soil adherence was estimated by weighing the carpet or aluminum samples loaded with play sand or lawn soil both before and after controlled contacts occurred and calculating the weight differences. Each experiment, using different combinations of pressure, contact duration, particle size, soil type, surface, and contact material, was repeated multiple times. Table 7-23 presents a comparison of the adherence values for contact with carpet and aluminum surfaces. Mean soil to skin adherence from contact with aluminum surfaces (1.18 mg/cm^2) was higher than from carpet (0.71 mg/cm^2). In general, soil transfer increased as pressure increased, and contact durations of 30 seconds or more did not appear to result in higher adherence. For carpets, larger particle size was associated with higher adherence, while smaller particle size was associated with higher adherence from aluminum (Ferguson et al., 2009a). Based on a comparison of data from experiments with multiple contacts, Ferguson et al. (2009c) found that, “on average, 8% of the original transfer amount will transfer during a second contact. Therefore, attaching a soil/adherence transfer of the original magnitude for every contact may result in overestimates for exposure.”

The advantages of these studies are that they provide data from controlled experiments in which a variety of conditions were tested. However, a single carpet type was used, and transfer may differ based on carpet type. Also, adherence may be different for different types of soil or house dust, as well as for different skin types and conditions. Differences in the nature of contact and the initial surface soil loadings also may affect adherence.

7.5. FILM THICKNESS OF LIQUIDS ON SKIN

Information on the thickness of liquids on human skin is sometimes used to estimate dermal exposure to contaminants in liquids that come into contact with the skin. For example, these data are used to estimate exposure to consumer products in U.S. EPA’s Exposure and Fate Assessment Screening Tool [EFAST; U.S. Environmental Protection Agency (2007b)]. Section 7.5.1 provides the available data on film thickness of liquids on the skin. However, these data are limited; therefore, studies related to this factor have not been categorized as key or relevant in this chapter, and specific recommendations are not provided for this factor.

7.5.1. U.S. EPA (1987)—Methods for Assessing Consumer Exposure to Chemical Substances; and U.S. EPA (1992c)—A Laboratory Method to Determine the Retention of Liquids on the Surface of Hands

U.S. EPA (1992c, 1987) reported on experiments that were conducted to measure the retention of liquids on hands after contact with six different types of liquids (mineral oil, cooking oil, water soluble bath oil, 50:50 oil/water emulsion, water, and 50:50 water ethanol). These liquids were selected because they were non-toxic and represented a range of viscosities and likely retention on the hands. Five exposure conditions were tested to simulate activities in which consumers’ hands may be exposed to liquids, including (1) contact with dry skin (initial contact), (2) contact with skin previously exposed to the liquid and still wet (secondary contact), (3) immersion of a hand into a liquid, (4) contact from handling a wet rag, and (5) contact during spill cleanup. For the initial contact scenario, a cloth saturated with liquid was rubbed over the front and back of both clean, dry hands for the first time during an exposure event. For the secondary contact scenario, a cloth saturated with liquid was rubbed over the front and back of both hands for a second time, after as much as possible of the liquid that adhered to skin during the first contact event was removed using a clean cloth. For the immersion scenario, one hand was immersed in a container of liquid and then removed; the liquid was allowed to drip back into the container for 30 seconds (60 seconds for cooking oil). For the scenario involving the handling of a rag, a cloth saturated with liquid was rubbed over the palms of both hands in a manner simulating handling of a wet cloth. For the spill cleanup scenario, a subject used a clean cloth to wipe up 50 mL of liquid poured onto a plastic laminate countertop. For each of the five scenarios, retention was measured immediately after applying the liquid to the hands and after partial and full removal by wiping. Partial wiping was defined as “lightly [wiping with a removal cloth] for 5 seconds (superficially).” Full wiping was defined as “thoroughly and completely as possible within 10 seconds removing as much liquid as possible.” Four human subjects were used in the experiments, and multiple replicates (four to six) were conducted for each subject and type of liquid and exposure condition. Retention of liquids on the skin was estimated by taking the difference between the weight of the cloth(s) before and after wiping and

Chapter 7—Dermal Exposure Factors

dividing by skin surface area. For the immersion scenario, retention was estimated as the weight difference in the immersion container before and after immersion. Film thickness (cm) was estimated as the amount of liquid retained on the skin (g/cm^2) divided by the density of the liquid (g/cm^3) used in the experiment.

Table 7-24 presents the estimated film thickness data from these experiments. Film thickness data may be used with information on the density of a liquid and the weight fraction of the chemical in the liquid to estimate the amount of contaminant retained on the skin (i.e., amount retained on skin [g/cm^2] = film thickness of liquid on skin [cm] \times density of liquid [g/cm^3] \times weight fraction [unitless]). Dermal exposure (g/event) may be estimated as the amount retained on the skin (g/cm^2) times the skin surface area exposed (cm^2/event).

The advantage of this study is that it provides data for a factor for which information is very limited. Data are provided for various types of liquids under various conditions. However, the data are based on a limited number of observations and may not be representative of all types of exposure scenarios.

7.6. RESIDUE TRANSFER

Several methods have been developed to quantify rates of residue transfer to the human skin of individuals performing activities on treated surfaces. These methods have been used to either develop transfer efficiencies or estimate residue transfer coefficients. Transfer efficiencies are the fraction (or percentage) of surface residues transferred to the skin. Transfer coefficients (cm^2/hour) represent the ratio of the dermal exposure during a specified time period (mg/hour) based on a specific exposure activity (e.g., harvesting a crop or performing indoor or outdoor activities) to the environmental concentration of the pesticide (mg/cm^2). Transfer coefficients are estimated in studies in which environmental residue levels are measured concurrently with exposure levels for particular job functions or activities. These studies have been conducted primarily for the purpose of estimating exposure to pesticides. Exposure levels are typically measured using dosimeter clothing that is worn by study subjects during the conduct of specific activities and then removed and analyzed for pesticide residues. Sometimes biomonitoring studies (i.e., urine analyses) or other methods (e.g., hand wash) are used to estimate exposure levels. Environmental residues are estimated using various techniques, including use of deposition coupons, wipe samples, or a residue collection tool such as a

“drag sled” or roller on indoor or outdoor surfaces, as described in U.S. EPA (1998).

Although chemical-specific transfer coefficients are typically preferred for estimating exposure, U.S. EPA (2009) has used data from published and unpublished residue transfer studies to develop some generic activity-specific transfer coefficient assumptions to use in exposure assessments when chemical-specific data are unavailable. Use of these generic transfer coefficients for pesticides is based on the assumption that the transfer of residues to human skin is based primarily on the types of activities being performed rather than on the specific characteristics of the pesticide. This section presents data for published residue transfer studies only (i.e., unpublished data are not included here).

A transfer coefficient, expressed in units of cm^2/hour , is used to estimate exposure to chemical residues by combining it with the environmental concentration (in units of mg/cm^2) and an exposure time in hours/days (e.g., exposure [mg/day] = transfer coefficient [cm^2/hour] \times environmental concentration [mg/cm^2] \times exposure time [hours/day]). When using transfer co-efficients, it is important to ensure that the residue levels used are consistent with the method for developing the transfer coefficient (e.g., residue levels based on deposition coupons should be used with transfer co-efficients based on deposition coupons; residue levels based on a residue collection tool such as the California Roller should be used with transfer coefficients based on the same type of tool). Information on methods that may be used to estimate transferrable residues from indoor surfaces and dislodgeable residues from turf may be found in Hsu et al. (1990), Geno et al. (1996), Camann et al. (1996), Fortune (1998a, b), and Fortune et al. (2000). U.S. EPA (2009) describes the use of generic transfer coefficients for a variety of activities involving pesticides. Section 7.6.1 discusses the published data on transfer efficiencies and transfer coefficients gathered from the scientific literature. Because residue transfer depends on the specific conditions under which exposure occurs (e.g., activity, contact surfaces, age), the studies described in Section 7.6.1 have not been categorized as key or relevant, and specific recommendations are not provided for this factor.

Chapter 7—Dermal Exposure Factors

7.6.1. Residue Transfer Studies**7.6.1.1. Ross et al. (1990)—Measuring Potential Dermal Transfer of Surface Pesticide Residue Generated From Indoor Fogger Use: An Interim Report**

Ross et al. (1990) utilized choreographed exercise routines to measure the amount of pesticide residues that may be transferred from carpets to adult skin. Five adult volunteers wore dosimeter clothing (i.e., cotton tight, shirt, gloves, and socks) over the skin areas that normally would be exposed and conducted exercise routines for 18.2 minutes in hotel rooms where pesticides (i.e., chlorpyrifos and d-trans-allevrin) were applied (20 minutes total exposure to account for entry and exit from the treated rooms). The exercise routines were performed at times ranging from 0 to 13 hours after pesticide application. The routines included “substantial body contact between the subject and treated carpet” and were “intended to represent a person’s day-long (16 hours) contact with pesticide-treated surfaces in a home in which a total discharge fogger had been used” (Krieger et al., 2000). The dosimeter clothing was assumed to retain the same amount of pesticide as the skin (Krieger et al., 2000). It was collected and analyzed for pesticide residues to estimate the amount of residues that had been transferred from the carpet to the skin. Environmental concentrations of the pesticides were measured in the rooms where the exercise routines took place by using gauze coupons placed in the rooms prior to pesticide application.

Ross et al. (1990) found that the transfer of pesticides (i.e., potential dermal exposure) differed according to the body part exposed and declined with time after pesticide application with a rapid decline in pesticide transfer between 6 and 12 hours. Some of the possible factors attributed to this decline were loss of formulation inerts, absorption by or adsorption to the carpet, breakdown to non-detected materials, downward migration into non-contact areas of the carpet or adsorption to dust particles, and volatilization. Table 7-25 provides the mean transfer efficiencies (i.e., percent of pesticide residues transferred to the various body parts from carpet), based on the time after application. These percentages represent the clothing residues divided by the environmental concentrations—based on deposition coupons—times 100 (Ross, 1990).

The study demonstrated the efficacy of using choreographed activities to estimate pesticide residue transfer. A limitation of this study is that the exercise routines used may not be representative of other types of indoor activities.

7.6.1.2. Ross et al. (1991)—Measuring Potential Dermal Transfer of Surface Pesticide Residue Generated From Indoor Fogger Use: Using the CDFA Roller Method: Interim Report II

Ross et al. (1991) reported on the use of the California Food and Drug Administration (CDFA) roller to estimate pesticide transfer from carpet. This study was conducted in parallel with the Ross et al. (1990) study. The roller device was tested as a surrogate for human subjects for measuring residue transfer from indoor surfaces. The roller was a 12-kg, foam-covered rolling cylinder equipped with stationary handles. A cotton cloth covered with plastic was placed over a pesticide-treated carpet, and the device was rolled over it 10 times. The cloth then was collected and analyzed for pesticide residues. Environmental residue levels were measured using gauze coupons placed on the carpet prior to pesticide application. Mean gauze dosimeter residues were compared to the amount of material transferred to the roller sheet. The results showed that the carpet roller method transferred 1 to 3% of carpet residue to the roller sheet. As in the 1990 study, pesticide transferability decreased with time and with contact with the treated surface. Using the data from Ross et al. (1990), which involved the collection of pesticide residues on dosimeter clothing worn by human subjects who engaged in choreographed exercise routines, and the roller data from this study, Ross et al. (1991) calculated residue transfer coefficients as the total μg of residues transferred to dosimetry clothing times hours of exposure/ $\mu\text{g}/\text{cm}^2$ residue transferred to the roller sheet. Mean transfer coefficients were $200,000 \pm 50,000 \text{ cm}^2/\text{hr}$ for chlorpyrifos and $140,000 \pm 30,000 \text{ cm}^2/\text{hr}$ for d-trans allethrin. Ross et al. (1991) concluded that the use of a carpet roller was a good surrogate for measuring residue transfer.

A limitation of this study is that transfer of surface residues from the carpet to CDFA roller may not be representative of transfer of residues based on various human activities.

7.6.1.3. Formoli (1996)—Estimation of Exposure of Persons in California to Pesticide Products That Contain Propetamphos

Formoli (1996) conducted a study to estimate exposure to propetamphos that was applied to carpets. Five adult subjects (two men and three women) wore whole body dosimeters and performed structured exercise routines for 20 minutes on the treated carpet. The subjects’ clothing was cut up and analyzed for pesticide residues. Transferable

Chapter 7—Dermal Exposure Factors

residues also were collected from the carpet by moving a roller device over cotton cloth that was subsequently analyzed for pesticide residues. Using the dermal exposure data from the dosimeters and the transferable residue data from the roller device, Formoli (1996) calculated a transfer coefficient of 43,800 cm²/hr.

These data are useful because they provide perspective on residue transfer data based on controlled experimental conditions. However, the limitations of this study are that the exercise routines used may not be representative of all types of activities in which transfer of surface residues occurs, and the data are based on a single pesticide and a limited number of observations.

7.6.1.4. Krieger et al. (2000)—Biomonitoring and Whole Body Dosimetry to Estimate Potential Human Dermal Exposure to Semi-Volatile Chemicals

Krieger et al. (2000) conducted a study similar to the Ross et al. (1991; 1990) studies. The purpose of the Krieger et al. (2000) study was to compare dermal exposure estimated by four different methods. The methods included (1) measurement of residues deposited onto foil coupons that had been placed on the carpet prior to pesticide application; (2) measurement of residues transferred to cotton cloth using the CDFA roller method, as described by Ross et al. (1991); (3) measurement of residues transferred to whole body cotton dosimeters during structured exercise routines; and (4) analysis of biomonitoring (urine) from subjects who participated in structured activities wearing either cotton whole body dosimeters or swimsuits. A total of 13 subjects wore whole body dosimeters while 21 subjects wore bathing suits. Foggers containing the pesticide chlorpyrifos were discharged from the centers of two identical rectangular meeting rooms at the University of California, Riverside. The rooms were kept unventilated for 2 hours and then were opened with a room divider removed during 30 minutes of ventilation. Surface deposition and dislodgeable residues were measured with three aluminum foil coupons and cotton sheets placed at two, four, and six feet from each fogger. The exercise routines were the same as those used in Ross et al. (1990). Biomonitoring was conducted by collecting four successive 24-hour urine samples from each subject 1 day prior to exposure and 3 days after exposure to chlorpyrifos.

The average amounts of pesticide transferred to the dosimeters were 0.27 µg/cm² based on the CDFA roller method and 0.73 µg/cm² based on the whole

body dosimetry method. These transfer amounts represent 7.5% and 20.2%, respectively, of the average concentration of pesticide on the surface of the carpet (3.6 µg/cm²) based on the deposition coupons. Calculating the transfer coefficient in the same way as Ross et al. (1991), the mean transfer coefficient would be approximately 154,000 cm²/hr (13,758 µg of residues transferred to dosimetry clothing per 0.33 hour of exposure/0.27 µg/cm² residue transferred to the roller sheet). Using the concentration of residues on the deposition coupons instead of those transferred to the roller cloth as the environmental concentration would give a transfer coefficient of approximately 12,000 cm²/hr (13,758 µg of residues transferred to dosimetry clothing per 0.33 hour of exposure/3.6 µg/cm² residue deposited on the carpet). Absorbed doses and biomonitoring data reported by Krieger et al. (2000) are not summarized because the data are specific to the pesticide (chlorpyrifos) studied. However, the biomonitoring data indicate that “both types of dosimeters [roller cloth and whole body] removed substantially more [pesticide] than was transferred and absorbed by human skin” (Krieger et al., 2000).

The advantage of this study is that it compared estimates of pesticide residue transfer using a variety of methods. However, the results are based on a single pesticide and may not be representative of other chemicals or activities that may result in exposure.

7.6.1.5. Clothier (2000)—Dermal Transfer Efficiency of Pesticides From New, Vinyl Sheet Flooring to Dry and Wetted Palms

Clothier (2000) compared the transfer of pesticide residues from vinyl flooring to dry, water-wetted, and saliva-wetted hands. Three different pesticides were used in the study (chlorpyrifos, piperonyl butoxide, and pyrethrin). Three male subjects participated in the study by pressing their hand palm down on the vinyl surface. Prior to performing the hand presses, the hands were either treated with a sample of their own saliva or water or received no pretreatment (dry hands). Transferable residues also were collected using the polyurethane foam (PUF) roller method described by Camann et al. (1996). Deposition coupons also were used to measure the amount of pesticide applied to the flooring. Transfer efficiencies were estimated as the rate of transfer to hands or PUF roller (µg/cm²) /mean surface loading (µg/cm²) times 100. Table 7-26 presents the transfer efficiencies from this study. Transfer efficiencies were higher for wetted palms than for dry palms and for the PUF roller than for dry hands.

Chapter 7—Dermal Exposure Factors

The advantage of this study is that it provides perspective on the effects of hand moisture on residue transfer. The data are based on three pesticides applied to vinyl surfaces and a limited number of subjects under controlled experimental conditions. However, the data may not reflect transfer associated with other chemicals or activities.

7.6.1.6. Bernard et al. (2001)—Environmental Residues and Biomonitoring Estimates of Human Insecticide Exposure From Treated Residential Turf

Bernard et al. (2001) conducted a study similar to those conducted by Ross et al. (1990) and Krieger et al. (2000), except that the exercise routines were conducted on pesticide-treated turf instead of on pesticide-treated carpets. Exposure was measured by analyzing whole body dosimeters worn by female participants during 20 minutes of exercise that occurred approximately 3.5 hours after pesticide had been applied to the turf. Pesticide deposition was estimated by collecting and analyzing cotton coupons present at the time of application. Dislodgeable residues were measured by collecting and rinsing foliage samples in an aqueous solution, and transferable turf residues were estimated using the CDFA roller 0, 1, and 3 days after application. Turf residues based on spray deposition (i.e., coupons), dislodgeable (aqueous wash) residues, and transferable (roller) residues were 12, 3.4, and $0.085 \mu\text{g}/\text{cm}^2$, respectively. This suggests that dislodgeable residues were approximately 28% of the deposition residues, and transferable residues were less than 1% of the deposition residues. Bernard et al. (2001) estimated that exposures based on transferable residues and those based on whole body dosimetry would be similar because transferable residues based on whole body dosimetry and those based on the roller technique were similar.

This study provides perspective on residue transfer from treated turf. However, the data are for a single pesticide and may not be representative of other chemical substances or exposure conditions.

7.6.1.7. Cohen Hubal et al. (2005)—Characterizing Residue Transfer Efficiencies Using a Fluorescent Imaging Technique

Cohen Hubal et al. (2005) used a fluorescent tracer method to evaluate the factors that affect the transfer of residues from indoor surfaces to the hands. The non-toxic fluorescent tracer vitamin B₂ riboflavin was applied to carpet and laminate flooring. Two levels of analyte loading were evaluated in the

study ($2 \mu\text{g}/\text{cm}^2$ and $10 \mu\text{g}/\text{cm}^2$). Three adult subjects participated in a series of controlled experiments in which the hands contacted the treated surfaces using one of two different levels of pressure for one of two different durations. Transfer as a result of multiple sequential contacts also was evaluated. The hands were characterized as dry, moist, or sticky prior to conducting the hand presses on the treated flooring materials. To simulate moist hands, the hands were placed under a cool mist vaporizer for 20 seconds; to simulate sticky conditions, 1.2 grams of Karo Syrup was applied to the hands. Dermal loading on the hands was measured by using a fluorescence imaging system. Transfer efficiencies were estimated by dividing the mass of tracer on the hand per unit surface area ($\mu\text{g}/\text{cm}^2$) divided by the loading of tracer on the carpet or laminate surface ($\mu\text{g}/\text{cm}^2$) times 100. Incremental transfer efficiency was calculated separately for each individual contact, whereas overall transfer efficiency was calculated cumulatively for the series of contacts. Table 7-27 provides the incremental and overall transfer efficiencies based on the hand conditions, the surface type, the surface loading, and the number of contacts. Based on the data in Table 7-27, the mean transfer efficiency after a single contact ranged from 3 to 14% for dry and sticky hands, respectively. According to Cohen Hubal et al. (2005), surface loading and skin condition were important parameters in characterizing transfer efficiency, but duration of contact and pressure did not have a significant effect on transfer.

An advantage of this study is that it uses a tracer method to estimate transfer efficiency from surfaces to human skin. It also provides perspective on various conditions that may affect transfer efficiency. A limitation is that the data may not reflect transfer associated with specific chemicals or activities.

7.6.1.8. Hubal et al. (2008)—Comparing Surface Residue Transfer Efficiencies to Hands Using Polar and Non-Polar Fluorescent Transfer

As a follow up to the Cohen Hubal et al. (2005) study, Hubal et al. (2008) conducted a study using a second fluorescent tracer, Uvitex OB, which has different physical-chemical properties than riboflavin. The fluorescent tracer, which was used as a surrogate for pesticide residues, was applied to carpet or laminate surfaces at two different loading levels, and controlled hand transfer experiments were conducted by using various pressures and motions (i.e., press and smudge), numbers of contacts, and different hand conditions (i.e., dry or moist). The

Chapter 7—Dermal Exposure Factors

mass of tracer transferred to the hands was measured using a fluorescent tracer imaging system. The results indicated that “overall percent transfer ranged from 0.8 to 45.5% for the first contact and 0.6 to 19.4% for the seventh contact,” and dermal loadings increased in a near linear fashion through the seventh contact. “Transfer was greater for laminate (over carpet), smudge (over press), and moist (over dry)” (Hubal et al., 2008). For lower surface loadings, dermal transfer increased through the seventh contact, suggesting that multiple contacts may be required to reach an effective equilibrium with the surface.

Similar to the previous study, the advantage of these data is that they are based on tracers and provide information on factors affecting residue transfer. However, the data may or may not accurately reflect transfer for specific chemicals or activities.

7.6.1.9. Beamer et al. (2009)—Developing Probability Distributions for Transfer Efficiencies for Dermal Exposure

Beamer et al. (2009) combined data from nine residue transfer studies and developed distributions for three pesticides (chlorpyrifos, pyrethrin I, and piperonyl butoxide) and three surface types (foil, vinyl, and carpet). The studies used for developing these distributions included Hsu et al. (1990), Ross et al. (1991), Camann et al. (1996; 1995), Geno et al. (1996), Fortune (1998a, b), Clothier (2000), and Krieger et al. (2000). Beamer et al. (2009) stratified the data by chemical and surface type. Statistical methods were used to develop the distributions, based on combined data from studies that used different sampling methods, surface concentrations, formulations, sampling time, and skin conditions (i.e., dry or wet). Transfer efficiencies were defined as the amount transferred to skin or a transfer media used as a surrogate for skin divided by the amount of pesticide applied to the surface.

Table 7-28 presents the lognormal parameter values for the three chemicals and three surface types evaluated. The results of statistical analyses indicated that the distributions of transfer efficiencies were statistically different for the surface types and chemicals shown in Table 7-28. Transfer efficiency was highest for foil for all chemicals, followed by vinyl and carpet. For example, the geometric mean transfer efficiencies ranged from 0.01 to 0.02 (i.e., 1 to 2%) for carpet, 0.03 to 0.04 (3 to 4%) for vinyl, and 0.83 to 0.86 (83 to 86%) for foil. According to Beamer et al. (2009), these distributions can be used for modeling transfer efficiencies.

An advantage of this data set is that it uses data from several of the studies described in this chapter to develop distributions for three pesticides and three surface types. However, there is some uncertainty with regard to the representativeness of these data for other chemicals or exposure conditions.

7.7. OTHER FACTORS

7.7.1. Frequency and Duration of Dermal (Hand) Contact

This section provides information from studies that evaluated activities that may affect dermal exposure. This includes information on the frequency and duration of dermal contact with objects and surfaces. Additional information on activities patterns and consumer product use that affect the frequency and duration of dermal contact is provided in Chapters 16 and 17. Information on hand-to-mouth contact frequency is presented in Chapter 4.

7.7.1.1. Zartarian et al. (1997)—Quantified Dermal Activity Data From a Four-Child Pilot Field Study

Zartarian et al. (1997) conducted a pilot field study in California in 1993 to estimate children’s dermal contact with objects in their environment. Four Mexican American farm worker children ages 2 to 4 years were videotaped to record their activities over a 1-day period. Five to 30% of the children’s time was spent outdoors, while the remainder was spent indoors. Videotape data were obtained over 6 to 11 waking hours for the four children (i.e., a total of 33 hours of videotape). The videotapes were translated to provide information about the objects that the children contacted, as well as the frequency and duration of contact. The data indicated that most objects were contacted for approximately 2 to 3 seconds in duration, and hard surfaces and hard toys were touched by children’s hands for the longest percent of the time (Zartarian et al., 1997). Table 7-29 provides the average contact frequency for the left and right hands of the four children who participated in the study. Frequency of contact was highest for hard surfaces and hard toys (see Table 7-29).

The advantage of this study is that it was the first in a series of papers that used video-transcription methods to evaluate children’s micro-activities relative to potential dermal exposure. However, the number of participants in this study (four children) was small, and the results may not be representative of all U.S. children.

Chapter 7—Dermal Exposure Factors

7.7.1.2. Reed et al. (1999)—Quantification of Children’s Hand and Mouthing Activities Through a Videotaping Methodology

Reed et al. (1999) used a videotaping methodology similar to that used by Zartarian et al. (1997) to quantify the hand contact activities of 30 children in New Jersey. A total of 20 children ages 3 to 6 years were observed in daycare facilities, while an additional 10 children, ages 2 to 5 years were observed in residential settings. Total videotaping time ranged from 3 to 7 hours for the daycare children and 5 to 6 hours for the residential children. Frequency of hand contact with objects and surfaces was quantified by recording touches with clothing, dirt, objects, and smooth or textured surfaces, as observed on video. According to Reed et al. (1999), “comparison of activities of children in home settings and daycare showed that rates of many of the activities did not differ significantly between venues and therefore, data from homes and daycare were combined.” Table 7-30 presents the hand contact frequency data for the 30 children observed in this study. High contact frequencies were observed for clothing, objects, other, and smooth surfaces.

The advantages of this study are that more children were observed than in the previous study, and both daycare and residential children were included. However, the children were from a single location and may not be representative of all U.S. children.

7.7.1.3. Freeman et al. (2001)—Quantitative Analysis of Children’s Micro-Activity Patterns: The Minnesota Children’s Pesticide Exposure Study

Freeman et al. (2001) conducted a survey response and video-transcription study of some of the respondents in a phased study of children’s pesticide exposures in the summer and early fall of 1997. A probability-based sample of 168 families with children ages 3 to <14 years old in urban (Minneapolis/St. Paul) and non-urban (Rice and Goodhue Counties) areas of Minnesota answered questions about children’s behaviors that might contribute to exposure via dermal contact or non-dietary ingestion. Of these 168 families, 19 agreed to videotaping of the study children’s activities for a period of 4 consecutive hours. The videotaped children ranged in age from 3 to 12 years of age but were divided into four age groups (3 to 4 years, 5 to 6 years, 7 to 8 years, and 10 to 12 years) for the purposes of quantifying microactivities. The frequency of touching clothing, textured surfaces (e.g., carpets and upholstered furniture), smooth

surfaces (e.g., wood or plastic furniture, hardwood floor), or objects (e.g., toys, pencils, or other things that could be manipulated) was quantified by observing the behaviors on the videotapes during a 4-hour observation period. Table 7-31 shows the frequency of hand contacts per hour for the 19 children.

An advantage to this study is that it included results for various ages of children. However, the children in this study may not be representative of all U.S. children. Also, the presence of unfamiliar persons following the children with a video camera may have influenced the video-transcription methodology results.

7.7.1.4. Freeman et al. (2005)—Contributions of Children’s Activities to Pesticide Hand Loadings Following Residential Pesticide Application

Freeman et al. (2005) gathered data on hand contacts with surfaces and objects as part of a study to evaluate pesticide exposure in residential settings. A convenience sample of 10 children between the ages of 24 and 55 months was selected for videotape observation on the 2nd day after their homes were treated with pesticides. The children were videotaped during a 4-hour period (only three children spent time outside the house, with outdoor times ranging from 21 to 57 minutes). The videotapes were transcribed to quantify contact rates in terms of frequency and duration. According to Freeman et al. (2005), “the duration of contact of most contact events was very short (2–3 seconds),” but contact with bottles, food, and objects tended to be somewhat longer (median durations ranged from 4.5 to 7.5 seconds for these items). Table 7-32 presents the right-hand contact rates (contacts per hour) for the various objects and surfaces. High contact items include objects and smooth surfaces.

The advantage of this study is that it provides additional information on hand contact frequency. However, the data are based on a limited number of children and were collected over a relatively short time period. Also, the presence of a video camera may have affected the children’s behavior.

7.7.1.5. AuYeung et al. (2006)—Young Children’s Hand Contact Activities; an Observational Study via Videotaping in Primarily Outdoor Residential Settings

AuYeung et al. (2006) gathered data on children’s hand contact activities by videotaping them in outdoor residential settings in 1998–1999. A total of 38 children ages 1 to 6 years from middle class

Chapter 7—Dermal Exposure Factors

suburban families were recruited from the San Francisco Bay peninsula area to participate in the study. Each child was videotaped during 2 hours of natural (i.e., unstructured) play in an outdoor location (i.e., park, playground, outdoor residential area). Videotapes then were translated using a software package specially designed for this use. Contacts were tabulated for 15 object surface categories and for all non-dietary objects and all objects and surfaces combined. Hourly contact frequency, median duration per contact, and hourly contact duration were calculated for each child for the left hand, right hand, and both hands combined, and summary statistics were developed for all children combined. Table 7-33 provides the data for outdoor locations. According to AuYeung et al. (2006), these data suggest that children have a large number of short-duration contacts with outdoor objects and surfaces. AuYeung et al. (2006) also collected some limited data for indoor locations. These data are based on nine children who were videotaped for 15 minutes or more indoors. Table 7-34 provides summary data for these children.

The advantage of this study is that it provides dermal (hand) contact data for a wide variety of outdoor objects and surfaces. The data for indoor environments were limited, however, and the presence of unfamiliar persons following the children with a video camera may have influenced the video-transcription methodology results.

7.7.1.6. Ko et al. (2007)—Relationships of Video Assessments of Touching and Mouthing Behaviors During Outdoor Play in Urban Residential Yards to Parental Perceptions of Child Behaviors and Blood Lead Levels

Ko et al. (2007) used video observation and transcription methods to assess children's hand contacts with outdoor surfaces as part of a study to assess the relationship between blood level levels and children's activities in urban environments. During the summers of 2000 and 2001, a total of 37 children ages 1 to 5 years were videotaped during 2-hour periods while playing in outdoor urban residential settings. The children were primarily from low-income, Hispanic families. Ko et al. (2007) tabulated surface contacts by reviewing the videotapes and counting the number of times a child's hands touched one of the following surfaces: (1) cement, stone, or steel on the ground (cement); (2) porch floor or porch steps (porch); (3) grass; and (4) bare soil. Distributions of contact frequency (contacts per hour) were developed using the data for the 37 children for the four surface types and for all

surfaces combined. According to Ko et al. (2007), the median contact frequency for all surfaces was 81 contacts per hour (geometric mean = 70 contacts per hour), with several children touching surfaces approximately 400 contacts per hour (see Table 7-35).

Similar to the AuYeung et al. (2006) study described in the previous section, the advantage of this study is that it provides data for outdoor dermal (hand) contacts with a variety of objects and surfaces. These surface types are somewhat different from those in AuYeung et al. (2006) but provide additional perspective on contact with outdoor surfaces. As with all studies that use videotape methods, however, the presence of unfamiliar persons following the children with a video camera may have influenced the results.

7.7.1.7. Beamer et al. (2008)—Quantified Activity Pattern Data From 6 to 27-Month-Old Farm Worker Children for Use in Exposure Assessment

Beamer et al. (2008) conducted a study in which children were videotaped to estimate contacts with objects and surfaces in their environment. A convenience sample of 23 children residing in the farm worker community of Salinas Valley, CA, participated in the study. Participants were 6- to 13-month-old infants and 20- to 26-month-old toddlers. Two researchers videotaped each child's activities for a minimum of 4 hours and kept a detailed written log of locations visited and objects and surfaces contacted by the child. A questionnaire was administered to an adult in the household to acquire demographic data, housing and cleaning characteristics, eating patterns, and other information pertinent to the child's potential pesticide exposure.

Table 7-36 presents the mean and median object and surface contact frequency in events per hour. The most frequently contacted objects included toys (121 contacts per hour) and clothing/towels (114 contacts per hour). The mean frequency of hand contact of all objects and surfaces for both hands combined was 686.3 contacts per hour. Table 7-36 also provides information on the duration of contact with these objects and surfaces in minutes per hour and in seconds per contact.

The advantage of this study is that it included both infants and toddlers. Also, it provided data for a wide variety of objects and surfaces. Differences between the two age groups, as well as sex differences, were observed. As with other video-transcription studies, however, the presence of non-family-member videographers and a video camera may have influenced the children's behavior.

Chapter 7—Dermal Exposure Factors

7.7.2. Thickness of the Skin

Although factors that influence dermal uptake (i.e., absorption) and internal dose are not the focus of this chapter, limited information on the physiological characteristics of the skin (i.e., thickness of the skin on various body parts) is presented here to provide some perspective on this topic. It should be noted that this is only one factor that may influence dermal uptake. Others include the condition of the skin (e.g., Williams et al. (2005; 2004), suggested that the presence of perspiration on the skin may affect uptake of contaminants) and chemical-specific factors (e.g., concentration of chemical in contact with the skin and characteristics of the chemical that affect its rate of absorption).

The skin consists of two distinct layers: the epidermis (outermost layer) and dermis. The outermost layer of the epidermis is the stratum corneum or horny layer. Because the stratum corneum serves as the body's outermost boundary, it is the layer where chemical exposures may occur. According to the International Commission on Radiological Protection (ICRP, 1975), the thickness of the stratum corneum of adults is "approximately one-tenth that of the epidermis except for palms [of hands] and soles [of feet] where it may be much thicker." Over most parts of the body, the stratum corneum is estimated to range in thickness from about 13 to 15 μm , but it may vary by region of the body, with the certain parts (e.g., the "horny pads") of the palms and soles being as high as 600 μm (ICRP, 1975). Holbrook and Odland (1974) used electron microscopy to measure the thickness of the stratum corneum from fixed tissues collected from the abdomen, back, forearm, and thigh of six subjects (three men and three women) ages 25 to 31 years old. The mean thicknesses for these four body regions were 8.2, 9.4, 12.9, and 10.9 μm , respectively. Schwindt et al. (1998) estimated thickness using skin at the same four sites in six women with a mean age of 33.2 years. Based on calculations from measurements of transepidermal water loss during tape stripping, mean thicknesses were estimated to be 7.7 ± 1.7 , 11.2 ± 2.6 , 12.3 ± 3.6 , and 13.1 ± 4.7 μm for the abdomen, back, forearm, and thigh, respectively (Schwindt et al., 1998). Using two methods of calculating thickness, Pirot et al. (1998) estimated the thickness of the stratum corneum on the forearms of 13 subjects (2 men and 11 women) between the ages of 23 and 60 years. The mean \pm standard deviation values were 11.3 ± 5.1 and 12.6 ± 5.3 μm . Russell et al. (2008) estimated the thickness of the stratum corneum on the forearm to be approximately 10 μm , based on 18 adults (3 men

and 15 women) between the ages of 22 and 43 years. Egawa et al. (2007) estimated the stratum corneum thickness on five body parts of 15 Japanese adults (6 men and 9 women) ages 23 to 49 years old. Mean \pm standard deviation thicknesses were 16.8 ± 2.8 , 21.8 ± 3.6 , 22.6 ± 4.3 , 29.3 ± 6.8 , and 173 ± 37.0 for the cheek, upper arm, forearm, back of hand, and palm of hand, respectively (Egawa et al., 2007).

For newborn infants, the stratum corneum "is extremely thin, but grows rapidly during the first month" (ICRP, 1975). Based on measurements of newborn skin that was fixed in formalin, thickness of the stratum corneum was about 10 μm on the back and about 80 to 140 μm on the sole of the foot of newborns. Based on measurement using non-fixed, fresh, frozen newborn skin, the thickness of the stratum corneum ranged from 10 to 50 μm for portions of the buttocks and abdomen and most other regions of the body except the hands and feet (ICRP, 1975).

Table 7-19. Summary of Field Studies That Estimated Activity-Specific Adherence Rates

Table 7-19. Summary of Field Studies That Estimated Activity-Specific Adherence Rates									
Activity	Month	Event ^a (hours)	N	M	F	Age (years)	Conditions	Clothing	Study
Indoor									
Tae Kwon Do	Feb.	1.5	7	6	1	8 to 42	Carpeted floor	All in long sleeve-long pants martial arts uniform, sleeves rolled back, barefoot	Kissel et al. (1996b)
Greenhouse Worker	Mar.	5.25	2	1	1	37 to 39	Plant watering, spraying, soil blending, sterilization	Long pants, elbow length short sleeve shirt, no gloves	
Indoor Kid No. 1	Jan.	2	4	3	1	6 to 13	Playing on carpeted floor	3 or 4 short pants, 2 of 4 short sleeves, socks, no shoes	Holmes et al. (1999)
Indoor Kid No. 2	Feb.	2	6	4	2	3 to 13	Playing on carpeted floor	5 of 6 long pants, 5 of 6 long sleeves, socks, no shoes	
Daycare Kid No. 1a	Aug.	3.5	6	5	1	1 to 6.5	Indoors: linoleum surface; Outdoors: grass, bare earth, barked area	4 of 6 long pants, 5 of 6 short sleeves, socks, shoes	
Daycare Kid No. 1b	Aug.	4	6	5	1	1 to 6.5	Indoors: linoleum surface; Outdoors: grass, bare earth, barked area	4 of 6 long pants, 5 of 6 short sleeves, 3 of 6 barefoot all afternoon, others barefoot half the afternoon	
Daycare Kid No. 2 ^b	Sept.	8	5	4	1	1 to 4	Indoors: low napped carpeting, linoleum surfaces	4 of 5 long pants, 3 of 5 long sleeves, all barefoot for part of the day	
Daycare Kid No. 3	Nov.	8	4	3	1	1 to 4.5	Indoors: linoleum surface, Outside: grass, bare earth, barked area	All long pants, 3 of 4 long sleeves, socks and shoes	
Outdoor									
Soccer No. 1	Nov.	0.67	8	8	0	13 to 15	Half grass/half bare earth	6 of 8 long sleeves, 4 of 8 long pants, 3 of 4 short pants and shin guards	Kissel et al. (1996b)
Soccer No. 2	Mar.	1.5	8	0	8	24 to 34	All weather field (sand-ground tires)	All in short sleeve shirts, shorts, knee socks, shin guards	
Soccer No. 3	Nov.	1.5	7	0	7	24 to 34	All weather field (sand-ground tires)	All in short sleeve shirts, shorts, knee socks, shin guards	
Groundskeeper No. 1	Mar.	1.5	2	1	1	29 to 52	Campus grounds, urban horticulture center, arboretum	All in long pants, intermittent use of gloves	
Groundskeeper No. 2	Mar.	4.25	5	3	2	22 to 37	Campus grounds, urban horticulture center, arboretum	All in long pants, intermittent use of gloves	
Groundskeeper No. 3	Mar.	8	7	5	2	30 to 62	Campus grounds, urban horticulture center, arboretum	All in long pants, intermittent use of gloves	

Table 7-19. Summary of Field Studies That Estimated Activity-Specific Adherence Rates (continued)

Activity	Month	Event ^a (hours)	N	M	F	Age (years)	Conditions	Clothing	Study
Outdoor (continued)									
Groundskeeper No. 4	Aug.	4.25	7	4	3	22 to 38	Campus grounds, urban horticulture center, arboretum	5 of 7 in short sleeve shirts, intermittent use of gloves	Kissel et al. (1996b)
Groundskeeper No. 5	Aug.	8	8	6	2	19 to 64	Campus grounds, urban horticulture center, arboretum	5 of 8 in short sleeve shirts, intermittent use of gloves	
Irrigation Installer	Oct.	3	6	6	0	23 to 41	Landscaping, surface restoration	All in long pants, 3 of 6 short sleeve or sleeveless shirts	
Rugby No. 1	Mar.	1.75	8	8	0	20 to 22	Mixed grass-bare wet field	All in short sleeve shirts, shorts, variable sock lengths	
Farmer No. 1	May	2	4	2	2	39 to 44	Manual weeding, mechanical cultivation	All in long pants, heavy shoes, short sleeve shirts, no gloves	
Farmer No. 2	July	2	6	4	2	18 to 43	Manual weeding, mechanical cultivation	2 of 6 short, 4 of 6 long pants, 1 of 6 long sleeve shirt, no gloves	
Reed Gatherer	Aug.	2	4	0	4	42 to 67	Tidal flats	2 of 4 short sleeve shirts/knee length pants, all wore shoes	
Kid-in-Mud No. 1	Sept.	0.17	6	5	1	9 to 14	Lake shoreline	All in short sleeve T-shirts, shorts, barefoot	
Kid-in-Mud No. 2	Sept.	0.33	6	5	1	9 to 14	Lake shoreline	All in short sleeve T-shirts, shorts, barefoot	
Gardener No. 1	Aug.	4	8	1	7	16 to 35	Weeding, pruning, digging a trench	6 of 8 long pants, 7 of 8 short sleeves, 1 sleeveless, socks, shoes, intermittent use of gloves	Holmes et al. (1999)
Gardener No. 2	Aug.	4	7	2	5	26 to 52	Weeding, pruning, digging a trench, picking fruit, cleaning	3 of 7 long pants, 5 of 7 short sleeves, 1 sleeveless, socks, shoes, no gloves	
Rugby No. 2	July	2	8	8	0	23 to 33	Grass field (80% of time) and all-weather field (mix of gravel, sand, and clay) (20% of time)	All in shorts, 7 of 8 in short sleeve shirts, 6 of 8 in low socks	
Rugby No. 3	Sept.	2.75	8	7	0	24 to 30	Compacted mixed grass and bare earth field	All short pants, 7 of 8 short or rolled up sleeves, socks, shoes	
Archeologist	July	11.5	7	3	4	16 to 35	Digging with trowel, screening dirt, sorting	6 of 7 short pants, all short sleeves, 3 no shoes or socks, 2 sandals	
Construction Worker	Sept.	8	8	8	0	21 to 30	Mixed bare earth and concrete surfaces, dust and debris	5 of 8 pants, 7 of 8 short sleeves, all socks and shoes	
Landscape/Rockery	June	9	4	3	1	27 to 43	Digging (manual and mechanical), rock moving	All long pants, 2 long sleeves, all socks and boots	

Table 7-19. Summary of Field Studies That Estimated Activity-Specific Adherence Rates (continued)

Activity	Month	Event ^a (hours)	N	M	F	Age (years)	Conditions	Clothing	Study
Outdoor (continued)									
Utility Worker No. 1	July	9.5	5	5	0	24 to 45	Cleaning, fixing mains, excavation (backhoe and shovel)	All long pants, short sleeves, socks, boots, gloves sometimes	Holmes et al. (1999)
Utility Worker No. 2	Aug.	9.5	6	6	0	23 to 44	Cleaning, fixing mains, excavation (backhoe and shovel)	All long pants, 5 of 6 short sleeves, socks, boots, gloves sometimes	
Equip. Operator No. 1	Aug.	8	4	4	0	21 to 54	Earth scraping with heavy machinery, dusty conditions	All long pants, 3 of 4 short sleeves, socks, boots, 2 of 4 gloves	
Equip. Operator No. 2	Aug.	8	4	4	0	21 to 54	Earth scraping with heavy machinery, dusty conditions	All long pants, 3 of 4 short sleeves, socks, boots, 1 gloves	
Shoreline Play (children)	Sept.	0.33–1.0	9	6	3	7 to 12	Tidal flat	No shirt or short sleeve T-shirts, shorts, barefoot	Shoaf et al. (2005b)
Clamming (adults)	Aug.	1–2	18	9	9	33 to 63	Tidal flat	T-shirt, shorts, shoes	Shoaf et al. (2005a)
^a Event duration. ^b Activities were confined to the house. N = Number of subjects. M = Males. F = Females.

Full wipe ^j	-	-	-	-	-	-

^a Density = 0.8720 g/cm³.^b Density = 0.9161 g/cm³.^c Density = 0.8660 g/cm³.^d Density = 0.9357 g/cm³; 50% water and 50% oil.^e Density = 0.9989 g/cm³.^f Density = 0.9297 g/cm³; 50% water and 50% ethanol.^g Initial contact = cloth saturated with liquid was rubbed over the front and back of both clean, dry hands for the first time during an exposure event.^h Retention of liquid on the skin was estimated without any intentional removal of liquid by wiping.ⁱ Retention was measured after 'partial' removal of liquids on the skin by wiping. Partial wiping was defined as "lightly [wiping with a removal cloth] for 5 seconds (superficially)."^j Retention was measured after 'full' removal of liquids on the skin by wiping. Full wiping was defined as "thoroughly and completely as possible within 10 seconds removing as much liquid as possible."^k Secondary contact = cloth saturated with liquid was rubbed over the front and back of both hands for a second time, after as much as possible of the liquid that adhered to skin during the first contact event was removed using a clean cloth.^l Immersion = one hand immersed in a container of liquid, removed, and liquid allowed to drip back into container for 30 seconds (60 seconds for cooking oil).^m Handling rag = cloth saturated with liquid was rubbed over the palms of both hands for the first time during an exposure event in a manner simulating handling of a wet cloth.ⁿ Spill cleanup = subject used a clean cloth to wipe up 50 mL of liquid poured onto a plastic laminate countertop.

- = no data.

Note: Data for mineral oil, cooking oil, and bath oil for initial contact, secondary contact, and immersion from U.S. EPA (1992c). All other data from U.S. EPA (1987).

APPENDIX 7A

FORMULAS FOR TOTAL BODY SURFACE AREA

Chapter 7—Dermal Exposure Factors

APPENDIX 7A—FORMULAS FOR TOTAL BODY SURFACE AREA

Most formulas for estimating surface area relate height to weight to surface area. The following formula was proposed by Gehan and George (1970):

$$SA = KW^{2/3} \quad (\text{Eqn. 7A-1})$$

where:

SA = surface area in square meters,
W = weight in kg, and
K = constant.

While this equation has been criticized because human bodies have different specific gravities and because the surface area per unit volume differs for individuals with different body builds, it gives a reasonably good estimate of surface area.

A formula published in 1916 that still finds wide acceptance and use is that of Du Bois and Du Bois (1989). Their model can be written:

$$SA = a_0 H^{a_1} W^{a_2} \quad (\text{Eqn. 7A-2})$$

where:

SA = surface area in square meters,
H = height in centimeters, and
W = weight in kg.

The values of a_0 (0.007182), a_1 (0.725), and a_2 (0.425) were estimated from a sample of only nine individuals for whom surface area was directly measured. Boyd (1935) stated that the Du Bois formula was considered a reasonably adequate substitute for measuring surface area. Nomograms for determining surface area from height and mass presented in Volume I of the Geigy Scientific Tables (Lentner, 1981) are based on the Du Bois and Du Bois formula.

Boyd (1935) developed new constants for the Du Bois and Du Bois model based on 231 direct measurements of body surface area found in the literature. These data were limited to measurements of surface area by coating methods (122 cases), surface integration (93 cases), and triangulation (16 cases). The subjects were Caucasians of normal body build for whom data on weight, height, and age (except for exact age of adults) were complete.

Resulting values for the constants in the Du Bois and Du Bois model were $a_0 = 0.01787$, $a_1 = 0.500$, and $a_2 = 0.4838$. Boyd also developed a formula based exclusively on weight, which was inferior to the Du Bois and Du Bois formula based on height and weight.

Gehan and George (1970) proposed another set of constants for the Du Bois and Du Bois model. The constants were based on a total of 401 direct measurements of surface area, height, and weight of all postnatal subjects listed in Boyd (1935). The methods used to measure these subjects were coating (163 cases), surface integration (222 cases), and triangulation (16 cases).

Gehan and George (1970) used a least-squares method to identify the values of the constants. The values of the constants chosen are those that minimize the sum of the squared percentage errors of the predicted values of surface area. This approach was used because the importance of an error of 0.1 square meter depends on the surface area of the individual. Gehan and George (1970) used the 401 observations summarized in Boyd (1935) in the least-squares method. The following estimates of the constants were obtained: $a_0 = 0.02350$, $a_1 = 0.42246$, and $a_2 = 0.51456$. Hence, their equation for predicting surface area is:

$$SA = 0.02350 H^{0.42246} W^{0.51456} \quad (\text{Eqn. 7A-3})$$

or in logarithmic form:

$$\ln SA = -3.75080 + 0.42246 \ln H + 0.51456 \ln W \quad (\text{Eqn. 7A-4})$$

where:

SA = surface area in square meters,
H = height in centimeters, and
W = weight in kg.

This prediction explains more than 99% of the variations in surface area among the 401 individuals measured (Gehan and George, 1970).

The equation proposed by Gehan and George (1970) was determined by the U.S. EPA (1985) to be the best choice for estimating total body surface area. However, the paper by Gehan and George gave insufficient information to estimate the standard error about the regression. Therefore, the 401 direct measurements of children and adults [i.e., Boyd (1935)] were reanalyzed in U.S. EPA (1985) using the formula of Du Bois and Du Bois (1989) and the

Chapter 7—Dermal Exposure Factors

Statistical Processing System (SPS) software package to obtain the standard error.

The Du Bois and Du Bois (1989) formula uses weight and height as independent variables to predict total body surface area and can be written as:

$$SA_i = a_0 H_i^{a_1} W_i^{a_2} e_i \quad (\text{Eqn. 7A-5})$$

or in logarithmic form:

$$\ln (SA)_i = \ln a_0 + a_1 \ln H_i + a_2 \ln W_i + \ln e_i \quad (\text{Eqn. 7A-6})$$

where:

SA_i	=	surface area of the i -th individual (m^2),
H_i	=	height of the i -th individual (cm),
W_i	=	weight of the i -th individual (kg),
$a_0, a_1, \text{ and } a_2$	=	parameters to be estimated, and
e_i	=	a random error term with mean zero and constant variance.

Using the least squares procedure for the 401 observations, the following parameter estimates and their standard errors were obtained:

$$a_0 = -3.73 \text{ (0.18)}, a_1 = 0.417 \text{ (0.054)}, a_2 = 0.517 \text{ (0.022)}$$

The model is then:

$$SA = 0.0239 H^{0.417} W^{0.517} \quad (\text{Eqn. 7A-7})$$

or in logarithmic form:

$$\ln SA = -3.73 + 0.417 \ln H + 0.517 \ln W \quad (\text{Eqn. 7A-8})$$

with a standard error about the regression of 0.00374. This model explains more than 99% of the total variation in surface area among the observations, and it is identical to two significant figures with the model developed by Gehan and George (1970).

When natural logarithms of the measured surface areas are plotted against natural logarithms of the surface predicted by the equation, the observed surface areas are symmetrically distributed around a

line of perfect fit with only a few large percentage deviations. Only five subjects differed from the measured value by 25% or more. Because each of the five subjects weighed less than 13 pounds, the amount of difference was small. Eighteen estimates differed from measurements by 15 to 24%. Of these, 12 weighed less than 15 pounds each, one was overweight (5 feet 7 inches, 172 pounds), one was very thin (4 feet 11 inches, 78 pounds), and four were of average build. Because the same observer measured surface area for these four subjects, the possibility of some bias in measured values cannot be discounted (Gehan and George, 1970). Gehan and George (1970) also considered separate constants for different age groups: less than 5 years old, 5 years old to less than 20 years old, and greater than 20 years old. Table 7A-1 presents the different values for the constants.

The surface areas estimated using the parameter values for all ages were compared to surface areas estimated by the values for each age group for subjects at the 3rd, 50th, and 97th percentiles of weight and height. Nearly all differences in surface area estimates were less than 0.01 m^2 , and the largest difference was 0.03 m^2 for an 18-year-old at the 97th percentile. The authors concluded that there is no advantage in using separate values of a_0 , a_1 , and a_2 by age interval.

Haycock et al. (1978), without knowledge of the work by Gehan and George (1970), developed values for the parameters a_0 , a_1 , and a_2 for the Du Bois and Du Bois model. Their interest in making the Du Bois and Du Bois model more accurate resulted from their work in pediatrics and the fact that Du Bois and Du Bois (1989) included only one child in their study group: a severely undernourished girl who weighed only 13.8 pounds at age 21 months. Haycock et al. (1978) used their own geometric method for estimating surface area from 34 body measurements for 81 subjects. Their study included newborn infants (10 cases), infants (12 cases), children (40 cases), and adult members of the medical and secretarial staffs of two hospitals (19 cases). The subjects all had grossly normal body structure, but the sample included subjects of widely varying physique ranging from thin to obese. Black, Hispanic, and Caucasian children were included in their sample. The values of the model parameters were solved for the relationship between surface area and height and weight by multiple regression analysis. The least squares best fit for this equation yielded the following values for the three co-efficients: $a_0 = 0.024265$, $a_1 = 0.3964$, and $a_2 = 0.5378$. The result was the following equation for estimating surface area:

Chapter 7—Dermal Exposure Factors

$$SA = 0.024265H^{0.3964} W^{0.5378} \quad (\text{Eqn. 7A-9})$$

expressed logarithmically as:

$$\ln SA = \ln 0.024265 + 0.3964 \ln H + 0.5378 \ln W \quad (\text{Eqn. 7A-10})$$

The co-efficients for this equation agree remarkably with those obtained by Gehan and George (1970) for 401 measurements.

George et al. (1979) agree that a model more complex than the model of Du Bois and Du Bois for estimating surface area is unnecessary. Based on samples of direct measurements by Boyd (1935) and Gehan and George (1970), and samples of geometric estimates by Haycock et al. (1978), these authors have obtained parameters for the Du Bois and Du Bois model that are different than those originally postulated in 1916. The Du Bois and Du Bois model can be written logarithmically as:

$$\ln SA = \ln a_0 + a_1 \ln H + a_2 \ln W \quad (\text{Eqn. 7A-11})$$

Table 7A-2 present the values for a_0 , a_1 , and a_2 obtained by the various authors discussed in this section.

The agreement between the model parameters estimated by Gehan and George (1970) and Haycock et al. (1978) is remarkable in view of the fact that Haycock et al. (1978) were unaware of the previous work. Haycock et al. (1978) used an entirely different set of subjects and used geometric estimates of surface area rather than direct measurements. It has been determined that the Gehan and George model is the formula of choice for estimating total surface area of the body because it is based on the largest number of direct measurements.

Sendroy and Cecchini (1954) proposed a method of creating a *nomogram*, a diagram relating height and weight to surface area. However, they do not give an explicit model for calculating surface area. The nomogram was developed empirically based on 252 cases, 127 of which were from the 401 direct measurements reported by Boyd (1935). In the other 125 cases, the surface area was estimated using the linear method of Du Bois and Du Bois (1989). Because the Sendroy and Cecchini method is graphical, it is inherently less precise and less accurate than the formulas of other authors discussed in this section.

Chapter 8—Body Weight Studies

8. BODY-WEIGHT STUDIES**8.1. INTRODUCTION**

There are several physiological factors needed to calculate potential exposures. These include skin surface area (see Chapter 7), inhalation rate (see Chapter 6) life expectancy (see Chapter 18), and body weight. The average daily dose (ADD) is a dose that is typically normalized to the average body weight of the exposed population. If exposure occurs only during childhood years, the average child body weight during the exposure period should be used to estimate risk (U.S. EPA, 1989). Conversely, if adult exposures are being evaluated, an adult body-weight value should be used.

The purpose of this chapter is to describe published studies on body weight in the general U.S. population. The recommendations for body weight are provided in the next section, along with a summary of the confidence ratings for these recommendations. The recommended values are based on one key study identified by U.S. Environmental Protection Agency (EPA) for this factor. Following the recommendations, the key study on body weight is summarized. Relevant data on body weight are also provided. These relevant data are included because they may be useful for trend analysis. Since obesity is a growing concern and may increase the risk of chronic diseases during adulthood, information on body mass index (BMI) and height is also provided.

8.2. RECOMMENDATIONS

The key study described in this section was used in selecting recommended values for body weight. The recommendations for body weight are

summarized in Table 8-1 and are based on data derived from the National Health and Nutrition Examination Survey (NHANES) 1999–2006. The recommended values represent mean body weights in kilograms for the age groups for children recommended by U.S. EPA in *Guidance for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005) and for adults. Table 8-2 presents the confidence ratings for the body-weight recommendations.

Table 8-1 shows the mean body weight for all adults (male and female, all age groups) combined is 80 kg. Section 8.3 presents percentile data.

The mean recommended value for adults (80 kg) is different from the 70 kg commonly assumed in U.S. EPA risk assessments. Assessors are encouraged to use values that most accurately reflect the exposed population. When using values other than 70 kg, however, the assessors should consider if the dose estimate will be used to estimate risk by combining it with a dose-response relationship that was derived assuming a body weight of 70 kg. If such an inconsistency exists, the assessor may need to adjust the dose-response relationship as described in the appendix to Chapter 1.

Use of upper percentile body-weight values are not routinely recommended for calculating ADDs because inclusion of an upper percentile value in the denominator of the ADD equation would be a non-conservative approach. However, Section 8.3 provides distributions of body-weight data. These distributions may be useful if probabilistic methods are used to assess exposure. Also, if sex-specific data are needed, or if data for finer age bins are needed, the reader should refer to the tables in Section 8.3.

Table 8-1. Recommended Values for Body Weight

Age Group	Mean (kg)	Multiple Percentiles	Source
Birth to <1 month	4.8		
1 to <3 months	5.9		
3 to <6 months	7.4		
6 to <11 months	9.2		
1 to <2 years	11.4	Table 8-3 through Table 8-5	U.S. EPA analysis of NHANES, 1999–2006 data
2 to <3 years	13.8		
3 to <6 years	18.6		
6 to <11 years	31.8		
11 to <16 years	56.8		
16 to <21 years	71.6		
Adults	80.0		

Table 8-2. Confidence in Recommendations for Body Weight

General Assessment Factors	Rationale	Rating
Soundness		High
<i>Adequacy of Approach</i>	The survey methodology and the secondary data analysis were adequate. NHANES consisted of a large sample size; sample size varied with age. Direct measurements were taken during a physical examination.	
<i>Minimal (or Defined) Bias</i>	No significant biases were apparent.	
Applicability and Utility		High
<i>Exposure Factor of Interest</i>	The key study is directly relevant to body weight.	
<i>Representativeness</i>	NHANES was a nationally representative sample of the U.S. population; participants are selected using a complex, stratified, multi-stage probability cluster sampling design.	
<i>Currency</i>	The U.S. EPA analysis used the most current NHANES data.	
<i>Data Collection Period</i>	The U.S. EPA analysis was based on four data sets of NHANES data covering 1999–2006.	
Clarity and Completeness		High
<i>Accessibility</i>	NHANES data are available from NCHS.	
<i>Reproducibility</i>	The methods used were well-described; enough information was provided to allow for reproduction of results.	
<i>Quality Assurance</i>	NHANES follows a strict QA/QC procedures; the U.S. EPA analysis has only been reviewed internally.	
Variability and Uncertainty		High
<i>Variability in Population</i>	The full distributions were given in the key study.	
<i>Uncertainty</i>	No significant biases were apparent in the NHANES data, nor in the secondary analyses of the data.	
Evaluation and Review		Medium
<i>Peer Review</i>	NHANES received a high level of peer review. The U.S. EPA analysis was not published in a peer-reviewed journal.	
<i>Number and Agreement of Studies</i>	The number of studies is 1.	
Overall Rating		High

8.3. KEY BODY-WEIGHT STUDY

8.3.1. U.S. EPA Analysis of NHANES 1999–2006 Data

The U.S. EPA analyzed data from the 1999–2006 NHANES to generate distributions of body weight for various age ranges of children and adults. NHANES is conducted annually by the Center for Disease Control (CDC), National Center of Health Statistics (NCHS). The survey's target population is the civilian, non-institutionalized U.S. population. The NHANES 1999–2006 survey was conducted on a nationwide probability sample of approximately 40,000 persons for all ages, of which approximately 20,000 were children. The survey is designed to obtain nationally representative information on the health and nutritional status of the population of the United States through interviews and direct physical examinations. A number of anthropometric measurements, including body weight, were taken for each participant in the study. Unit non-response to the household interview was 19%, and an additional 4% did not participate in the physical examinations (including body-weight measurements).

The NHANES 1999–2006 survey includes over-sampling of low-income persons, adolescents 12–19 years, persons 60+ years of age, African Americans and Mexican Americans. Sample data were assigned weights to account both for the disparity in sample sizes for these groups and for other inadequacies in sampling, such as the presence of non-respondents. Because the U.S. EPA utilized four NHANES data sets in its analysis (NHANES 1999–2000, 2001–2002, 2003–2004, and 2005–2006) sample weights were developed for the combined data set in accordance with CDC guidance from the NHANES' website (http://www.cdc.gov/nchs/about/major/nhanes/nhanes2005-2006/faqs05_06.htm#question%2012).

Using the data and the weighting factors from the four NHANES data sets, U.S. EPA calculated body-weight statistics for the standard age categories. The mean value for a given group was calculated using the following formula:

$$\bar{x} = \frac{\sum_i w_i x_i}{\sum_i w_i} \quad (\text{Eqn. 8-1})$$

where:

- \bar{x} = sample mean,
- x_i = the i^{th} observation, and
- w_i = sample weight assigned to observation x_i .

Percentile values were generated by first calculating the sum of the sample weights for all observations in a given group and multiplying this sum by the percentile of interest (e.g., multiplying by 0.25 to determine the 25th percentile). The observations were then ordered from least to greatest, and each observation was assigned a cumulative sample weight, equal to its own sample weight plus all sample weights listed before the observation. The 1st observation listed with a cumulative sample weight greater than the value calculated for the percentile of interest was selected.

Table 8-3 presents the body-weight means and percentiles, by age category, for males and females combined. Table 8-4 and Table 8-5 present the body-weight means and percentiles for males and females, respectively.

The advantage of this study is that it provides body-weight distributions ranging from infancy to adults. A limitation of the study is that combining the data from various years of NHANES beginning in 1999 through 2006 may underestimate current body weights due to an observed upward trend in body weights (Ogden et al., 2004). However, these data are based on the most recent available NHANES data. The NHANES data are nationally representative and remain the principal source of body-weight data collected nationwide from a large number of subjects.

8.4. RELEVANT GENERAL POPULATION BODY-WEIGHT STUDIES

8.4.1. Najjar and Rowland (1987)—Anthropometric Reference Data and Prevalence of Overweight, United States, 1976–1980

Najjar and Rowland (1987) collected anthropometric measurement data for body weight for the U.S. population as part of the 2nd National Health and Nutrition Examination Survey (NHANES II). NHANES II began in February 1976 and was completed in February 1980. The survey was conducted on a nationwide probability sample of 27,801 persons aged six months to 74 years from the civilian, non-institutionalized population of the United States. A total of 20,322 individuals in the sample were interviewed and examined, resulting in a response rate of 73.1%. The sample was selected so that certain subgroups thought to be at high risk of malnutrition (persons with low incomes, preschool

Chapter 8—Body Weight Studies

children, and the elderly) were over sampled. The estimates were weighted to reflect national population estimates. The weighting was accomplished by inflating examination results for each subject by the reciprocal of selection probabilities, adjusting to account for those who were not examined, and post-stratifying by race, age, and sex.

NHANES II collected standard body measurements of sample subjects, including height and weight, that were made at various times of the day and in different seasons of the year. This technique was used because an individual's weight may vary between winter and summer and may fluctuate with patterns of food and water intake and other daily activities (Najjar and Rowland, 1987). Najjar and Rowland (1987) provided descriptive statistics of the body-weight data. Table 8-6 and Table 8-7 present means and percentiles, by age category, for males and females, respectively. Although the NHANES data are nationally representative, a limitation of the study is the age of the data used.

8.4.2. Brainard and Burmaster (1992)—Bivariate Distributions for Height and Weight of Men and Women in the United States

Brainard and Burmaster (1992) examined data on the height and weight of adults published by the U.S. Public Health Service and fit bivariate distributions to the tabulated values for men and women, separately. Height and weight of 5,916 men and 6,588 women in the age range of 18 to 74 years were taken from the NHANES II (1976–1980) study and statistically adjusted to represent the U.S. population aged 18 to 74 years with regard to age structure, sex, and race. Estimation techniques were used to fit normal distributions to the cumulative marginal data, and goodness-of-fit tests were used to test the hypothesis that height and lognormal weight follow a normal distribution for each sex. It was found that the marginal distributions of height and lognormal weight for both men and women are Gaussian (normal) in form. This conclusion was reached by visual observation and the high R^2 values for best-fit lines obtained using linear regression. The R^2 values for men's height and lognormal weight were reported to be 0.999. The R^2 values for women's height and lognormal weight were reported as 0.999 and 0.985, respectively.

Brainard and Burmaster (1992) fit bivariate distributions to estimated numbers of men and women aged 18 to 74 years in cells representing one-

inch height intervals and 10-pound weight intervals. Adjusted height and lognormal weight data for men were fit to a single bivariate normal distribution with an estimated mean height of 1.75 meters (69.2 inches) and an estimated mean weight of 78.6 kg (173.2 pounds). For women, height and lognormal weight data were fit to a pair of superimposed bivariate normal distributions (Brainard and Burmaster, 1992). The average height and weight for women were estimated from the combined bivariate analyses. Mean height for women was estimated to be 1.62 meters (63.8 inches), and mean weight was estimated to be 65.8 kg (145.0 pounds). For women, a calculation using a single bivariate normal distribution gave poor results (Brainard and Burmaster, 1992).

The advantage of this study is that it provides distributions that are suitable for use in Monte Carlo simulation. However, these distributions are now based on dated information.

8.4.3. Burmaster and Crouch (1997)—Lognormal Distributions for Body Weight as a Function of Age for Males and Females in the United States, 1976–1980

Burmaster and Crouch (1997) performed data analysis to fit normal and lognormal distributions to the body weights of females and males aged 9 months to 70 years. The data used in this analysis were from NHANES II, which was based on a national probability sample of 27,801 persons 6 months to 74 years of age in the United States. (Burmaster and Crouch, 1997). The NHANES II data had been statistically adjusted for non-response and probability of selection, and stratified by age, sex, and race to reflect the entire U.S. population prior to reporting. Burmaster and Crouch (1997) conducted exploratory and quantitative data analyses and fit normal and lognormal distributions to percentiles of body weights as a function of age. Cumulative distribution functions were plotted for female and male body weights on both linear and logarithmic scales.

Burmaster and Crouch (1997) used “maximum likelihood” estimation to fit lognormal distributions to the data. Linear and quadratic regression lines were fitted to the data. A number of goodness-of-fit measures were conducted on the data generated. The investigators found that lognormal distributions gave strong fits to the data for each sex across all age groups. Table 8-8 and Table 8-9 present the statistics for the lognormal probability plots for females and males aged 9 months to 70 years, respectively. As

indicated in Burmaster and Crouch (1997), Φ_2 , and σ_2 are the mean and standard deviation of the logarithm of body weight for an age group. The exponential of Φ_2 provides an estimate of the median of body weight, and σ_2 is approximately equal to the coefficient of variation of the body weight. These data can be used for further analyses of body-weight distribution (i.e., application of Monte Carlo analysis).

The advantage of this study is that NHANES data were used for the analysis and the data are representative nationally. It also provides statistics for probability plot regression analyses for females and males from 9 months to 70 years of age. However, the analysis is based on an older set of NHANES data.

8.4.4. U.S. EPA (2000)—Body-Weight Estimates on NHANES III Data

U.S. EPA's Office of Water has estimated body weights by age and sex using data from NHANES III, which was conducted from 1988 to 1994. NHANES III collected body-weight data for approximately 30,000 individuals between the ages of 2 months and 44 years. Table 8-10 presents the body-weight estimates in kilograms by age and sex. Table 8-11 shows the body-weight estimates for infants 2 and 3 months of age.

The limitations of this analysis are that data were not available for infants under 2 months old, and that the data are roughly 15 to 20 years old. With the upward trends in body weight from NHANES II (1976–1980) to NHANES III, which may still be valid, the data in Table 8-10 and Table 8-11 may underestimate current body weights. However, the data are national in scope and represent the general population.

8.4.5. Kuczmarski et al. (2002)—CDC Growth Charts for the United States: Methods and Development

NCHS published growth charts for infants, birth to 36 months of age, and children and adolescents, 2 to 20 years of age (Kuczmarski et al., 2002). Growth charts were developed with data from five national health examination surveys: National Health Examination Survey (NHES) II (1963–1965) for ages 6–11 years, NHES III (1966–1970) for ages 12–17 years, NHANES I (1971–1974) for ages 1–17 years, NHANES II (1976–1980) beginning at 6 months of age, and NHANES III (1988–1994) beginning at 2 months of age. Data from these national surveys were pooled because no single survey had enough observations to develop these

charts. For the infant charts, a limited number of additional data points were obtained from other sources where national data were either not available or insufficient. Birth weights <1,500 grams were excluded when generating the charts for weights and lengths. Also, the length-for-age charts exclude data from NHANES III for ages <3.5 months. Supplemental birth certificate data from the U.S. vital statistics were used in the weight-for-age charts and supplemental birth certificate data from Wisconsin and Missouri vital statistics, CDC Pediatric Nutrition Surveillance System data were used for ages 0.5, 1.5, 2.5, 3.5, and 4.5 months for the length-for-age charts. The Missouri and Wisconsin birth certificate data were also used to supplement the surveys for the weight-for-length charts. Table 8-12 presents the percentiles of weight by sex and age. Figure 8-1 and Figure 8-2 present weight by age percentiles for boys and girls, aged birth to 36 months, respectively. Figure 8-3 and Figure 8-4 present weight by length percentiles for boys and girls, respectively. Figure 8-5 and Figure 8-6 provide the BMI for boys and girls aged 2 to 20 years old.

The advantages of this analysis are that it is based on a nationally representative sample of the U.S. population and it provides body weight on a month-by-month basis up to 36 months of age, as well as BMI data for children through age 20 years. A limitation of this analysis is that trends in the weight data cannot be assessed because data from various years were combined. Also, the analysis is based on an older data set.

8.4.6. U.S. EPA (2004)—Estimated Per Capita Water Ingestion and Body Weight in the United States—An Update

U.S. EPA (2004) developed estimates from empirical distributions of body weights based on data from the U.S. Department of Agriculture (USDA's) 1994–1996 and the 1998 Continuing Survey of Food Intake by Individuals (CSFII). The weights recorded in the survey, and, consequently, the estimates reported, are based on self-reported data by the participants.

When viewed across sexes and all age categories, the average self-reported body weight for individuals in the United States during the 1994–1996 and 1998 period is 65 kg, or 143 lb. The estimated median body weight for all individuals is 67 kg (147 lb). Table 8-13 provides the estimated distribution of body weights for all individuals.

For the fine age categories reported in the summary data, the mean and median estimated body weights are the same for children in categories less

Chapter 8—Body Weight Studies

than 2 years of age. This suggests that body weights follow an approximately normal distribution. After the age of 2 years, estimated mean body weights are higher than estimated median body weights as age categories increase. This suggests that the distributions of body weights are skewed to the right. When viewed across ages, the estimated median body weight is higher than the estimated mean body weight. This suggests that the body-weight distribution across the entire survey weighted sample is slightly skewed to the left. The limitations of this analysis are that body weights were self-reported and that it is based on an older data set.

8.4.7. Ogden et al. (2004)—Mean Body Weight, Height, and Body Mass Index, United States, 1960–2002

Ogden et al. (2004) analyzed trends in body weight measured by the NHES II and III, NHANES I, II, and III, and NHANES 1999–2002. The surveys covered the period from 1960 to 2002. Table 8-14 presents the measured body weights for various age groups as measured in NHES and NHANES. Table 8-15 and Table 8-16 present the mean height and BMI data for the same population, respectively. The BMI data were calculated as weight (in kilograms) divided by the square of height (in meters). Population means were calculated using sample weights to account for variation in sampling for certain subsets of the U.S. population, non-response, and non-coverage (Ogden et al., 2004). The data indicate that mean body weight has increased over the period analyzed.

There is some uncertainty inherent in such an analysis, however, because of changes in sampling methods during the 42-year time span covered by the studies. This serves to illustrate the importance of the use of timely data when analyzing body weight. Because this study is based on an analysis of NHANES data, its limitations are the same as those for that study. Another limitation is that the data are based on an older NHANES data set and may not be entirely representative of current BMI values.

8.4.8. Freedman et al. (2006)—Racial and Ethnic Differences in Secular Trends for Childhood BMI, Weight, and Height

Freedman et al. (2006) examined sex and race/ethnicity differences in secular trends for childhood BMI, overweight, weight, and height in the United States using data from NHANES I (1971–1974), NHANES II (1976–1980), NHANES III (1988–1994), and NHANES 1999–2002. The analyses includes children 2 to 17 years old. Persons

with missing weight or height information were excluded from the analyses (Freedman et al., 2006). The authors categorized the data across the four examinations and presented the data for non-Hispanic White, non-Hispanic Black, or Mexican American. Freedman et al. (2006) excluded other categories of race/ethnicity, such as other Hispanics, because the sample sizes were small. Height and weight data were obtained for each survey, and BMI was calculated as weight in kilograms divided by height in meters square. Sex specific z-scores and percentiles of weight-for-age, height-for-age, and BMI-for-age were calculated. Childhood overweight was defined as BMI-for-age $\geq 95^{\text{th}}$ percentile, and childhood obesity was defined as children with a BMI-for-age $\geq 99^{\text{th}}$ percentile.

In the analyses, sample weights were used to account for differential probabilities, non-selection, non-response, and non-coverage. Table 8-17 presents the sample sizes used in the analyses by age, sex, race, and survey. Table 8-18 provides mean BMI levels for ages 2 to 17. Table 8-19 shows BMI mean levels for adults 20 years and older (Ogden et al., 2004). Table 8-18 shows that in the 1971–1974 survey total population, Mexican American children had the highest mean BMI level (18.6 kg/m²). However, the greatest increase throughout the survey occurred among Black children, increasing from 17.8 to 20 kg/m² (Freedman et al., 2006). Table 8-20 shows the prevalence of overweight and obesity for children 2 to 17 years old. These results show that 2 to 5 year-old White children had slightly larger increases in overweight, but among the older children, the largest increases were among the Black and Mexican American children (Freedman et al., 2006). Overall, in most sex-age groups, Mexican Americans experienced the greater increase in BMI and overweight than what was experienced by Black and White children (Freedman et al., 2006). Black children experienced larger secular increases in BMI, weight, and height than did White children (Freedman et al., 2006). According to Freedman et al. (2006), racial/ethnicity differences were less marked in the children aged two to five years old.

The advantages of the study are that the sample size is large and the analysis was designed to represent the general population of the racial and ethnic groups studied. The disadvantage is that some ethnic population groups were excluded because of small sample sizes and that it is based on older NHANES data sets.

8.4.9. Martin et al. (2007)—Births: Final Data for 2005

Martin et al. (2007) provided statistics on the percentage of live births categorized as having low or very low birth weights in the United States. Low birth weight was defined as <2,500 grams (<5 pounds 8 ounces), and very low birth weight was defined as <1,500 grams (<three pounds four ounces). The data used in the analysis were from birth certificates registered in all states and the District of Columbia for births occurring in 2005. Data were presented for maternal demographic characteristics including race ethnicity: non-Hispanic White, non-Hispanic Black, and Hispanic.

The numbers of live births within various weight ranges, and the percentages of live births with low or very low birth weights are presented in Table 8-21. The percentage of live births with low birth weights was 8.2, and the percentage of very low birth weights was 1.5 in 2005. Non-Hispanic Blacks had the highest percentage of low birth weights (14.0%) and very low birth weights (3.3%). Martin et al. (2007) also provided statistics on the numbers and percentages of pre-term live births in the United States. Of the 4,138,349 live births in the United States in 2005, 522,913 were defined as pre-term (i.e., less than 37 weeks gestation). A total of 43.3% of these pre-term infants had low birth weights, and 11.3% had very low birth weights. The advantage of this data set is that it is nationally representative and provides data for infants. It provides data on prevalence of low birth weight in the population.

8.4.10. Portier et al. (2007)—Body Weight Distributions for Risk Assessment

Portier et al. (2007) provided age-specific distributions of body weight based on NHANES II, III, and IV data. The number of observations in these surveys is 20,322, 33,311, and 9,965, respectively. Portier et al. (2007) computed the means and standard deviations of body weight as back transformations of the weighted means and standard deviations of natural log-transformed body weights. Body-weight distributions were computed by sex and various age brackets (Portier et al., 2007). The estimated mean body weights are shown in Table 8-22, Table 8-23, and Table 8-24 using NHANES II, III, and IV data, respectively. The sample size (*N*) shown in the tables is the observed number of individuals and not the expected population size (sum of the sample weights) in each age category (Portier et al., 2007). Table 8-25 provides estimates for age groups that are often considered in risk assessments (Portier et al., 2007). The authors concluded that the

data show changes in the average body weight over time and that the changes are not constant for all ages. The reader is referred to Portier et al. (2007) for equations suggested by the authors to be used when performing risk assessments where shifts and changes in body-weight distributions need factoring in.

The advantages of this study are that it represents the U.S. general population, it provides distribution data, and can be used for trend analysis. In addition, the data are provided for both sexes and for single-year age groups. The study results are also based on a large sample size.

8.4.11. Kahn and Stralka (2009)—Estimated Daily Average Per Capita Water Ingestion by Child and Adult Age Categories Based on USDA's 1994–1996 and 1998 Continuing Survey of Food Intakes

As part of an analysis of water ingestion, Kahn and Stralka (2009) provided body-weight distributions for the U.S. population. The analysis was based on self-reported body weights from the 1994–1996, 1998 CSFII. The average body weight across all individuals was 65 kg. According to Kahn and Stralka (2009), 10 kg, which is often used as the default body weight for babies, is the 95th value of the distribution of body weight for children in the 3 to <6 months category. The median weight is 9 kg for the 6 to 12-month age category and 11 kg for the one-to-two-year old-category (Kahn and Stralka, 2009). Table 8-26 presents the body-weight distributions, and Table 8-27 presents the intervals around the mean and 90th and 95th percentiles.

The advantages of the study are its large sample size and that it is representative of the U.S. population for the age groups presented. A limitation of the study is that the data are based on self-reporting from the participants and that the data are now somewhat dated.

8.5. RELEVANT STUDIES—PREGNANT WOMEN BODY-WEIGHT STUDIES**8.5.1. Carmichael et al. (1997)—The Pattern of Maternal Weight Gain in Women With Good Pregnancy Outcomes**

The Institute of Medicine (IOM) publishes recommendations for total gestational weight gain. Carmichael et al. (1997) conducted a study in a cohort of 7,002 who had good pregnancy outcomes to obtain the distribution of maternal weight gain by trimester and to compare these with women who achieved the IOM recommendations. Good outcome

Chapter 8—Body Weight Studies

was defined as having a vaginal delivery, 37 weeks or more of gestation, delivery of a live infant of an average size for gestational age, and from mothers with no diabetes or hypertension. The women were selected from records from the Department of Obstetrics, Gynecology and Reproductive Sciences Perinatal Database at the University of California, San Francisco. Distributions were derived for 4,218 women for whom complete data on pattern of gain for all trimesters were obtained. The mean age of the women was 27.7 years with a mean pre-pregnancy weight of 57.6 kg. Twenty-nine percent of the women were underweight, 61% were of normal weight, 5% were overweight, and 4% were obese, based on BMI calculations. Total weight gain was calculated as the difference between the self-reported pre-pregnancy weight and the last measured weight. A linear regression was applied to estimate the rate of gain in the 2nd and 3rd trimesters. Table 8-28 presents the distributions of weight gain in underweight, normal weight, overweight, and obese women during the 1st, 2nd, and 3rd trimesters. The average weight gains for the 1st, 2nd, and 3rd trimesters were 1.98 kg, 6.73 kg, and 6.37 kg, respectively. The weight gain for the 2nd and 3rd trimesters was calculated by taking the gain rate from Table 8-28 and multiplying it by 13 weeks. These data can be used to calculate the average weight of pregnant women for the 1st, 2nd, and 3rd trimesters by adding the average weight gain for the 1st trimester to the average pre-pregnancy weight of 57.6 kg and subsequently adding the average weight gain for the 2nd and 3rd trimesters to the resulting weight from the previous trimester. These calculations result in a total weight of 59.6 kg, 66.3 kg, and 72.7 kg for the 1st, 2nd, and 3rd trimesters, respectively.

The advantages of this study are that it has a large sample size, and it provides distributional data. The sample, however, may not be representative of the United States. The sample also only included pregnancies with good outcomes. The study did not provide estimates of the weight for each trimester. Instead, it provides weight gain for the 1st trimester and the rates of weight gain for the 2nd and 3rd trimesters. The total weight was estimated by the U.S. EPA based on the mean weight gain for each trimester.

8.5.2. U.S. EPA Analysis of 1999–2006 NHANES Data on Body Weight of Pregnant Women

In 2010, U.S. EPA analyzed the combined 1999–2006 NHANES data sets to examine body

weight of pregnant women. Data for 1,248 pregnant women with weight measurements were extracted based from the data set based on either a positive lab pregnancy test or self-reporting of pregnancy at the examination. The NHANES data included a few very large and improbable body weights, as extreme as 186 kg from a respondent in the 1st trimester. These outliers were removed from the database ($N = 26$) using SAS. Table 8-29 presents the body-weight data by trimester, based on the remaining 1,222 respondents. The statistically weighted average body weight of all pregnant women was 75 kg. Due to a few large weight (>90 kg) respondents with very large sample weights (>18,000), the weighted mean body weight of 1st trimester women (76 kg) is larger than that of 2nd trimester women (73 kg).

The advantage of this study is that by combining eight years of the most recent NHANES data, an adequate sample size was achieved to estimate body weight of pregnant women by trimester. A limitation of this analysis is that high-weight respondents with large sample weight may result in uncertainties as described above.

8.6. RELEVANT FETAL WEIGHT STUDIES

8.6.1. Brenner et al. (1976)—A Standard of Fetal Growth for the United States of America

Brenner et al. (1976) determined fetal weights for 430 fetuses aborted at 8 to 20 weeks of gestation and for 30,772 liveborn infants delivered at 21 to 44 weeks of gestation. Gestational age for the aborted fetuses was determined through a combination of the physician's estimate of uterine size and the patient's stated last normal menstrual period. Data were not used when these two estimates differed by more than two weeks. To determine fetal growth, the fetuses were weighed and measured (crown-to-rump and crown-to-heel lengths). All abortions were legally performed at Memorial Hospital, University of North Carolina, at Chapel Hill, from 1972 to 1975. For the liveborn infants, data were analyzed from single birth deliveries with the infant living at the onset of labor, among pregnancies not complicated by pre-eclampsia, diabetes or other disorders. Infants were weighed on a balance scale immediately after delivery. The liveborn infants were delivered at MacDonald House, University Hospitals of Cleveland, OH, from 1962 to 1969.

Table 8-30 shows percentiles for fetal weight, calculated from the data at each week of gestation. The resulting percentile curves were smoothed with two-point weighted means. Variables associated with

Chapter 8—Body Weight Studies

significant differences in fetal weight in the latter part of pregnancy (after 34–38 weeks of gestation) included maternal parity and race, and fetal sex.

The advantage of this study is the large sample size. Limitations of the study are that the data were collected more than 30 years ago in only two U.S. states. In addition, a number of variables that may affect fetal weight (i.e., maternal smoking, disease, nutrition, and addictions) were not evaluated in this study.

8.6.2. Doubilet et al. (1997)—Improved Birth Weight Table for Neonates Developed From Gestations Dated by Early Ultrasonography

Doubilet et al. (1997) matched a database of obstetrical ultrasonograms over a period of five years from 1988 to 1993 to birth records for 3,718 infants (1,857 males and 1,861 females). The study population included 1,514 Whites, 770 Blacks, 1,256 Hispanics, and 178 who were either unclassified, or classified as “other.” Birth weights were obtained from hospital records, and a gestational age was assigned based on the earliest 1st trimester sonogram. The database was screened for possible outliers, defined as infants with birth weights that exceeded 5,000 grams. Labor and delivery records and mother-infant medical records were retrieved to correct any errors in data entry for infants with birth weights exceeding 5,000 grams. The mean gestational age at initial sonogram was 9.5 ± 2.3 weeks. Regression analysis techniques were used to derive weight tables for neonates at each gestational age for 25 weeks of gestation onward. Weights for each gestational age were found to conform to a natural logarithm distribution. Polynomial equations were derived from the regression analysis to estimate mean weight by gestational age for males, females, and males and females combined. Table 8-31 provides the distribution of neonatal weights by gestational age from 25 weeks of gestation onward. The advantage of this study is that it provides body weights for neonates based on a relatively large sample. A limitation is the age of the data.

		Black	155 (9.0)	538 (9.0)	363 (9.1)
		Mexican American	40 (9.3)	581 (8.9)	361 (9.0)
12 to 17	Boys	White	786 (15.1)	282 (14.9)	449 (14.9)
		Black	155 (15.1)	412 (15.0)	543 (14.9)
		Mexican American	49 (15.0)	406 (15.0)	648 (15.0)
	Girls	White	695 (15.1)	344 (15.0)	456 (14.9)
		Black	159 (15.0)	450 (14.9)	528 (14.8)
		Mexican American	37 (15.2)	421 (14.8)	631 (14.9)
20 to 39	Male	White	-	-	607
		Black	-	-	279
		Mexican American	-	-	399
	Female	White	-	-	569
		Black	-	-	298
		Mexican American	-	-	358
40 to 59	Male	White	-	-	676
		Black	-	-	289
		Mexican American	-	-	310
	Female	White	-	-	632
		Black	-	-	297
		Mexican American	-	-	332
60 and over ^c	Male	White	-	-	866
		Black	-	-	256
		Mexican American	-	-	318
	Female	White	-	-	862
		Black	-	-	275
		Mexican American	-	-	329
^a	Race was recorded in the 1 st two examinations (using data concerning ancestry/national origin) to create comparable categories in all surveys.				
^b	Mean ages are shown in parentheses. There are no mean ages available for the older age group data (ages 20 and above).				
^c	Data from Ogden et al. (2004).				
-	No data available.				
Sources: Freedman et al. (2006); Ogden et al. (2004).					

Table 8-18. Mean BMI (kg/m²) Levels and Change in the Mean Z-Scores by Race-Ethnicity and Sex (ages 2 to 17)

		Examination Year ^a				Increase in Mean z-score from 1971–1974 to 1999–2002			
		Race	1971–1974	1976–1980	1988–1994	1999–2002	BMI	Weight	Height
Overall	White	18.0 ^b	18.0	18.8	19.0	+0.33	+0.36	+0.20	
	Black	17.8	18.2	19.1	20.0	+0.61	+0.63	+0.31

^a Secular trends for BMI, BMI-for-age, weight-for-age, and height-for-age were each statistically significant at the 0.001 level. Trends in BMI, BMI-for-age, and weight also differed ($p < 0.001$) by race.

^b Mean BMI levels have been adjusted for differences in age and sex across exams.

	^a Overweight is defined as a BMI $\geq 95^{\text{th}}$ percentile or $\geq 30 \text{ kg/m}^2$; obesity is defined as a BMI $\geq 99^{\text{th}}$ percentile or $\geq 40 \text{ kg/m}^2$.							
	^b Values are percentage of overweight children (percentage of obese children).

All ages	19,850	65	-	-	95	-	-	104	-	-
^a	Sample size does meet minimum reporting requirements as described in the 3 rd Report on Nutrition Monitoring in the United States (Vol. I) (FASEB/LSRO, 1995). Interval estimates may involve aggregation of variance estimation units when data are too sparse to support estimation of variance.									
CI	= Confidence interval.									
BI	= Percentile intervals estimated using percentile bootstrap method with 1,000 bootstrap replications.									
-	= Data unavailable.

9. INTAKE OF FRUITS AND VEGETABLES

9.1. INTRODUCTION

This document is an update to Chapter 9 (Intake of Fruits and Vegetables) of the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011). New information that has become available since 2011 has been added, and the recommended values have been revised as needed to reflect the new information. The recommended values for the general population in this chapter have been updated using National Health and Nutrition Examination Survey (NHANES) data for 2005-2010; the 2011 version of this chapter used NHANES data for 2003-2006. The 2018 recommendations include some more disaggregated age groupings than the 2011 Handbook (for those under age 1 and for adults), and for some childhood age groups provide more statistically reliable estimates because the new analysis uses six years of NHANES data versus four in the 2011 estimates.

Estimates of the mean per capita intake of total vegetables did not change in adults over age 21 and for total fruit there was some increase in those ages 21 to 50 years of age, but not in those over 50 years of age. For younger and more disaggregated ages, there is no simple pattern in the updates to the estimates, but Appendix A provides a comparison of the recommended values in this update to those of the 2011 Handbook.

This update also provides, for the first time, intake data for pregnant and lactating women based on NHANES 2005-2010 data. Recent relevant studies based on data other than NHANES are also summarized to provide additional perspective on fruit and vegetable intake.

This chapter includes a comprehensive review of the scientific literature through 2016. The new literature was identified via formal literature searches conducted by U.S. Environmental Protection Agency (EPA) staff as well as targeted Internet searches conducted by the authors of this chapter. Appendix B provides a list of the key terms that were used in the literature searches. Revisions to this chapter have been made in accordance with the approved quality assurance plan for the *Exposure Factors Handbook*.

The American food supply is generally considered to be one of the safest in the world. Nevertheless, fruits and vegetables can become contaminated with toxic chemicals by several different pathways. Ambient pollutants from the air may be deposited on or absorbed by the plants or dissolved in rainfall or irrigation waters that contact the plants. Pollutants may also be absorbed through plant roots from contaminated soil and ground water. The addition of pesticides, soil additives, and fertilizers may also

result in contamination of fruits and vegetables. To assess exposure through this pathway, information on fruit and vegetable ingestion rates is needed.

A variety of terms may be used to define intake of fruits and vegetables (e.g., consumer-only intake, per capita intake, total fruit intake, total vegetable intake, as-consumed intake, dry-weight intake). These terms are defined below to assist the reader in interpreting and using the intake rates that are appropriate for the exposure scenario being assessed.

Consumer-only intake is defined as the quantity of fruits and vegetables consumed by individuals during the survey period. These data are generated by averaging intake across only the individuals in the survey who consumed these food items. Per capita intake rates are generated by averaging consumer-only intakes over the entire population (including those individuals that reported no intake). In general, per capita intake rates are appropriate for use in exposure assessments for which average dose estimates are of interest because they represent both individuals who ate the foods during the survey period and individuals who may eat the food items at some time, but did not consume them during the survey period. Per capita intake, therefore, represents an average across the entire population of interest, but does so at the expense of underestimating consumption for the subset of the population that consumed the food in question. Total fruit intake refers to the sum of all fruits consumed in a day including canned, dried, frozen, and fresh fruits. Likewise, total vegetable intake refers to the sum of all vegetables consumed in a day including canned, dried, frozen, and fresh vegetables.

Intake rates may be expressed on the basis of the as-consumed weight (e.g., cooked or prepared) or on the uncooked or unprepared weight. As-consumed intake rates are based on the weight of the food in the form that it is consumed and should be used in assessments where the basis for the contaminant concentrations in foods is also indexed to the as-consumed weight. Some of the food ingestion values provided in this chapter are expressed as as-consumed intake rates because that is the way in which data were reported by survey respondents. Other values are provided as uncooked weights based on analyses of survey data that account for weight changes that occur during cooking. This is important to know because concentration data to be used in the dose equation are often measured in uncooked food samples. It should be recognized that cooking can either increase or decrease food weight. Similarly, cooking can increase the mass of contaminants in food (due to formation reactions, or absorption from cooking oils or water) or decrease the mass of contaminants in food (due to vaporization, fat loss, or

leaching). The combined effects of changes in weight and changes in contaminant mass can result in either an increase or decrease in contaminant concentration in cooked food. Therefore, if the as-consumed ingestion rate and the uncooked concentration are used in the dose equation, the dose may be underestimated or overestimated. It is important for the assessor to be aware of these issues and choose intake rate data that best match the concentration data that are being used. For more information on cooking losses and conversions necessary to account for such losses, refer to Chapter 13 of this handbook.

Sometimes contaminant concentrations in food are reported on a dry-weight basis. When these data are used in an exposure assessment, it is recommended that dry-weight intake rates also be used. Dry-weight food concentrations and intake rates are based on the weight of the food consumed after the moisture content has been removed. For information on converting the intake rates presented in this chapter to dry-weight intake rates, refer to Section 9.4.

The purpose of this chapter is to provide intake data for fruits and vegetables. The recommendations for fruit and vegetable ingestion rates are provided in the next section, along with a summary of the confidence ratings for these recommendations. The recommended values are based on the key study identified by U.S. EPA for these factors. As described in Chapter 1 of the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011), the key studies represent the most up-to-date and scientifically sound ones for deriving recommendations for exposure factors, whereas other studies are designated “relevant,” meaning applicable or pertinent, but not necessarily the most important. For example, studies that provide supporting data or information related to the factor of interest (e.g., percentage of the population consuming fruits and vegetables), or have study designs or approaches that make the data less applicable to the general population (e.g., older studies or studies that targeted specific populations) have been designated as relevant rather than key. Key studies were selected based on the general assessment factors described in Chapter 1 of the handbook. Following the recommendations, the key study on fruit and vegetable ingestion is summarized (see Section 9.3.1). Relevant data on ingestion of fruits and vegetables are also provided (see Section 9.3.2). These data are presented to provide the reader with added perspective on the current state-of-knowledge pertaining to ingestion of fruits and vegetables. Data on pregnant and lactating women are provided in Section 9.3.3.

9.2. RECOMMENDATIONS

Table 9-1 presents a summary of the recommended values for per capita and consumer-only intake of fruits and vegetables for use in exposure and risk assessments. Table 9-2 provides confidence ratings for the fruit and vegetable intake recommendations.

The U.S. EPA analysis of data from the 2005–2010 NHANES was used in selecting recommended intake rates for the general population. The U.S. EPA analysis was conducted using the childhood age groups from U.S. EPA’s *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005).

The NHANES data on which the recommendations are based are short-term survey data and may not necessarily reflect the long-term distribution of average daily intake rates. However, because broad categories of food (i.e., total fruits and total vegetables) are eaten on a daily basis throughout the year with minimal seasonality, the short-term distribution may be a reasonable approximation of the long-term distribution, although it will display somewhat increased variability. This implies that the upper percentiles shown here may tend to overestimate the corresponding percentiles of the true long-term distribution. In general, the recommended values based on U.S. EPA’s analysis of NHANES data represent the uncooked weight of the edible portion of fruits and vegetables.

U.S. Department of Agriculture (USDA) and the U.S. Department of Health and Human Services (USDHHS) jointly developed *Dietary Guidelines for Americans: 2010* that provide information and advice for choosing healthy eating patterns (USDA and USDHHS, 2010). The guidance may differ from the recommended intake rates for fruits and vegetables that are provided in this chapter for use in exposure/risk assessment because NHANES and similar surveys reflect actual intake rather than dietary goals.

Table 9-1. Recommended Values for Intake of Fruits and Vegetables (edible portion, uncooked weight) (Continued)

^a	Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption.
^b	For more information on the recipes used to convert the foods people reported eating to the quantities of agricultural commodities eaten, refer to the Frequently Asked Questions at http://fcid.foodrisk.org/ .
^c	Total fruits includes: acerola; apple, dried; apple, dried-baby food; apple, fruit with peel; apple, peeled fruit; apple, peeled fruit-baby food; apple, sauce; apple, sauce-baby food; apricot; apricot, dried; apricot-baby food; avocado; banana; banana, dried; banana, dried-baby food; banana-baby food; blackberry; blueberry; blueberry-baby food; boysenberry; breadfruit; canistel; cherimoya; cherry; cherry-baby food; citrus hybrids; crabapple; cranberry; cranberry, dried; cranberry-baby food; currant; currant, dried; date; dragon fruit; eggplant; elderberry; feijoa; fig; fig, dried; gooseberry; grape; grape, raisin; guava; guava-baby food; huckleberry; jackfruit; kiwifruit, fuzzy; kumquat; lemon; lemon, peel; lime; loganberry; longan; loquat; lychee; lychee, dried; mamey apple; mango; mango, dried; mango-baby food; nectarine; orange; orange, peel; papaya; papaya, dried; papaya-baby food; passionfruit; passionfruit-baby food; pawpaw; peach; peach, dried; peach, dried-baby food; peach-baby food; pear; pear, dried; pear-baby food; persimmon; pineapple; pineapple, dried; pineapple-baby food; plantain; plantain, dried; plum; plum, prune, dried; plum, prune, dried-baby food; plum, prune, fresh; plum, prune, fresh-baby food; plum-baby food; pomegranate; prickly pear fruit; pummelo; quince; raspberry; raspberry-baby food; sapote, mamey; soursop; Spanish lime; starfruit; strawberry; strawberry-baby food; sugar apple; tamarind; tangerine.
^d	Estimates are less statistically reliable based on guidance published in the Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations (NCHS, 1993).
^e	Total vegetables includes: alfalfa, seed; amaranth, leafy; arrowroot, flour; arrowroot, flour-baby food; artichoke, globe; artichoke, Jerusalem; arugula; asparagus; balsam pear; bamboo, shoots; basil, dried leaves; basil, dried leaves-baby food; basil, fresh leaves; basil, fresh leaves-baby food; bean, cowpea, succulent; bean, kidney, seed; bean, lima, seed; bean, lima, succulent; bean, mung, seed; bean, navy, seed; bean, pink, seed; bean, pinto, seed; bean, snap, succulent; bean, snap, succulent-baby food; beet, garden, roots; beet, garden, roots-baby food; beet, garden, tops; belgium endive; broccoli; broccoli raab; broccoli, Chinese; broccoli-baby food; brussels sprouts; cabbage; cabbage, Chinese, bok choy; cabbage, Chinese, mustard; cabbage, Chinese, napa; cactus; cantaloupe; cardoon; carrot; carrot-baby food; cassava; cassava-baby food; cauliflower; celeriac; celery; celery-baby food; celtuce; chayote, fruit; chickpea, flour; chickpea, seed; chickpea, seed-baby food; chicory, roots; chicory, tops; Chinese waxgourd; chive, fresh leaves; chrysanthemum, garland; cilantro, leaves; cilantro, leaves-baby food; cinnamon; cinnamon-baby food; coriander, seed; coriander, seed-baby food; dandelion, leaves; dasheen, corm; dasheen, leaves; dill, seed; dillweed; fennel, Florence; garlic, bulb; garlic, bulb-baby food; ginger; ginger, dried; ginger-baby food; ginseng, dried; grape, leaves; guar, seed; guar, seed-baby food; herbs, other; herbs, other-baby food; kale; kohlrabi; leek; lemongrass; lettuce, head; lettuce, leaf; marjoram; marjoram-baby food; okra; onion, bulb; onion, bulb, dried; onion, bulb, dried-baby food; onion, bulb-baby food; onion, green; palm heart, leaves; parsley, dried leaves; parsley, dried leaves-baby food; parsley, leaves; parsley, turnip rooted; parsnip; parsnip-baby food; pea, dry; pea, dry-baby food; pea, edible podded, succulent; pea, pigeon, seed; pea, pigeon, succulent; pea, succulent; pea, succulent-baby food; pepper, bell; pepper, bell, dried; pepper, bell, dried-baby food; pepper, bell-baby food; pepper, black and white; pepper, black and white-baby food; pepper, nonbell; pepper, nonbell, dried; pepper, nonbell-baby food; peppermint; potato, chips; potato, dry (granules/flakes); potato, dry (granules/flakes)-baby food; potato, flour; potato, flour-baby food; potato, tuber, without peel; potato, tuber, without peel-baby food; potato, tuber, with peel; potato, tuber, with peel-baby food; pumpkin; radicchio; radish, oriental, roots; radish, oriental, tops; radish, roots; radish, tops; rape greens; rhubarb; rutabaga; salsify, roots; salsify, tops; savory; seaweed; seaweed-baby food; shallot, bulb; soybean, flour; soybean, flour-baby food; soybean, seed; spices, other; spices, other-baby food; squash, summer; squash, summer-baby food; squash, winter; squash, winter-baby food; sweet potato; sweet potato-baby food; Swiss chard; taniel, corm; tomatillo; tomato, dried; tomato, dried-baby food; tomato, paste; tomato, paste-baby food; tomato, puree; tomato, puree-baby food; tomato-baby food; tree tomato; turmeric; turnip, greens; turnip, roots; water chestnut; watercress; watermelon; yam bean; yam, true.

CSFII = Continuing Survey of Food Intake among Individuals.
HNIS = Human Nutrition Information Service.
NCHS = National Center for Health Statistics.

Table 9-2. Confidence in Recommendations for Intake of Fruits and Vegetables		
General Assessment Factors	Rationale	Rating
Soundness		
<i>Adequacy of Approach</i>	The survey methodology and data analysis were adequate. The survey sampled nearly 25,000 individuals. However, sample sizes for some individual fruits and vegetables for some of the age groups are small. An analysis of primary data was conducted.	High for total fruits and vegetables, low for some individual fruits and vegetables with small sample size
<i>Minimal (or defined) Bias</i>	No physical measurements were taken. The method relied on recent recall of fruits and vegetables eaten.	
Applicability and Utility		High
<i>Exposure Factor of Interest</i>	The key study was directly relevant to fruit and vegetable intake.	
<i>Representativeness</i>	The data were demographically representative of the U.S. population (based on stratified random sample).	
<i>Currency</i>	Data were collected between 2005 and 2010.	
<i>Data Collection Period</i>	Data were collected for two nonconsecutive days.	
Clarity and Completeness		High
<i>Accessibility</i>	The NHANES data and the the FCID Consumption Calculator are publicly available.	
<i>Reproducibility</i>	The methodology used was clearly described; enough information was included to reproduce the results.	
<i>Quality Assurance</i>	NHANES follows strict QA/QC procedures. Data generated by the FCID Consumption Calculator has been reviewed by EPA.	
Variability and Uncertainty		Medium to high for averages, low for long-term upper percentiles; low for individual fruits and vegetables
<i>Variability in Population</i>	Full distributions were provided for total fruits and total vegetables. Means were provided for individual fruits and vegetables.	
<i>Uncertainty</i>	Data collection was based on recall of consumption for a 2-day period; the accuracy of using these data to estimate long-term intake (especially at the upper percentiles) is uncertain. However, use of short-term data to estimate chronic ingestion can be assumed for broad categories of foods such as total fruits and total vegetables. Uncertainty is greater for individual fruits and vegetables.	
Evaluation and Review		Medium
<i>Peer Review</i>	The NCHS NHANES survey received a high level of peer review. The U.S. EPA analysis of these data has not been peer reviewed outside the Agency, but the methodology used has been peer reviewed in an analysis of previous data.	
<i>Number and Agreement of Studies</i>	There was one key study.	

Table 9-2. Confidence in Recommendations for Intake of Fruits and Vegetables (Continued)		
General Assessment Factors	Rationale	Rating
Overall Rating		Medium to High confidence in the averages; Low for some individual fruits and vegetables with small sample size; Low confidence in the long-term upper percentiles
FCID = Food Commodity Intake Database NCHS = National Center for Health Statistics. QA/QC = quality assurance/quality control.		

Chapter 9—Intake of Fruits and Vegetables

9.3. INTAKE STUDIES

9.3.1 Key Fruit and Vegetable Intake Study

9.3.1.1 U.S. EPA Analysis of Consumption Data from 2003–2006 National Health and Nutrition Examination Survey (NHANES)

The key source of recent information on consumption rates of fruits and vegetables is the U.S. Centers for Disease Control and Prevention's National Center for Health Statistics' (NCHS) NHANES. Data from NHANES 2005–2010 have been used by the U.S. EPA to generate per capita and consumer-only intake rates for both individual fruits and vegetables and total fruits and vegetables.

NHANES is designed to assess the health and nutritional status of adults and children in the United States. In 1999, the survey became a continuous program that interviews a nationally representative sample of approximately 7,000 persons each year and examines a nationally representative sample of about 5,000 persons each year, located in counties across the country, 15 of which are visited each year. Data are released on a 2-year basis; thus, for example, the 2005 data are combined with the 2006 data to produce NHANES 2005–2006.

The dietary interview component of NHANES is called *What We Eat in America* (WWEIA) and is conducted by the USDA and the U.S. Department of Health and Human Services (DHHS). DHHS' NCHS is responsible for the sample design and data collection, and USDA's Food Surveys Research Group is responsible for the dietary data collection methodology, maintenance of the databases used to code and process the data, and data review and processing. Beginning in 2003, two nonconsecutive days of 24-hour intake data were collected. The 1st day is collected in-person, and the 2nd day is collected by telephone 3 to 10 days later. These data are collected using USDA's dietary data collection instrument, the Automated Multiple Pass Method. This method provides an efficient and accurate means of collecting intakes for large-scale national surveys. It is fully computerized and uses a five-step interview. Details can be found at USDA's Agriculture Research Service (<http://www.ars.usda.gov/ba/bhnrc/fsrg>).

The 2005–2010 NHANES surveys are stratified, multistage probability samples of the civilian noninstitutionalized U.S. population. The sampling frame was based on the 2000 U.S. population census estimates. NHANES oversamples low-income persons, adolescents 12 to 19 years, persons 60 years and older, African Americans, and Mexican Americans. Several sets of sampling weights are available for use with the intake data. By using appropriate weights, data for all 6 years of the surveys

can be combined. Additional information on NHANES can be obtained at <http://www.cdc.gov/nchs/nhanes.htm>.

The U.S. EPA, Office of Pesticide Programs (OPP) used NHANES 2005–2010 data to update the Food Commodity Intake Database (FCID) that was developed in earlier analyses of data from the USDA's Continuing Survey of Food Intake among Individuals (CSFII) (USDA, 2000; U.S. EPA, 2000) (see Section 9.3.2.4). The updated FCID is available at: <http://fcid.foodrisk.org/>, along with the FCID Consumption Calculator, which was used to develop the estimates provided in this chapter for various age and racial/ethnic groups. The calculator may also be used to develop estimates for other age groups or populations, customized to the users' needs. In the FCID, NHANES data on the foods people reported eating were converted to the quantities of agricultural commodities eaten. "Agricultural commodity" is a term used by U.S. EPA to mean plant (or animal) parts used as feed or consumed by humans as food. When such items are raw or unprocessed, they are referred to as "raw agricultural commodities." For example, an apple pie may contain the commodities apples, flour, fat, sugar, and spices. FCID contains approximately 560 unique commodity names and 8-digit codes. The FCID commodity names and codes were selected and defined by U.S. EPA and were based on the U.S. EPA Food Commodity Vocabulary (<https://www.epa.gov/pesticide-tolerances/food-and-feed-commodity-vocabulary>). Appendix C provides the codes and definitions used to determine the various fruit and vegetable commodities used in the U.S. EPA analysis of the WWEIA-FCID data.

Intake rates were generated for a variety of food items/groups based on the agricultural commodities included in the FCID. These intake rates represent intake of all forms of the product (e.g., both home produced and commercially produced) for 2 survey days. For respondents who reported intake on both days, their intake rate represents the average rate for the 2 survey days. For respondents who reported consumption on one day and no consumption on the other day, their intake rate represents the average of zero and nonzero consumption. Two-day average intake rates were calculated for all individuals in the database for each of the food items/groups. These average daily intake rates were divided by each individual's reported body weight to generate intake rates in units of grams per kilogram of body weight per day (g/kg-day). The data were weighted according to the 6-year, 2-day sample weights provided in NHANES 2005–2010 to adjust the data for the sample population to reflect the national population. The 2005–2010 analysis of NHANES/FCID data for fruits

and vegetables included data for nearly 25,000 respondents.

Summary statistics were generated on a consumer-only and on a per capita basis. Summary statistics, including number of observations, percentage of the population consuming the fruits or vegetables being analyzed, mean intake rate, and standard error of the mean intake rate, were calculated for total fruits, total vegetables, and selected individual fruits and vegetables. Individual fruits and vegetables were selected to be consistent with Chapter 13 of this handbook, which was based on having at least 30 households reporting consumption for the particular fruit or vegetable. Percentiles of the intake rate distribution (i.e., 1st, 5th, 10th, 25th, 50th, 75th, 90th, 95th, 99th, and the maximum value) were also provided for total fruits and total vegetables. Data were provided for the following childhood age groups: <1 month, 1 to <3 months, 3 to <6 months, 6 to <12 months, 1 to <2 years, 2 to <3 years, 3 to <6 years, 6 to <11 years, 11 to <16 years, and 16 to <21 years to be consistent with those recommended in U.S. EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). Data for the birth to <1-year age group were also provided to be consistent with the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011). For adults, data were provided for ages 21 to <30 years, 30 to <40 years, 40 to <50 years, 50 to <60 years, 60 to <70 years, 70 to <80 years, and 80+ years, and for ages 21 to <50 years and 50+ years. Data were also provided according to the following racial/ethnic groups: Mexican American, non-Hispanic black, non-Hispanic white, other Hispanic, and other race including multiple races.

Table 9-3 presents per capita intake data for total fruits and total vegetables in g/kg-day; Table 9-4 provides consumer-only intake data for total fruits and total vegetables in g/kg-day. Table 9-5 provides per capita intake data for individual fruits and vegetables in g/kg-day, and Table 9-6 provides consumer-only intake data for individual fruits and vegetables in g/kg-day. Tables 9-7 and 9-8 provide per capita and consumer-only data, respectively, for "exposed" and "protected" fruits and vegetables. Exposed fruits and vegetables are those that are grown above ground and are likely to be contaminated by pollutants deposited on surfaces of the foods that are eaten. Protected fruits and vegetables are those that have outer protective coatings that are typically removed before consumption. In general, these data represent intake of the edible portions of uncooked foods.

Because the results are presented in units of g/kg-day, use of these data in calculating potential dose does not require the body-weight factor to be

included in the denominator of the average daily dose equation. Note, however, that converting these intake rates into units of g/day by multiplying by a single average body weight is inappropriate because individual intake rates were indexed to the reported body weights of the survey respondents. If intake data in units of g/day are needed, they can be obtained using the FCID Consumption Calculator, which is available at <http://fcid.foodrisk.org/>. Also, it should be noted that the distribution of average daily intake rates generated using short-term data (e.g., 2-day) does not necessarily reflect the long-term distribution of average daily intake rates. The distributions generated from short-term and long-term data will differ to the extent that each individual's intake varies from day to day; the distributions will be similar to the extent that individuals' intakes are constant from day to day. Day-to-day variation in intake among individuals will be high for fruits and vegetables that are highly seasonal and for fruits and vegetables that are eaten year-round, but that are not typically eaten every day. For these fruits and vegetables, the intake distribution generated from short-term data will not be a good reflection of the long-term distribution. On the other hand, for broad categories of foods (e.g., total fruits and total vegetables) that are eaten on a daily basis throughout the year, the short-term distribution may be a reasonable approximation of the true long-term distribution, although it will show somewhat more variability. In this chapter, distributions are provided only for broad categories of fruits and vegetables (i.e., total fruits and total vegetables). Because of the increased variability of the short-term distribution, the short-term upper percentiles shown here may overestimate the corresponding percentiles of the long-term distribution. For individual foods, only the mean, standard error, and percentage of respondents consuming are provided.

An advantage of using the U.S. EPA's analysis of NHANES data is that it provides distributions of intake rates for various age groups of children and adults, normalized by body weight. The data set was designed to be representative of the U.S. population and includes 6 years of intake data combined. Another advantage is the currency of the data; the NHANES data are from 2005–2010. However, short-term dietary data may not accurately reflect long-term eating patterns, and the upper percentiles may overestimate the corresponding percentiles of the true long-term distribution. However, because these are 2-day averages, consumption estimates at the upper end of the intake distribution may be underestimated if these consumption values are used to assess acute (i.e., short-term) exposures.

9.3.2 Relevant Fruit and Vegetable Intake Studies

9.3.2.1 U.S. Department of Agriculture (USDA) (1980, 1992, 1996a, b)—Food and Nutrient Intakes of Individuals in 1 Day in the United States

USDA calculated mean intake rates for total fruits and total vegetables using data from the 1977–1978 and 1987–1988 Nationwide Food Consumption Surveys (NFCS) (USDA, 1980, 1992) and CSFII data from 1994 and 1995 (USDA, 1996a, b). Table 9-9 presents the mean per capita total intake rates for total fruits and total vegetables from the 1977–1978 NFCS. Table 9-10 presents similar data from the 1987–1988 NFCS and the 1994 and 1995 CSFII. Note that the age classifications used in these surveys were slightly different than those used in the 1977–1978 NFCS. Tables 9-9 and 9-10 include both per capita intake rates and intake rates for consumers-only for various ages of individuals. Intake rates for consumers-only were calculated by dividing the per capita consumption rate by the fraction of the population consuming vegetables or fruits in a day.

The advantages of using these data are that they provide intake estimates for all fruits or all vegetables, combined. Again, these estimates are based on 1-day dietary data, which may not reflect usual consumption patterns. These data are based on older surveys and may not be entirely representative of current eating patterns, but may provide some historical perspective on intake of these foods.

9.3.2.2 U.S. Department of Agriculture (USDA) (1999a)—Food Consumption, Prices, and Expenditures, 1970–1997

The USDA's Economic Research Service calculates the amount of food available for human consumption in the United States on an annual basis (USDA, 1999a). Supply and utilization balance sheets are generated based on the flow of food items from production to end uses for Years 1970 to 1997. Total available supply is estimated as the sum of production and imports (USDA, 1999a). The availability of food for human use commonly termed as "food disappearance" is determined by subtracting exported foods from the total available supply (USDA, 1999a). USDA (1999a) calculates the per capita food consumption by dividing the total food disappearance by the total U.S. population. USDA (1999a) estimated per capita consumption data for various fruit and vegetable products from 1970–1997. Table 9-11 presents retail weight per capita data. These data have been derived from the annual per capita values in units

of pounds per year, presented by USDA (1999a), by converting to units of g/day.

An advantage of this study is that it provides per capita consumption rates for fruits and vegetables that are representative of long-term intake because disappearance data are generated annually. One of the limitations of this study is that disappearance data do not account for losses from the food supply from waste or spoilage. As a result, intake rates based on these data may overestimate daily consumption because they are based on the total quantity of marketable commodity utilized. Thus, these data represent bounding estimates of intake rates only. It should also be noted that per capita estimates based on food disappearance are not a direct measure of actual consumption or quantity ingested; instead, the data are used as indicators of changes in usage over time (USDA, 1999a). These data are based on older surveys and may not be entirely representative of current consumption patterns.

9.3.2.3 U.S. Department of Agriculture (USDA) (1999b)—Food and Nutrient Intakes by Children 1994–1996, 1998, Table Set 17

USDA (1999b) calculated national probability estimates of food and nutrient intake by children based on 4 years of the CSFII (1994–1996 and 1998) for children ages 9 years and under, and on CSFII 1994–1996 only for children ages 10 years and over. The CSFII was a series of surveys designed to measure the kinds and amounts of foods eaten by Americans. Intake data, based on 24-hour dietary recall, were collected through in-person interviews on two nonconsecutive days. Section 9.3.2.4 provides additional information on these surveys.

USDA (1999b) used sample weights to adjust for nonresponse, to match the sample to the U.S. population in terms of demographic characteristics, and to equalize intakes over the 4 quarters of the year and the 7 days of the week. A total of 503 breast-fed children were excluded from the estimates, but both consumers and nonconsumers were included in the analysis.

USDA (1999b) provided data on the mean per capita quantities (grams) of various food products/groups consumed per individual for 1 day, and the percentage of individuals consuming those foods in 1 day of the survey. Tables 9-12 through 9-15 present data on the mean quantities (grams) of fruits and vegetables consumed per individual for 1 day, and the percentage of survey individuals consuming fruits and vegetables on that survey day. Data on mean intakes or mean percentages are based on respondents' Day 1 intakes.

The advantage of the USDA (1999b) study is that it uses the 1994–1996, 1998 CSFII data set, which includes 4 years of intake data, combined, and includes the supplemental data on children. These data are expected to be generally representative of the U.S. population, and they include data on a wide variety of fruits and vegetables. The data set is one of a series of USDA data sets that are publicly available. One limitation of this data set is that it is based on 1 day, and short-term dietary data may not accurately reflect long-term eating patterns. Other limitations of this study are that it only provides mean values of food intake rates, consumption is not normalized by body weight, and presentation of results is not consistent with U.S. EPA's recommended age groups. These data are based on older surveys and may not be entirely representative of current eating patterns, but may provide some historical perspective on intake of these foods.

9.3.2.4 U.S. EPA Analysis of Continuing Survey of Food Intake among Individuals (CSFII) 1994–1996, 1998 Based on U.S. Department of Agriculture (USDA) (2000) and U.S. EPA (2000)

U.S. EPA/OPP, in cooperation with USDA's Agricultural Research Service, used data from the 1994–1996, 1998 CSFII to develop the FCID (U.S. EPA, 2000; USDA, 2000), as described in Section 9.3.1.1. The CSFII 1994–1996 was conducted between January 1994 and January 1997 with a target population of noninstitutionalized individuals in all 50 states and Washington, DC. In each of the 3 survey years, data were collected for a nationally representative sample of individuals of all ages. The CSFII 1998 was conducted between December 1997 and December 1998 and surveyed children 9 years of age and younger. It used the same sample design as the CSFII 1994–1996 and was intended to be merged with CSFII 1994–1996 to increase the sample size for children. The merged surveys are designated as CSFII 1994–1996, 1998 (USDA, 2000). Additional information on the CSFII can be obtained at <http://www.ars.usda.gov/Services/docs.htm?docid=14531>.

The CSFII 1994–1996, 1998 collected dietary intake data through in-person interviews on two nonconsecutive days. The data were based on 24-hour recall. A total of 21,662 individuals provided data for the 1st day; of those individuals, 20,607 provided data for a 2nd day. The 2-day response rate for the 1994–1996 CSFII was approximately 76%. The 2-day response rate for CSFII 1998 was 82%. The CSFII 1994–1996, 1998 surveys were based on a complex

multistage area probability sample design. The sampling frame was organized using the 1990 U.S. population census estimates, and the stratification plan took into account geographic location, degree of urbanization, and socioeconomic characteristics. Several sets of sampling weights are available for use with the intake data. By using appropriate weights, data for all 4 years of the surveys can be combined. USDA recommends that all 4 years be combined in order to provide an adequate sample size for children.

The fruits and vegetable items/groups selected for the U.S. EPA analysis included total fruits and vegetables, and various individual fruits and vegetables. CSFII data on the foods people reported eating were converted to the quantities of agricultural commodities eaten. Intake rates for these food items/groups were calculated, and summary statistics were generated on both a per capita and a consumer-only basis using the same general methodology as in the U.S. EPA analysis of 2003–2006 NHANES data, as described in Section 9.3.1.1. Because these data were developed for use in U.S. EPA's pesticide registration program, the childhood age groups used are slightly different than those recommended in U.S. EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005).

Table 9-16 presents per capita intake data for total fruits and total vegetables in g/kg-day; Table 9-17 provides consumer-only intake data for total fruits and total vegetables in g/kg-day. Table 9-18 provides per capita intake data for individual fruits and vegetables, and Table 9-19 provides consumer-only intake data for individual fruits and vegetables. In general, these data represent intake of the edible portions of uncooked foods. Tables 9-20 through 9-24 present data for exposed/protected fruits and vegetables and root vegetables. These five tables were created using only CSFII 1994–1996. These data represent as-consumed intake rates.

Because the results are presented in units of g/kg-day, use of these data in calculating potential dose does not require the body-weight factor to be included in the denominator of the average daily dose equation. The cautions about converting these intake rates into units of g/day by multiplying by a single average body weight, and the discussion of the use of short term data in the NHANES description in Section 9.3.1.1, apply to the CSFII estimates as well.

A strength of U.S. EPA's analysis is that it provides distributions of intake rates for various age groups of children and adults, normalized by body weight. The analysis uses the 1994–1996, 1998 CSFII data set, which was designed to be representative of

the U.S. population. Also, the data set includes 4 years of intake data combined and is based on a 2-day survey period. However, as discussed above, short-term dietary data may not accurately reflect long-term eating patterns and may under-represent infrequent consumers of a given food. This is particularly true for the tails (extremes) of the distribution of food intake. Also, the analysis was conducted using slightly different childhood age groups than those recommended in U.S. EPA's Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants (U.S. EPA, 2005). However, given the similarities in the age groups used, the data should provide suitable intake estimates for the age groups of interest. While the CSFII data are older than the NHANES data, they provide relevant information on consumption by season, region of the United States, and urbanization, breakdowns that are not available in the publicly released NHANES data.

9.3.2.5 Smiciklas-Wright et al. (2002)—Foods Commonly Eaten in the United States: Quantities Consumed per Eating Occasion and in a Day, 1994–1996

Using data gathered in the 1994–1996 USDA CSFII, Smiciklas-Wright et al. (2002) calculated distributions for the quantities of fruits and vegetables consumed per eating occasion by members of the U.S. population (i.e., serving sizes). The estimates of serving size were based on data obtained from 14,262 respondents, ages 2 years and above, who provided 2 days of dietary intake information. Only dietary intake data from users of the specified food were used in the analysis (i.e., consumer-only data).

Table 9-25 presents serving size data for selected fruits and vegetables, and Table 9-26 presents serving size data by age group. These data are presented on an as-consumed basis (grams) and represent the quantity of fruits and vegetables consumed per eating occasion. These estimates may be useful for assessing acute exposures to contaminants in specific foods, or other assessments where the amount consumed per eating occasion is necessary. Only the mean and standard deviation serving size data and percentage of the population consuming the food during the 2-day survey period are presented in this handbook. Percentiles of serving sizes of the foods consumed by these age groups of the U.S. population can be found in Smiciklas-Wright et al. (2002).

The advantages of using these data are that they were derived from the USDA CSFII and are representative of the U.S. population. The analysis conducted by Smiciklas-Wright et al. (2002)

accounted for individual foods consumed as ingredients of mixed foods. Mixed foods were disaggregated via recipe files so that the individual ingredients could be grouped together with similar foods that were reported separately. Thus, weights of foods consumed as ingredients were combined with weights of foods reported separately to provide a more thorough representation of consumption. Note, however, that because the recipes for the mixed foods consumed were not provided by the respondents, standard recipes were used. As a result, the estimates of quantity consumed for some food types are based on assumptions about the types and quantities of ingredients consumed as part of mixed foods. This study used data from the 1994 to 1996 CSFII; data from the 1998 children's supplement were not included.

9.3.2.6 Vitolins et al. (2002)—Quality of Diets Consumed by Older Rural Adults

Vitolins et al. (2002) conducted a survey to evaluate the dietary intake, by food groups, of older (>70 years) rural adults. The sample consisted of 130 community dwelling residents from two rural counties in North Carolina. Data on dietary intake over the preceding year were obtained in face-to-face interviews conducted in participants' homes, or in a few cases, a senior center. The food frequency questionnaire used in the survey was a modified version of the National Cancer Institute Health Habits and History Questionnaire; this modified version included an expanded food list containing a greater number of ethnic foods than the original food frequency form. Demographic and personal data collected included sex, ethnicity, age, education, denture use, marital status, chronic disease, and weight. Food items reported in the survey were separated into food groups similar to the USDA Food Guide Pyramid and the National Cancer Institute's *5 A Day for Better Health* program. These groups are: (1) fruits and vegetables; (2) bread, cereal, rice, and pasta; (3) milk, yogurt, and cheese; (4) meat, fish, poultry, beans, and eggs; and (5) fats, oils, sweets, and snacks. Medians, ranges, frequencies, and percentages were used to summarize intake of each food group, broken down by demographic and health characteristics. To assess the univariate associations of these characteristics with consumption, Wilcoxon rank-sum tests were used. In addition, multivariate regression models were used to determine which demographic and health factors were jointly predictive of intake of each of the five food groups.

Thirty-four percent of the survey participants were African American, 36% were European American,

and 30% were Native American. Sixty-two percent were female, 62% were not married at the time of the interview, and 65% had some high school education or were high school graduates. Almost all of the participants (95%) had one or more chronic diseases. Sixty percent of the respondents were between 70 and 79 years of age; the median age was 78 years old. Table 9-27 presents the median servings of fruits and vegetables broken down by demographic and health characteristic. The only variable predictive of fruit and vegetable intake was ethnicity ($p = 0.02$), with European Americans consuming significantly more of these foods than either African Americans or Native Americans. The multiple regression model indicated a statistically significant interaction between sex and ethnicity ($p = 0.04$) and a significant main effect for chronic disease ($p = 0.04$) for fruit and vegetable consumption. Among males, European Americans consumed significantly more fruits and vegetables than either African Americans or Native Americans. Men and women did not differ significantly in their fruit and vegetable consumption, except for African Americans, where women had a significantly greater intake ($p = 0.01$).

An advantage of this study is that dietary information was collected on older individuals (>70 years of age). One limitation of the study, as noted by the study authors, is that the study did not collect information on the length of time the participants had been practicing the dietary behaviors reported in the survey. Also, the survey results are based on dietary recall; the questionnaire required participants to report the frequency of food consumption during the past year. The study authors noted that, currently, there are no dietary assessment tools that allow collecting comprehensive dietary data over years of food consumption. Another limitation of the study is that the small sample size used makes associations by sex and ethnicity difficult.

9.3.2.7 Fox et al. (2004)—Feeding Infants and Toddlers Study: What Foods Are Infants and Toddlers Eating

Fox et al. (2004) used data from the 2002 *Feeding Infants and Toddlers Study* (FITS) to assess food consumption patterns in infants and toddlers. The FITS was sponsored by Gerber Products Company and was conducted to obtain current information on food and nutrient intakes of children, ages 4 to 24 months old, in the 50 states and the District of Columbia. The FITS is described in detail in Devaney et al. (2004). FITS 2002 was based on a random sample of 3,022 infants and toddlers for which dietary intake data were collected by telephone from their parents or

caregivers between March and July 2002. An initial recruitment and household interview was conducted, followed by an interview to obtain information on intake based on 24-hour recall. The interview also addressed growth, development, and feeding patterns. A second dietary recall interview was conducted for a subset of 703 randomly selected respondents. The study oversampled children in the 4- to 6-month and 9- to 11-month age groups; sample weights were adjusted for nonresponse, oversampling, and undercoverage of some population groups. The response rate for the FITS 2002 was 73% for the recruitment interview. Of the recruited households, there was a response rate of 94% for the dietary recall interviews (Devaney et al., 2004).

Fox et al. (2004) analyzed the first set of 24-hour recall data collected from all study participants. For this analysis, children were grouped into six age categories: 4 to 6 months, 7 to 8 months, 9 to 11 months, 12 to 14 months, 15 to 18 months, and 19 to 24 months. Table 9-28 provides the percentage of infants and toddlers consuming different types of vegetables at least once in a day. The percentages of children eating any type of vegetable ranged from 39.9% for 4- to 6-month-olds to 81.6% for 19- to 24-month-olds. Table 9-29 provides the top five vegetables consumed by each age group. Some of the highest percentages ranged from baby food carrots (9.6%) in the 4- to 6-month-old group to French fries (25.5%) in the 19- to 24-month-old group. Table 9-30 provides the percentage of children consuming different types of fruit at least once per day. The percentages of children eating any type of fruit ranged from 41.9% to 4- to 6-month-olds to 77.2% for 12 to 14-month-olds. Table 9-31 provides information on the top five fruits eaten by infants and toddlers at least once per day. The highest percentages were for bananas among infants 9 to 24 months old, and baby food applesauce among infants 4 to 8 months old.

The advantages of this study are that the study population represented the U.S. population and the sample size was large. One limitation of the analysis done by Fox et al. (2004) was that only frequency data were provided; no information on actual intake rates was included. In addition, Devaney et al. (2004) noted several limitations associated with the FITS data. For the FITS, a commercial list of infants and toddlers was used to obtain the sample used in the study. Because many of the households could not be located and did not have children in the target population, a lower response rate than would have occurred in a true national sample was obtained (Devaney et al., 2004). In addition, the sample was likely from a higher socioeconomic status when compared with all U.S. infants in this age group (4 to 24 months old), and the

use of a telephone survey may have omitted lower income households without telephones (Devaney et al., 2004).

9.3.2.8 Ponza et al. (2004)—Nutrient Food Intakes and Food Choices of Infants and Toddlers Participating in Women, Infants, and Children (WIC)

Ponza et al. (2004) conducted a study using selected data from the 2002 FITS to assess feeding patterns, food choices, and nutrient intake of infants and toddlers participating in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). Ponza et al. (2004) evaluated FITS data for the following age groups: 4 to 6 months ($N = 862$), 7 to 11 months ($N = 1,159$), and 12 to 24 months ($N = 996$).

The foods consumed were analyzed by tabulating the percentage of infants who consumed specific foods/food groups per day (Ponza et al., 2004). Weighted data were used in all of the analyses used in the study (Ponza et al., 2004). Table 9-32 provides information on the food choices for the infants and toddlers studied. There was little difference in vegetable choices among WIC participants and nonparticipants (see Table 9-32). However, there were some differences for fruits.

An advantage of this study is that it had a relatively large sample size and was representative of the U.S. general population of infants and children. A limitation of the study is that intake values for foods were not provided. Other limitations are those associated with the FITS data, as described previously in Section 9.3.2.7.

9.3.2.9 Fox et al. (2006)—Average Portion of Foods Commonly Eaten by Infants and Toddlers in the United States

Fox et al. (2006) estimated average portion sizes consumed per eating occasion by children 4 to 24 months of age who participated in the 2002 FITS. Section 9.3.2.7 describes the FITS, which is a cross-sectional study designed to collect and analyze data on feeding practices, food consumption, and usual nutrient intake of U.S. infants and toddlers. It included a stratified random sample of 3,022 children between 4 and 24 months of age.

Using the 24-hour recall data, Fox et al. (2006) derived average portion sizes for major food groups, including fruits and vegetables. Average portion sizes for select individual foods within these major groups were also estimated. For this analysis, children were grouped into six age categories: 4 to 5 months, 6 to 8 months, 9 to 11 months, 12 to 14 months, 15 to

18 months, and 19 to 24 months. Tables 9-33 and 9-34 present the average portion sizes for fruits and vegetables for infants and toddlers, respectively.

An advantage of this study is that it had a relatively large sample size and was representative of the U.S. general population of infants and children. Limitations are those associated with the FITS data, as described previously in Section 9.3.2.7.

9.3.2.10 Mennella et al. (2006)—Feeding Infants and Toddlers Study: The Types of Foods Fed to Hispanic Infants and Toddlers

Mennella et al. (2006) investigated the types of food and beverages consumed by Hispanic infants and toddlers in comparison to the non-Hispanic infants and toddlers in the United States. The FITS 2002 data for children between 4 and 24 months of age were used for the study. The data represent a random sample of 371 Hispanic and 2,367 non-Hispanic infants and toddlers (Mennella et al., 2006). Mennella et al. (2006) grouped the infants as follows: 4 to 5 months ($N = 84$ Hispanic; 538 non-Hispanic), 6 to 11 months ($N = 163$ Hispanic; 1,228 non-Hispanic), and 12 to 24 months ($N = 124$ Hispanic; 871 non-Hispanic) of age.

Table 9-35 provides the percentages of Hispanic and non-Hispanic infants and toddlers consuming fruits and vegetables. In most instances, the percentages consuming the different types of fruits and vegetables were similar. However, 4- to 5-month-old Hispanic infants were more likely to eat fruits than non-Hispanic infants in this age group. Table 9-36 provides the top five fruits and vegetables consumed and the percentage of children consuming these foods at least once in a day. Apples and bananas were the fruits with the highest percentage of infants and toddlers consuming them in both the Hispanic and non-Hispanic study groups. Potatoes and carrots were the vegetables with the highest percentage of infants and toddlers consuming them in both study groups.

The advantage of the study is that it provides information on food preferences for Hispanic and non-Hispanic infants and toddlers. A limitation is that the study did not provide food intake data, but provided frequency-of-use data instead. Other limitations are those noted previously in Section 9.3.2.7 for the FITS data.

9.3.2.11 Colon-Ramos et al. (2009)—Differences in Fruit and Vegetable Intake among Hispanic Subgroups in California: Results from the 2005 California Health Interview Survey

Colon-Ramos et al. (2009) used data from the 2005/2006 California Health Interview Survey to look for differences in fruit and vegetable intake among

Hispanic/Latino survey participants. A total of 7,954 participants were grouped into six subgroups based on their geographic location of origin: Mexican, Central American, Caribbean, Spanish American, South American, and individuals with more than one of the other Hispanic or Latino origin groups (>1 origin). Daily intakes of seven categories of fruits and vegetables (fruit; 100% fruit juice; green leafy lettuce or salad; cooked dried beans; French fries, home fries, or hash browns; other potatoes; and other vegetables) were estimated as cup equivalents using data on frequency of consumption and estimated portion sizes.

Table 9-37 presents the mean daily intake rates for the fruit and vegetable categories in cup equivalents. Colon-Ramos observed no statistical differences between Hispanic subgroups for total fruits and vegetables, but there were some statistical differences between subgroups for cooked dried beans and other white potatoes.

The advantage of this study is that it compares intake rates between Hispanic subgroups. However, the data are presented in cup equivalents instead of in units of g/day, and the data are limited to California.

9.3.2.12 Locke et al. (2009)—Seasonal Variation in Fruit and Vegetable Consumption in a Rural Agricultural Community

Locke et al. (2009) conducted a study during 2004 and 2005 in the Lower Yakima Valley of Washington State. Its purpose was to investigate seasonal variations in fruit and vegetable consumption among Hispanic farmworkers and nonfarmworkers in a rural agricultural community, and the sources of the fruits and vegetables that were consumed by this population. Questionnaires were administered to 101 farmworker families and 100 nonfarmworker families at three different time periods corresponding to agricultural seasons for apples and pears: thinning, which occurred between June and July (summer); harvest, which occurred in September and October (fall); and the nonspray period for pesticides, which occurred in December and January (winter). Participants were asked about the fruits and vegetables that they had consumed during the previous month and whether it was purchased fresh, dried, canned, or frozen. They were also asked about whether they had obtained the produce at a grocery store, fruit stand, work, at their own or a friend's garden, or other location.

Table 9-38 presents the number and percentage of study participants that reported obtaining their produce from the various sources. The grocery store and work were the most common places where the study participants obtained their produce, but a higher

percentage of nonfarmworkers obtained their produce from the grocery store than farmworkers, and the results varied by season. Table 9-39 provides the number and percentage of study participants that consumed the various types of fruits and vegetables according to agricultural season.

The advantage of this study is that it provides information on the sources of fruits and vegetables consumed by farmworkers and nonfarmworkers and information on seasonal variations in consumption. However, data on actual intake rates are not provided and the data are limited to Washington State.

9.3.2.13 Fox et al. (2010)—Food Consumption Patterns of Young Preschoolers: Are They Starting off on the Right Path?; Siega-Riz et al. (2010)—Food Consumption Patterns of Infants and Toddlers: Where Are We Now?; Deming et al. (2014)—Infant Feeding Practices and Consumption Patterns of Children Participating in Women, Infants, and Children (WIC)

In 2008, a second FITS study was conducted (Fox et al., 2010; Siega-Riz, 2010; Deming et al., 2014). The study population included 3,273 children ages 0–47.9 months. Siega-Riz et al. (2010) described the dietary consumption patterns of 1,596 infants (4–5.9 months and 6–11.9 months) and toddlers (12–23.9 months) in the 2008 FITS. As in the 2002 FITS, parents or primary caregivers of study participants were interviewed by telephone to collect demographic and dietary information (two 24-hour dietary recalls). Food group data were used to calculate the percentage of children who consumed specific foods or food groups at least once per day. Table 9-40 provides the percentage of infants and toddlers consuming fruits and fruit juices at least once per day in 2008 (Siega-Riz et al., 2010). The percentage of infants and toddlers consuming any type of fruit and fruit juice ranged from 21.8% for the 4- to 5.9-month age group to 92.8% for the 21- to 23.9-month age group (see Table 9-41). The percentage of infants and toddlers consuming any kind of vegetable ranged from 25.9% for the 4- to 5.9-month age group to 72.4% for the 12- to 14.9-month age group (see Table 9-41). Apples and bananas were the most commonly eaten fruits among these age groups. Potatoes (sweet, mashed/whipped, and French fried/other potatoes) were the most commonly eaten vegetables (Siega-Riz et al., 2010).

Fox et al. (2010) presented similar data for 2- and 3-year-old children. The mean percentage of 2- and 3-year-old children eating any type of vegetable in a day was 70%. The most commonly eaten vegetables

were French fries and other fried potatoes (~19% of children). Approximately 87% of 2- and 3-year-olds consumed some types of fruit or juice in a day with fresh fruit being the most common type of fruit eaten (62%). The data for 2- and 3-year-olds from the 2008 FITS are provided in Tables 9-35 and 9-36.

Deming et al. (2014) used the data for children 6–11, 12–23, and 24–47 months of age from the 2008 FITS. The percentage of children consuming fruits and vegetables was estimated based on participation (N = 794) or nonparticipation (N = 2,477) in the WIC program. Deming et al. (2014) reported that a high percentage of WIC infants 6 to 8.9 months old consumed fruit or fruit juice than nonparticipants, but fewer WIC infants consumed vegetables than nonparticipants (see Table 9-42).

The limitations of these studies are that the FITS dietary data were reported as the percentage of the respondents consuming per day and not as amounts of fruits and vegetables consumed per day. However, useful information was provided for the consumption of fruits and vegetables by infants and toddlers.

9.3.2.14 Briefel et al. (2010)—*The Feeding Infants and Toddlers Study 2008; Study Design and Methods*

Briefel et al. (2010) used a subsample of the 2008 FITS data to estimate the amount of fruits and vegetables consumed per eating occasion among children ages 12–23.9 months. The data were collected as part of a “bridging” study aimed at testing the effects of changes made to the food model booklet and protocol since the 2002 FITS was conducted. A total of 123 children were included in the sample. Table 9-43 provides the mean amount consumed per eating occasion for 2008.

The advantage of the Briefel et al. (2010) study is that it provides quantitative information on the amount of fruits and vegetables consumed by eating occasion; other FITS studies provide only percentages of the population eating certain foods. Because this study was based on a subsample of the study population, the sample size is relatively small.

9.3.2.15 U.S. Department of Agriculture (USDA) (2010)—*Canned Fruit and Vegetable Consumption in the United States*

USDA’s Economic Research Service (ERS) estimated the per capita availability of canned fruits and vegetables in 2008 (USDA, 2010), using data from the ERS Food Availability Data System. The amounts of canned fruits and vegetables were assumed to be “proxies” for the amounts actually consumed. According to USDA (2010), “In the Food Availability

Data System, food available for domestic consumption is calculated as a residual. That is, for a given year, the total supply is the sum of production, imports, and beginning inventories; from this amount, exports, farm and industrial uses, and ending stocks are subtracted, leaving domestic consumption as the remainder.” Because food availability data overestimate the amount of food actually ingested, the food availability data were adjusted to account for “the amount of food lost at the market and consumer levels (e.g., plate waste and spoilage).” For the purposes of developing these estimates, “canned” fruits and vegetables were defined as those marketed in traditional airtight, shelf-stable metal cans and containers as well as other newer and increasingly popular types of airtight containers, such as single-serving plastic cups.

Table 9-44 provides the 2008 estimated per capita availability of canned fruits and vegetables, adjusted for losses. The most popular canned fruits and canned vegetables were apples and applesauce and tomatoes, respectively.

This study provides data for canned fruits and vegetables. However, the data are based on the food supply (or the disappearance of food into the food marketing system). Because the data are based on economic consumption and spending estimates, they may not be entirely representative of actual intake.

9.3.2.16 Demydas (2011)—*Consumer Segmentation Based on the Level and Structure of Fruit and Vegetable Intake: An Empirical Evidence for U.S. Adults from the National Health and Nutrition Examination Survey (NHANES) 2005–2006*

Demydas (2011) identified adult intake patterns on the basis of the degree of processing of the consumed fruits and vegetables using a clustering approach. The sample population consisted of 2,444 nonpregnant/nonlactating adults, aged 20–59 years, taken from the 2005–2006 NHANES. Two 24-hour dietary recalls were used to collect fruit and vegetable intake from each respondent. For statistical analysis, a two-stage clustering procedure was applied, identifying groups of subjects with similar fruit and vegetable consumption patterns. The fruit subgroups, arranged by the degree of processing, were raw, juice, and canned/frozen/dried/dessert. The vegetable subgroups were: raw, cooked, mixed dishes, and fried.

The mean daily fruit and vegetable intake was 359.4 g for all consumers, and intake dropped to 285.1 g when fruit juice was excluded (see Table 9-45). The major contributors to the fruit group were fruit juice (236.5 g/day) and raw fruit (139.3 g/day).

Three intake patterns were identified. The first group of 1,802 individuals represented the majority of the sample population (74%). This group was characterized by low intake from all of the fruit and vegetable subgroups (mean intake of 255 g/day). A large portion of this group was made up of individuals with lower education, smokers, and those that ate out often/very often. The second group was comprised of 323 individuals (13% of the sample population), and had a mean fruit and vegetable intake of 599 g/day. The second group was characterized by healthier choices (a higher consumption of raw fruits, raw vegetables, and cooked vegetables without dressings and lower intake of fried vegetables). Females, older individuals, married individuals, and those with higher education and household income were associated with this consumption pattern. The third group of 319 individuals (13% of the sample population) consumed a large amount of fruit and vegetables when fruit juice was included (700 g/day); however, this intake dropped to 284 g/day when fruit juice was excluded. This consumption pattern was associated with males, younger individuals, non-Hispanic blacks, and those with lower household incomes.

The advantages of this study are that the sample population was large and daily fruit and vegetable amounts were provided. In addition, intake for various preparation forms was included in the study. However, the study used 2-day dietary recall data, which may not be representative of longer term fruit and vegetable intake.

9.3.2.17 Arcan et al. (2014)—Dietary and Weight-Related Behaviors and Body Mass Index among Hispanic, Hmong, Somali, and White Adolescents. *J of the Academy of Nutrition and Dietetics*. 113(3): 375–383

Arcan et al. (2014) evaluated the dietary behaviors of adolescents living in an urban community in Minnesota. The purpose of the study was to assess potential differences between ethnic groups using data from the 2010 Eating and Activity among Teens (EAT) study. EAT participants self-report on a number of factors on weight-status and weight-related behaviors. For 2010, data were available for 1,672 adolescents (Hispanic [33.6%], Hmong [28.5%], Somali [6.8%], and white [31.1%]). Arcan et al. (2014) tabulated the usual daily number of servings of vegetables (excluding potatoes) and fruits (excluding fruit juices) over the previous year (see Table 9-46). Vegetable and fruit intake was low across all ethnic groups. On average, adolescents consumed 1.5 servings of vegetables and 1.3 servings of fruit per day (Arcan et al., 2014).

This study provides information on usual servings of fruits and vegetables among urban adolescents in various ethnic groups. However, the data are for a specific geographic area and may not be representative of the U.S population. Also, the data are for servings per day. No data are provided on the quantity of foods consumed per serving.

9.3.2.18 Wolfson and Bleich (2015)—Fruit and Vegetable Consumption and Food Values: National Patterns in the United States by Supplemental Nutrition Assistance Program Eligibility and Cooking Frequency

Wolfson and Bleich (2015) used data from NHANES 2007–2010 (N = 9,560) to evaluate fruit and vegetable intake among nonpregnant, nondiabetic adults, ages 20 years and older, according to household cooking frequency and participation in the Supplemental Nutrition Assistance Program (SNAP). Fruit and vegetable intake was based on 24-hour dietary recall data. Wolfson and Bleich (2015) defined fruits and vegetables as total fruits/vegetables and fresh fruits/vegetables. Total fruits and vegetables included those that were raw, fresh, frozen, canned, dried, and pickled, and fresh fruits/vegetables included only those that were fresh, raw, or cooked from raw. Neither white potatoes nor sauces (e.g., tomato sauce) were included in the vegetable category. Responses to the question, “During the past seven days, how many times did you or someone else in your family cook food for dinner or supper at home?” were used to assess cooking frequency. For each survey respondent, SNAP status was categorized in one of three ways: receiving SNAP, income-eligible but not receiving SNAP, or income-ineligible for SNAP, and was based on self-reported participation, or family income. Table 9-47 provides mean consumer-only fruit and vegetable intake rates based on cooking frequency and SNAP status. According to Wolfson and Bleich (2015), the “overall results show few differences by SNAP status suggesting that income may not be a primary barrier to produce consumption.” Also, “Frequent cooking (>6 times/week) was associated with increased volume of consumption of fresh vegetables only among those ineligible for SNAP.”

This study provides information on fruit and vegetable intake by SNAP status and cooking frequency. As indicated previously, studies based on 24-hour dietary recall data may not be representative of longer term fruit and vegetable intake.

9.3.2.19 Guerrero et al. (2016)—Racial and Ethnic Disparities in Dietary Intake among California Children

Guerrero et al. (2016) used data for 15,902 children, ages 2–11 years, from the 2007 and 2009 California Health Interview Survey (CHIS) to assess differences in fruit and vegetable intake based on race and ethnicity. The CHIS is a population-based telephone survey, designed to be representative of California's population. In addition to collecting demographic data, participants also respond to a variety of health-related questions. For children, responses are provided by their caregivers. Examples of questions related to the children's intake include: "Yesterday, how many servings of fruit, such as an apple or banana, did he/she eat?" and "Yesterday, how many glasses of fruit juice, such as orange or apple juice, did he/she drink?" Guerrero et al. (2016) evaluated the response data for four race/ethnic groups: white, Latino, African American, and Asian. The Latino and Asian groups were further subdivided according to the language in which the survey was administered (e.g., English or Spanish for Latinos). Table 9-48 provides data on the percentage of individuals in each of these groups that consumed less than 2 servings of fruit or vegetables in a day, and ≥ 2 serving of fruit juice in a day.

This study provides information on percentages of race/ethnic groups consuming less (or more) than a predefined number of servings of fruits, vegetables, or fruit juices in a day. No intake data in g/day or g/kg-day are provided. Also, these data are based on California's population and may not be representative of the general population of the United States.

9.3.3 Pregnant and Lactating Women

EPA estimated food intake rates for pregnant, lactating, and all women of child-bearing age (13 to <50 years) using data from the NHANES for the years 2005 to 2010 and the FCID Consumption Calculator available at <http://fcid.foodrisk.org/>, as described in Section 9.3.1.1. NHANES 2005–2010 collected data on dietary recall of foods eaten over the previous 24-hour period on two nonconsecutive days. Two-day data were available for 426 pregnant women, 101 lactating women, and 5,543 women of child-bearing age (13 to <50 years). EPA's FCID converted the NHANES "as eaten" food consumption data into consumption of individual fruit and vegetable commodities, as described in Section 9.3.1.1, and the data were weighted according to sampling weights provided for Years 2005 to 2010. Two-day average intake rates were calculated for each survey respondent for total fruits and total vegetables, and for

a variety of individual fruits and vegetables. Summary statistics were calculated for the populations of pregnant, lactating, and females of child-bearing age (i.e., 13 to <50 years) on both a consumer-only and on a per capita basis. Table 9-49 provides summary statistics for per capita intake of total fruits and total vegetables, and Table 9-50 provides the same data on a consumer-only basis. Table 9-51 provides data on individual fruits and vegetables, and Table 9-52 provides data on exposed and protected fruits and vegetables.

Lactating women had a slightly higher per capita mean intake of total vegetables (2.9 g/kg-day) than pregnant women (2.8 g/kg-day) and women of child-bearing years (2.4 mg/kg-day) (see Table 9-49). The per capita consumption of total fruits for lactating women (1.9 mg/kg-day) was also slightly higher than that of pregnant women (1.8 g/kg-day) and women of child-bearing years (1.1 mg/kg-day) (see Table 9-49).

As indicated in Section 9.3.1.1, an advantage of using the U.S. EPA's analysis of NHANES data is that it was designed to be representative of the U.S. population. The data set used in this analysis used 6 years of intake data combined. However, the sample sizes for pregnant and lactating women were relatively small, and short-term dietary data may not accurately reflect long-term eating patterns. This is particularly true for the tails (extremes) of the distribution of food intake.

Limited data are available on the differences in food intake rates between pregnant and nonpregnant women, based on race, ethnicity, and demographic variables. Dubowitz et al. (2007) conducted a study in a multiethnic sample of 662 low-income, postpartum women in the Boston, MA metropolitan area and found that foreign-born women ate 2.5 more servings of fruits and vegetables than women born in the United States. Leslie et al. (2012) observed differences in fruits and vegetables servings between low and high socioeconomic position among breastfeeding mothers in Melbourne, Australia. Crozier et al. (2009) collected dietary data using a food frequency questionnaire for 2,270 women in early pregnancy (11.4–12.3 weeks gestation); 2,649 women in late pregnancy (34.3–34.9 weeks gestation); and 12,572 nonpregnant women in Southampton, U.K. Data on the consumption of 48 foods or food groups were collected. During early pregnancy, intake of 21 foods or food groups increased, including: fruits and fruit juices, and dried fruit. Intake of 10 foods or food groups decreased during pregnancy, including: salad vegetables, other vegetables, and vegetable dishes (Crozier et al., 2009). Although these results indicate that fruit and vegetable intake rates may change over the course of pregnancy, the consumption

patterns or food choices observed in this study may not be representative of pregnant women in the United States. Also, while there may be differences in food choices over the course of pregnancy, the data are insufficient to draw specific conclusions. This limitation may need to be considered when assessing exposure among pregnant women.

9.4. CONVERSION BETWEEN WET- AND DRY-WEIGHT INTAKE RATES

The intake data presented in this chapter are reported in units of wet weight (i.e., as-consumed or edible portion uncooked fruits and vegetables consumed per day or per eating occasion). However, data on the concentration of contaminants in fruits and vegetables may be reported in units of either wet or dry weight (e.g., mg contaminant per gram dry weight of fruits and vegetables). It is essential that exposure assessors be aware of this difference so that they may ensure consistency between the units used for intake rates and those used for concentration data (i.e., if the contaminant concentration is measured in dry weight of fruits and vegetables, then the dry-weight units should be used for their intake values).

If necessary, wet-weight (e.g., as-consumed) intake rates may be converted to dry-weight intake rates using the moisture content percentages presented in Table 9-53 (USDA, 2007) or Table 9-54 (Popkin et al., 2010) and the following equation:

$$IR_{dw} = IR_{ww} \left[\frac{100 - W}{100} \right] \quad (\text{Eqn. 9-1})$$

where:

IR_{dw} = dry-weight intake rate,
 IR_{ww} = wet-weight intake rate, and
 W = percentage water content.

Alternatively, dry-weight residue levels in fruits and vegetables may be converted to wet-weight residue levels for use with wet-weight (e.g., as-consumed) intake rates as follows:

$$C_{ww} = C_{dw} \left[\frac{100 - W}{100} \right] \quad (\text{Eqn. 9-2})$$

where:

C_{ww} = wet-weight concentration,
 C_{dw} = dry-weight concentration, and

W = percentage water content.

Table 9-53 presents moisture data for selected fruits and vegetables taken from USDA (2007). Table 9-54 provides additional data on the water content of foods based on data from Popkin et al. (2010).

^a Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption.														

Table 9-3. Per Capita 2-Day Average^a Intake of Total Fruits^b and Total Vegetables^c Based on 2005–2010 National Health and Nutrition Examination Survey (NHANES) (g/kg-day, edible portion, uncooked weight)^d (Continued)

^b	Total fruits includes: acerola; apple, dried; apple, dried-baby food; apple, fruit with peel; apple, peeled fruit; apple, peeled fruit-baby food; apple, sauce; apple, sauce-baby food; apricot; apricot, dried; apricot-baby food; avocado; banana; banana, dried; banana, dried-baby food; banana-baby food; blackberry; blueberry; blueberry-baby food; boysenberry; breadfruit; canistel; cherimoya; cherry; cherry-baby food; citrus hybrids; crabapple; cranberry; cranberry, dried; cranberry-baby food; currant; currant, dried; date; dragon fruit; eggplant; elderberry; feijoa; fig; fig, dried; gooseberry; grape; grape, raisin; guava; guava-baby food; huckleberry; jackfruit; kiwifruit, fuzzy; kumquat; lemon; lemon, peel; lime; loganberry; longan; loquat; lychee; lychee, dried; mamey apple; mango; mango, dried; mango-baby food; nectarine; orange; orange, peel; papaya; papaya, dried; papaya-baby food; passionfruit; passionfruit-baby food; pawpaw; peach; peach, dried; peach, dried-baby food; peach-baby food; pear; pear, dried; pear-baby food; persimmon; pineapple; pineapple, dried; pineapple-baby food; plantain; plantain, dried; plum; plum, prune, dried; plum, prune, dried-baby food; plum, prune, fresh; plum, prune, fresh-baby food; plum-baby food; pomegranate; prickly pear fruit; pummelo; quince; raspberry; raspberry-baby food; sapote, mamey; soursoy; Spanish lime; starfruit; strawberry; strawberry-baby food; sugar apple; tamarind; tangerine.
^c	Total vegetables includes: alfalfa, seed; amaranth, leafy; arrowroot, flour; arrowroot, flour-baby food; artichoke, globe; artichoke, Jerusalem; arugula; asparagus; balsam pear; bamboo, shoots; basil, dried leaves; basil, dried leaves-baby food; basil, fresh leaves; basil, fresh leaves-baby food; bean, cowpea, succulent; bean, kidney, seed; bean, lima, seed; bean, lima, succulent; bean, mung, seed; bean, navy, seed; bean, pink, seed; bean, pinto, seed; bean, snap, succulent; bean, snap, succulent-baby food; beet, garden, roots; beet, garden, roots-baby food; beet, garden, tops; belgian endive; broccoli; broccoli raab; broccoli, Chinese; broccoli-baby food; brussels sprouts; cabbage; cabbage, Chinese, bok choy; cabbage, Chinese, mustard; cabbage, Chinese, napa; cactus; cantaloupe; cardoon; carrot; carrot-baby food; cassava; cassava-baby food; cauliflower; celeriac; celery; celery-baby food; celtuce; chayote, fruit; chickpea, flour; chickpea, seed; chickpea, seed-baby food; chicory, roots; chicory, tops; Chinese waxgourd; chive, fresh leaves; chrysanthemum, garland; cilantro, leaves; cilantro, leaves-baby food; cinnamon; cinnamon-baby food; coriander, seed; coriander, seed-baby food; dandelion, leaves; dasheen, corm; dasheen, leaves; dill, seed; dillweed; fennel, Florence; garlic, bulb; garlic, bulb-baby food; ginger; ginger, dried; ginger-baby food; ginseng, dried; grape, leaves; guar, seed; guar, seed-baby food; herbs, other; herbs, other-baby food; kale; kohlrabi; leek; lemongrass; lettuce, head; lettuce, leaf; marjoram; marjoram-baby food; okra; onion, bulb; onion, bulb, dried; onion, bulb, dried-baby food; onion, bulb-baby food; onion, green; palm heart, leaves; parsley, dried leaves; parsley, dried leaves-baby food; parsley, leaves; parsley, turnip rooted; parsnip; parsnip-baby food; pea, dry; pea, dry-baby food; pea, edible podded, succulent; pea, pigeon, seed; pea, pigeon, succulent; pea, succulent; pea, succulent-baby food; pepper, bell; pepper, bell, dried; pepper, bell, dried-baby food; pepper, bell-baby food; pepper, black and white; pepper, black and white-baby food; pepper, nonbell; pepper, nonbell, dried; pepper, nonbell-baby food; peppermint; potato, chips; potato, dry (granules/flakes); potato, dry (granules/flakes)-baby food; potato, flour; potato, flour-baby food; potato, tuber, without peel; potato, tuber, without peel-baby food; potato, tuber, with peel; potato, tuber, with peel-baby food; pumpkin; radicchio; radish, oriental, roots; radish, oriental, tops; radish, roots; radish, tops; rape greens; rhubarb; rutabaga; salsify, roots; salsify, tops; savory; seaweed; seaweed-baby food; shallot, bulb; soybean, flour; soybean, flour-baby food; soybean, seed; spices, other; spices, other-baby food; squash, summer; squash, summer-baby food; squash, winter; squash, winter-baby food; sweet potato; sweet potato-baby food; Swiss chard; tanager, corm; tomatillo; tomato; tomato, dried; tomato, dried-baby food; tomato, paste; tomato, paste-baby food; tomato, puree; tomato, puree-baby food; tomato-baby food; tree tomato; turmeric; turnip, greens; turnip, roots; water chestnut; watercress; watermelon; yam bean; yam, true.
^d	For more information on the recipes used to convert the foods people reported eating to the quantities of agricultural commodities eaten, refer to the Frequently Asked Questions at http://fcid.foodrisk.org/ .
^e	Represents the percentage of individuals consuming these foods at least once over the 2-day survey period. Rounded to whole numbers; thus, values of 100 percent mean that ≥99.5 percent of the population consumed the foods during the 2-day survey period.
^f	Estimates are less statistically reliable based on guidance published in the Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations (NCHS, 1993).
HNIS	= Human Nutrition Information Service.
N	= Sample size.
SE	= Standard error.

^a Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption. Single day rates can be generated using <http://fcid.foodrisk.org/>.

^b For more information on the recipes used to convert the foods people reported eating to the quantities of agricultural commodities eaten, refer to the Frequently Asked Questions at <http://fcid.foodrisk.org/>.

Table 9-5. Per Capita 2-Day Average^a Intake of Individual Fruits and Vegetables Based on the 2005–2010 National Health and Nutrition Examination Survey (NHANES) (g/kg-day, edible portion, uncooked weight)^b (Continued)

c	Apples: apple, dried; apple, dried-baby food; apple, fruit with peel; apple, peeled fruit; apple, peeled fruit-baby food; apple, sauce; apple, sauce-baby food.
d	Asparagus: asparagus.
e	Bananas: banana; banana, dried; banana, dried-baby food; banana-baby food.
f	Beans: bean, black, seed; bean, broad, seed; bean, broad, succulent; bean, cowpea, seed; bean, cowpea, succulent; bean, great northern, seed; bean, kidney, seed; bean, lima, seed; bean, lima, succulent; bean, mung, seed; bean, navy, seed; bean, pink, seed; bean, pinto, seed; bean, snap, succulent; bean, snap, succulent-baby food.
g	Beets: beet, garden, roots; beet, garden, roots-baby food; beet, garden, tops.
h	Berries and small fruits: blackberry; blueberry; blueberry-baby food; boysenberry; cranberry; cranberry, dried; cranberry-baby food; currant; currant, dried; elderberry; gooseberry; grape; grape, leaves; grape, raisin; huckleberry; kiwifruit, fuzzy; loganberry; mulberry; raspberry; raspberry-baby food; strawberry; strawberry-baby food.
i	Broccoli: broccoli; broccoli-baby food.
j	Bulb vegetables: chive, fresh leaves; garlic, bulb; garlic, bulb-baby food; leek; onion, bulb; onion, bulb, dried; onion, bulb, dried-baby food; onion, bulb-baby food; onion, green; shallot, bulb.
k	Cabbage: cabbage; cabbage, Chinese, mustard; cabbage, Chinese, napa.
l	Carrots: carrot.
m	Citrus fruits: citron; citrus hybrids; grapefruit; kumquat; lemon; lemon, peel; lime; orange; orange, peel; pummelo; tangerine.
n	Corn: corn, field, bran; corn, field, flour; corn, field, flour-baby food; corn, field, meal; corn, field, meal-baby food; corn, field, starch; corn, field, starch-baby food; corn, pop; corn, sweet; corn, sweet-baby food.
o	Cucumbers: cucumber.
p	Cucurbit vegetables: balsam pear; cantaloupe; chayote, fruit; Chinese waxgourd; cucumber; honeydew melon; pumpkin; pumpkin, seed; squash, summer; squash, summer-baby food; squash, winter; squash, winter-baby food; watermelon.
q	Fruiting vegetables: eggplant; okra; pepper, bell; pepper, bell, dried; pepper, bell, dried-baby food; pepper, bell-baby food; pepper, nonbell; pepper, nonbell, dried; pepper, nonbell-baby food; tomatillo; tomato; tomato, dried; tomato, dried-baby food; tomato, paste; tomato, paste-baby food; tomato, puree; tomato, puree-baby food; tomato-baby food.
r	Leafy vegetables (brassica and nonbrassica): amaranth, leafy; arugula; beet, garden, tops; belgium endive; broccoli; broccoli raab; broccoli, Chinese; broccoli-baby food; brussels sprouts; cabbage; cabbage, Chinese, bok choy; cabbage, Chinese, mustard; cabbage, Chinese, napa; cardoon; cauliflower; celery; celery-baby food; celtuce; chicory, tops; chrysanthemum, garland; collards; cress, garden; cress, upland; dandelion, leaves; dasheen, leaves; endive; fennel, florence; kale; kohlrabi; lettuce, head; lettuce, leaf; mustard greens; parsley, leaves; radicchio; radish, oriental, tops; radish, tops; rape greens; rhubarb; salsify, tops; seaweed; seaweed-baby food; spinach; spinach-baby food; Swiss chard; turnip, greens; watercress.
s	Legume vegetables: bean, black, seed; bean, broad, seed; bean, broad, succulent; bean, cowpea, seed; bean, cowpea, succulent; bean, great northern, seed; bean, kidney, seed; bean, lima, seed; bean, lima, succulent; bean, mung, seed; bean, navy, seed; bean, pink, seed; bean, pinto, seed; bean, snap, succulent; bean, snap, succulent-baby food; chickpea, flour; chickpea, seed; chickpea, seed-baby food; guar, seed; guar, seed-baby food; lentil, seed; pea, dry; pea, dry-baby food; pea, edible podded, succulent; pea, pigeon, seed; pea, pigeon, succulent; pea, succulent; pea, succulent-baby food; soybean, seed; soybean, soy milk; soybean, soy milk-baby food or infant formula.
t	Lettuce: lettuce, head; lettuce, leaf.
u	Onions: onion, bulb; onion, bulb, dried; onion, bulb, dried-baby food; onion, bulb-baby food; onion, green.
v	Peaches: peach; peach, dried; peach, dried-baby food; peach-baby food.
w	Pears: pear; pear, dried; pear-baby food.
x	Peas: pea, dry; pea, dry-baby food; pea, edible podded, succulent; pea, pigeon, seed; pea, pigeon, succulent; pea, succulent; pea, succulent-baby food.
y	Pome fruits: apple, dried; apple, dried-baby food; apple, fruit with peel; apple, peeled fruit; apple, peeled fruit-baby food; apple, sauce; apple, sauce-baby food; crabapple; loquat; pear; pear, dried; pear-baby food; quince.
z	Pumpkin: pumpkin; pumpkin, seed.

Table 9-5. Per Capita 2-Day Average^a Intake of Individual Fruits and Vegetables Based on the 2005–2010 National Health and Nutrition Examination Survey (NHANES) (g/kg-day, edible portion, uncooked weight)^b (Continued)

aa	Root and tuber vegetables: arrowroot, flour; arrowroot, flour-baby food; artichoke, Jerusalem; beet, garden, roots; beet, garden, roots-baby food; beet, garden, tops; beet, sugar; beet, sugar-baby food; burdock; carrot; carrot-baby food; cassava; cassava-baby food; celeriac; chicory, roots; dasheen, corm; ginger; ginger, dried; ginger-baby food; ginseng, dried; horseradish; parsley, turnip rooted; parsnip; parsnip-baby food; potato, chips; potato, dry (granules/flakes); potato, dry (granules/flakes)-baby food; potato, flour; potato, flour-baby food; potato, tuber, without peel; potato, tuber, without peel-baby food; potato, tuber, with peel; potato, tuber, with peel-baby food; radish, Oriental, roots; radish, roots; rutabaga; sweet potato; sweet potato-baby food; tanier, corm; turmeric; turnip, roots; water chestnut; yam bean; yam, true.
bb	Stalk and stem vegetable and edible fungi: artichoke, globe; asparagus; bamboo, shoots; mushroom; palm heart, leaves.
cc	Stone fruits: apricot; apricot, dried; apricot-baby food; cherry; cherry-baby food; nectarine; peach; peach, dried; peach, dried-baby food; peach-baby food; plum; plum, prune, dried; plum, prune, dried-baby food; plum, prune, fresh; plum, prune, fresh-baby food; plum-baby food.
dd	Strawberries: strawberry; strawberry-baby food.
ee	Tomatoes: tomato; tomato, dried; tomato, dried-baby food; tomato, paste; tomato, paste-baby food; tomato, puree; tomato, puree-baby food; tomato-baby food.
ff	Tropical fruits: acerola; bamboo, shoots; banana; banana, dried; banana, dried-baby food; banana-baby food; breadfruit; canistel; cherimoya; date; dragon fruit; feijoa; fig; fig, dried; guava; guava-baby food; jackfruit; longan; lychee; lychee, dried; mamey apple; mango; mango, dried; mango-baby food; papaya; papaya, dried; papaya-baby food; passionfruit; passionfruit-baby food; pawpaw; pineapple; pineapple, dried; pineapple-baby food; plantain; plantain, dried; pomegranate; prickly pear fruit; sapote, mamey; sourp; Spanish lime; starfruit; sugar apple; tamarind.
gg	White potatoes: potato, chips; potato, dry (granules/flakes); potato, dry (granules/flakes)-baby food; potato, flour; potato, flour-baby food; potato, tuber, without peel; potato, tuber, without peel-baby food; potato, tuber, with peel; potato, tuber, with peel-baby food.
N	= Sample size.
PC	= Percent consuming. Represents the percentage of individuals consuming these foods at least once over the 2-day survey period. Rounded to whole numbers; thus, values of 100 percent mean that ≥ 99.5 percent of the population consumed the foods during the 2-day survey period.
SE	= Standard error.
Note:	Data for fruits and vegetables for which only small percentages of the population reported consumption may be less reliable than data for fruits and vegetables with higher percentages consuming.
Source:	Based on U.S. EPA analysis of 2005–2010 NHANES using the FCID Consumption Calculator available at http://fcid.foodrisk.org/ .

^a Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption. Single day rates can be generated using <http://fcid.foodrisk.org/>.

^b For more information on the recipes used to convert the foods people reported eating to the quantities of agricultural commodities eaten, refer to the Frequently Asked Questions at <http://fcid.foodrisk.org/>.

Table 9-6. Consumer-Only 2-Day Average^a Intake of Individual Fruits and Vegetables Based on the 2005–2010 National Health and Nutrition Examination Survey (NHANES) (g/kg-day, edible portion, uncooked weight)^b (Continued)

c	Apples: apple, dried; apple, dried-baby food; apple, fruit with peel; apple, peeled fruit; apple, peeled fruit-baby food; apple, sauce; apple, sauce-baby food.
d	Asparagus: asparagus.
e	Bananas: banana; banana, dried; banana, dried-baby food; banana-baby food.
f	Beans: bean, black, seed; bean, broad, seed; bean, broad, succulent; bean, cowpea, seed; bean, cowpea, succulent; bean, great northern, seed; bean, kidney, seed; bean, lima, seed; bean, lima, succulent; bean, mung, seed; bean, navy, seed; bean, pink, seed; bean, pinto, seed; bean, snap, succulent; bean, snap, succulent-baby food.
g	Beets: beet, garden, roots; beet, garden, roots-baby food; beet, garden, tops.
h	Berries and small fruits: blackberry; blueberry; blueberry-baby food; boysenberry; cranberry; cranberry, dried; cranberry-baby food; currant; currant, dried; elderberry; gooseberry; grape; grape, leaves; grape, raisin; huckleberry; kiwifruit, fuzzy; loganberry; mulberry; raspberry; raspberry-baby food; strawberry; strawberry-baby food.
i	Broccoli: broccoli; broccoli-baby food.
j	Bulb vegetables: chive, fresh leaves; garlic, bulb; garlic, bulb-baby food; leek; onion, bulb; onion, bulb, dried; onion, bulb, dried-baby food; onion, bulb-baby food; onion, green; shallot, bulb.
k	Cabbage: cabbage; cabbage, Chinese, mustard; cabbage, Chinese, napa.
l	Carrots: carrot.
m	Citrus fruits: citron; citrus hybrids; grapefruit; kumquat; lemon; lemon, peel; lime; orange; orange, peel; pummelo; tangerine.
n	Corn: corn, field, bran; corn, field, flour; corn, field, flour-baby food; corn, field, meal; corn, field, meal-baby food; corn, field, starch; corn, field, starch-baby food; corn, pop; corn, sweet; corn, sweet-baby food.
o	Cucumbers: cucumber.
p	Cucurbit vegetables: balsam pear; cantaloupe; chayote, fruit; Chinese waxgourd; cucumber; honeydew melon; pumpkin; pumpkin, seed; squash, summer; squash, summer-baby food; squash, winter; squash, winter-baby food; watermelon.
q	Fruiting vegetables: eggplant; okra; pepper, bell; pepper, bell, dried; pepper, bell, dried-baby food; pepper, bell-baby food; pepper, nonbell; pepper, nonbell, dried; pepper, nonbell-baby food; tomatillo; tomato; tomato, dried; tomato, dried-baby food; tomato, paste; tomato, paste-baby food; tomato, puree; tomato, puree-baby food; tomato-baby food.
r	Leafy vegetables (brassica and nonbrassica): amaranth, leafy; arugula; beet, garden, tops; belgium endive; broccoli; broccoli raab; broccoli, Chinese; broccoli-baby food; brussels sprouts; cabbage; cabbage, Chinese, bok choy; cabbage, Chinese, mustard; cabbage, Chinese, napa; cardoon; cauliflower; celery; celery-baby food; celtuce; chicory, tops; chrysanthemum, garland; collards; cress, garden; cress, upland; dandelion, leaves; dasheen, leaves; endive; fennel, florence; kale; kohlrabi; lettuce, head; lettuce, leaf; mustard greens; parsley, leaves; radicchio; radish, oriental, tops; radish, tops; rape greens; rhubarb; salsify, tops; seaweed; seaweed-baby food; spinach; spinach-baby food; Swiss chard; turnip, greens; watercress.
s	Legume vegetables: bean, black, seed; bean, broad, seed; bean, broad, succulent; bean, cowpea, seed; bean, cowpea, succulent; bean, great northern, seed; bean, kidney, seed; bean, lima, seed; bean, lima, succulent; bean, mung, seed; bean, navy, seed; bean, pink, seed; bean, pinto, seed; bean, snap, succulent; bean, snap, succulent-baby food; chickpea, flour; chickpea, seed; chickpea, seed-baby food; guar, seed; guar, seed-baby food; lentil, seed; pea, dry; pea, dry-baby food; pea, edible podded, succulent; pea, pigeon, seed; pea, pigeon, succulent; pea, succulent; pea, succulent-baby food; soybean, seed; soybean, soy milk; soybean, soy milk-baby food or infant formula.
t	Lettuce: lettuce, head; lettuce, leaf.
u	Onions: onion, bulb; onion, bulb, dried; onion, bulb, dried-baby food; onion, bulb-baby food; onion, green.
v	Peaches: peach; peach, dried; peach, dried-baby food; peach-baby food.
w	Pears: pear; pear, dried; pear-baby food.
x	Peas: pea, dry; pea, dry-baby food; pea, edible podded, succulent; pea, pigeon, seed; pea, pigeon, succulent; pea, succulent; pea, succulent-baby food.
y	Pome fruits: apple, dried; apple, dried-baby food; apple, fruit with peel; apple, peeled fruit; apple, peeled fruit-baby food; apple, sauce; apple, sauce-baby food; crabapple; loquat; pear; pear, dried; pear-baby food; quince.
z	Pumpkin: pumpkin; pumpkin, seed.

Table 9-6. Consumer-Only 2-Day Average^a Intake of Individual Fruits and Vegetables Based on the 2005–2010 National Health and Nutrition Examination Survey (NHANES) (g/kg-day, edible portion, uncooked weight)^b (Continued)

aa	Root and tuber vegetables: arrowroot, flour; arrowroot, flour-baby food; artichoke, Jerusalem; beet, garden, roots; beet, garden, roots-baby food; beet, garden, tops; beet, sugar; beet, sugar-baby food; burdock; carrot; carrot-baby food; cassava; cassava-baby food; celeriac; chicory, roots; dasheen, corm; ginger; ginger, dried; ginger-baby food; ginseng, dried; horseradish; parsley, turnip rooted; parsnip; parsnip-baby food; potato, chips; potato, dry (granules/flakes); potato, dry (granules/flakes)-baby food; potato, flour; potato, flour-baby food; potato, tuber, without peel; potato, tuber, without peel-baby food; potato, tuber, with peel; potato, tuber, with peel-baby food; radish, Oriental, roots; radish, roots; rutabaga; sweet potato; sweet potato-baby food; tanager, corm; turmeric; turnip, roots; water chestnut; yam bean; yam, true.
bb	Stalk and stem vegetable and edible fungi: artichoke, globe; asparagus; bamboo, shoots; mushroom; palm heart, leaves.
cc	Stone fruits: apricot; apricot, dried; apricot-baby food; cherry; cherry-baby food; nectarine; peach; peach, dried; peach, dried-baby food; peach-baby food; plum; plum, prune, dried; plum, prune, dried-baby food; plum, prune, fresh; plum, prune, fresh-baby food; plum-baby food.
dd	Strawberries: strawberry; strawberry-baby food.
ee	Tomatoes: tomato; tomato, dried; tomato, dried-baby food; tomato, paste; tomato, paste-baby food; tomato, puree; tomato, puree-baby food; tomato-baby food.
ff	Tropical fruits: acerola; bamboo, shoots; banana; banana, dried; banana, dried-baby food; banana-baby food; breadfruit; canistel; cherimoya; date; dragon fruit; feijoa; fig; fig, dried; guava; guava-baby food; jackfruit; longan; lychee; lychee, dried; mamey apple; mango; mango, dried; mango-baby food; papaya; papaya, dried; papaya-baby food; passionfruit; passionfruit-baby food; pawpaw; pineapple; pineapple, dried; pineapple-baby food; plantain; plantain, dried; pomegranate; prickly pear fruit; sapote, mamey; sourp; Spanish lime; starfruit; sugar apple; tamarind.
gg	White potatoes: potato, chips; potato, dry (granules/flakes); potato, dry (granules/flakes)-baby food; potato, flour; potato, flour-baby food; potato, tuber, without peel; potato, tuber, without peel-baby food; potato, tuber, with peel; potato, tuber, with peel-baby food.
N	= Sample size.
SE	= Standard error.

Table 9-7. Per Capita 2-Day Average^a Intake of Exposed and Protected^b Fruits and Vegetables Based on the 2005–2010 National Health and Nutrition Examination Survey (NHANES) (g/kg-day, edible portion, uncooked weight)^c (Continued)

^a	Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption. Single day rates can be generated using http://fcid.foodrisk.org/ .
^b	Exposed fruits and vegetables are those that are grown above ground and are likely to be contaminated by pollutants deposited on surfaces of the foods that are eaten. Protected fruits and vegetables are those that have outer protective coatings that are typically removed before consumption.
^c	For more information on the recipes used to convert the foods people reported eating to the quantities of agricultural commodities eaten, refer to the Frequently Asked Questions at http://fcid.foodrisk.org/ .
^d	Exposed fruits: acerola; apple, dried; apple, dried-baby food; apple, fruit with peel; apple, peeled fruit; apple, peeled fruit-baby food; apple, sauce; apple, sauce-baby food; apricot; apricot, dried; apricot-baby food; blackberry; blueberry; blueberry-baby food; boysenberry; canistel; cherry; cherry-baby food; crabapple; cranberry; cranberry, dried; cranberry-baby food; currant; currant, dried; date; eggplant; elderberry; fig; fig, dried; gooseberry; grape; grape, raisin; guava; guava-baby food; huckleberry; loganberry; nectarine; peach; peach, dried; peach, dried-baby food; peach-baby food; pear; pear, dried; pear-baby food; persimmon; plum; plum, prune, dried; plum, prune, dried-baby food; plum, prune, fresh; plum, prune, fresh-baby food; plum-baby food; quince; raspberry; raspberry-baby food; starfruit; strawberry; strawberry-baby food.
^e	Protected fruits: avocado; banana; banana, dried; banana, dried-baby food; banana-baby food; breadfruit; cherimoya; citrus hybrids; feijoa; jackfruit; kiwifruit, fuzzy; kumquat; lemon; lemon, peel; lime; longan; loquat; lychee; lychee, dried; mamey apple; mango; mango, dried; mango-baby food; orange; orange, peel; papaya; papaya, dried; papaya-baby food; passionfruit; passionfruit-baby food; pawpaw; pineapple; pineapple, dried; pineapple-baby food; plantain; plantain, dried; pomegranate; pummelo; sapote, mamey; soursop; Spanish lime; sugar apple; tamarind; tangerine.
^f	Exposed vegetables: alfalfa, seed; amaranth, leafy; artichoke, globe; artichoke, Jerusalem; arugula; asparagus; balsam pear; basil, dried leaves; basil, dried leaves-baby food; basil, fresh leaves; basil, fresh leaves-baby food; Belgium endive; broccoli; broccoli raab; broccoli, Chinese; broccoli-baby food; brussels sprouts; cabbage; cabbage, Chinese, bok choy; cabbage, Chinese, mustard; cabbage, Chinese, napa; cauliflower; celery; celery-baby food; celtuce; chayote, fruit; chicory, tops; chive, fresh leaves; chrysanthemum, garland; cilantro, leaves; cilantro, leaves-baby food; coriander, seed; coriander, seed-baby food; dandelion, leaves; dasheen, leaves; dill, seed; dillweed; fennel, Florence; grape, leaves; herbs, other; herbs, other-baby food; kale; lemongrass; lettuce, head; lettuce, leaf; marjoram; marjoram-baby food; okra; palm heart, leaves; parsley, dried leaves; parsley, dried leaves-baby food; parsley, leaves; pepper, bell; pepper, bell, dried; pepper, bell, dried-baby food; pepper, bell-baby food; pepper, black and white; pepper, black and white-baby food; pepper, nonbell; pepper, nonbell, dried; pepper, nonbell-baby food; peppermint; radicchio; rape greens; rhubarb; salsify, tops; savory; seaweed; seaweed-baby food; spices, other; spices, other-baby food; Swiss chard; tomatillo; tomato; tomato, dried; tomato, dried-baby food; tomato, paste; tomato, paste-baby food; tomato, puree; tomato, puree-baby food; tomato-baby food; tree Tomato; watercress.
^g	Protected vegetables: bamboo, shoots; bean, cowpea, succulent; bean, kidney, seed; bean, lima, seed; bean, lima, succulent; bean, mung, seed; bean, navy, seed; bean, pink, seed; bean, pinto, seed; bean, snap, succulent; bean, snap, succulent-baby food; cactus; cantaloupe; cardoon; cassava; cassava-baby food; chickpea, flour; chickpea, seed; chickpea, seed-baby food; Chinese waxgourd; cinnamon; cinnamon-baby food; guar, seed; guar, seed-baby food; pea, dry; pea, dry-baby food; pea, edible podded, succulent; pea, pigeon, seed; pea, pigeon, succulent; pea, succulent; pea, succulent-baby food; pumpkin; soybean, flour; soybean, flour-baby food; soybean, seed; squash, summer; squash, summer-baby food; squash, winter; squash, winter-baby food; water chestnut; watermelon.
<i>N</i>	= Sample size.
PC	= Percent consuming. Represents the percentage of individuals consuming these foods at least once over the 2-day survey period. Rounded to whole numbers; thus, values of 100 percent mean that ≥99.5 percent of the population consumed the foods during the 2-day survey period.
SE	= Standard error.
Note:	Data for fruits and vegetables for which only small percentages of the population reported consumption may be less reliable than data for fruits and vegetables with higher percentages consuming.

^a Based on USDA NFCS (1987–1988) and CSFII (1994 and 1995) data for 1 day.									
^b Intake for users only was calculated by dividing the per capita intake rate by the fraction of the population consuming fruits in a day.									
Source: USDA (1996a, b).									

Table 9-11. Per Capita Consumption of Fresh Fruits and Vegetables in 1997 ^a			
Fresh Fruits		Fresh Vegetables	
Food Item	Per Capita Consumption (g/day) ^b	Food Item	Per Capita Consumption (g/day) ^b
Citrus		Artichokes	0.6
Oranges (includes Temple oranges)	16.9	Asparagus	0.7
Tangerines and tangelos	3.0	Bell peppers	8.3
Lemons	3.4	Broccoli	6.0
Limes	1.4	Brussel sprouts	0.4
Grapefruit	7.6	Cabbage	11.8
Total fresh citrus	32.2	Carrots	15.1
		Cauliflower	1.9
Noncitrus		Celery	7.0
Apples	22.0	Sweet corn	9.2
Apricots	0.1	Cucumber	7.2
Avocados	1.6	Eggplant	0.5
Bananas	34.5	Escarole/endive	0.2
Cherries	0.6	Garlic	2.1
Cranberries	0.1	Head lettuce	28.1
Grapes	9.1	Romaine lettuce	7.0
Kiwi fruit	0.5	Onions	20.9
Mangoes	1.7	Radishes	0.5
Peaches and nectarines	6.7	Snap beans	1.6
Pears	4.1	Spinach	0.6
Pineapple	2.9	Tomatoes	20.0
Papayas	0.6	Total fresh vegetables	149.8
Plums and prunes	1.9		
Strawberries	4.9		
Melons	34.5		
Total fresh noncitrus	125.6		
Total fresh fruits	157.8		
^a	Based on retail-weight equivalent. Includes imports; excludes exports and foods grown in home gardens. Data for 1997 were used.		
^b	Original data were presented in lbs/year; data were converted to g/day by multiplying by a factor of 454 g/lb and dividing by 365 day/year.		
Source: USDA (1999a).

^a Represents the percentage of individuals consuming these foods at least once over the 2-day survey period.

N = Sample size.

SE = Standard error.

^a Represents the percentage of individuals consuming these foods at least once over the 2-day survey period.
N = Sample size.
 SE = Standard error.
 Note: Data for fruits and vegetables for which only small percentages of the population reported consumption may be less reliable than data for fruits and vegetables with higher percentages consuming.
 Source: U.S. EPA analysis of 1994–1996, 1998 CSFII.

^a Indicates a statistic that is potentially unreliable because of a small sample size and a large SE.

PC = Percentage consuming at least once in 2 days.

SE = Standard error of the mean.

N = Sample size.
