Table 9-49. Per Capita 2-Day Average^a Intake of Total Fruits^b and Total Vegetables^c: Pregnant, Lactating, and All Women of Child-Bearing Age (13 to <50 years) (g/kg-day) (Continued)

^a	Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption. Single day rates can be generated using http://fcid.foodrisk.org/ .	two
^b	Total fruits includes: acerola; apple, dried; apple, dried-baby food; apple, fruit with peel; apple, peeled fruit; apple, peeled fruit-baby food; apple, sauce; apple, sauce-baby food; apricot; apricot, dried; apricot-baby food; avocado; banana; banana, dried; banana, dried-baby food; banana-baby food; blackberry; blueberry; blueberry-baby food; boysenberry; breadfruit; canistel; cherimoya; cherry; cherry-baby food; citrus hybrids; crabapple; cranberry; cranberry, dried; cranberry-baby food; currant; currant, dried; date; dragon fruit; eggplant; elderberry; feijoa; fig; fig, dried; gooseberry; grape; grape, raisin; guava; guava-baby food; huckleberry; jackfruit; kiwifruit, fuzzy; kumquat; lemon; lemon, peel; lime; loganberry; longan; loquat; lychee; lychee, dried; mamey apple; mango; mango, dried; mango-baby food; nectarine; orange; orange, peel; papaya; papaya, dried; papaya-baby food; passionfruit; passionfruit-baby food; pawpaw; peach; peach, dried; peach, dried-baby food; peach-baby food; pear; pear, dried; pear-baby food; persimmon; pineapple; pineapple, dried; pineapple-baby food; plantain; plantain, dried; plum; plum, prune, dried; plum, prune, dried-baby food; plum, prune, fresh; plum, prune, fresh-baby food; plum-baby food; pomegranate; prickly pear fruit; pummelo; quince; raspberry; raspberry-baby food; sapote, mamey; soursop; Spanish lime; starfruit; strawberry; strawberry-baby food; sugar apple; tamarind; tangerine.	
^c	Total vegetables includes: alfalfa, seed; amaranth, leafy; arrowroot, flour; arrowroot, flour-baby food; artichoke, globe; artichoke, Jerusalem; arugula; asparagus; balsam pear; bamboo, shoots; basil, dried leaves; basil, dried leaves-baby food; basil, fresh leaves; basil, fresh leaves-baby food; bean, cowpea, succulent; bean, kidney, seed; bean, lima, seed; bean, lima, succulent; bean, mung, seed; bean, navy, seed; bean, pink, seed; bean, pinto, seed; bean, snap, succulent; bean, snap, succulent-baby food; beet, garden, roots; beet, garden, roots-baby food; beet, garden, tops; belgium endive; broccoli; broccoli raab; broccoli, Chinese; broccoli-baby food; brussels sprouts; cabbage; cabbage, Chinese, bok choy; cabbage, Chinese, mustard; cabbage, Chinese, napa; cactus; cantaloupe; cardoon; carrot; carrot-baby food; cassava; cassava-baby food; cauliflower; celeriac; celery; celery-baby food; celtuce; chayote, fruit; chickpea, flour; chickpea, seed; chickpea, seed-baby food; chicory, roots; chicory, tops; Chinese waxgourd; chive, fresh leaves; chrysanthemum, garland; cilantro, leaves; cilantro, leaves-baby food; cinnamon; cinnamon-baby food; coriander, seed; coriander, seed-baby food; dandelion, leaves; dasheen, corm; dasheen, leaves; dill, seed; dillweed; fennel, Florence; garlic, bulb; garlic, bulb-baby food; ginger; ginger, dried; ginger-baby food; ginseng, dried; grape, leaves; guar, seed; guar, seed-baby food; herbs, other; herbs, other-baby food; kale; kohlrabi; leek; lemongrass; lettuce, head; lettuce, leaf; marjoram; marjoram-baby food; okra; onion, bulb; onion, bulb, dried; onion, bulb, dried-baby food; onion, bulb-baby food; onion, green; palm heart, leaves; parsley, dried leaves; parsley, dried leaves-baby food; parsley, leaves; parsley, turnip rooted; parsnip; parsnip-baby food; pea, dry; pea, dry-baby food; pea, edible podded, succulent; pea, pigeon, seed; pea, pigeon, succulent; pea, succulent; pea, succulent-baby food; pepper, bell; pepper, bell, dried; pepper, bell, dried-baby food; pepper, bell-baby food; pepper, black and white; pepper, black and white-baby food; pepper, nonbell; pepper, nonbell, dried; pepper, nonbell-baby food; peppermint; potato, chips; potato, dry (granules/flakes); potato, dry (granules/flakes)-baby food; potato, flour; potato, flour-baby food; potato, tuber, without peel; potato, tuber, without peel-baby food; potato, tuber, with peel; potato, tuber, with peel-baby food; pumpkin; radicchio; radish, oriental, roots; radish, oriental, tops; radish, roots; radish, tops; rape greens; rhubarb; rutabaga; salsify, roots; salsify, tops; savory; seaweed; seaweed-baby food; shallot, bulb; soybean, flour; soybean, flour-baby food; soybean, seed; spices, other; spices, other-baby food; squash, summer; squash, summer-baby food; squash, winter; squash, winter-baby food; sweet potato; sweet potato-baby food; Swiss chard; taniel, corm; tomatillo; tomato; tomato, dried; tomato, dried-baby food; tomato, paste; tomato, paste-baby food; tomato, puree; tomato, puree-baby food; tomato-baby food; tree tomato; turmeric; turnip, greens; turnip, roots; water chestnut; watercress; watermelon; yam bean; yam, true.	
^d	Represents the percentage of individuals consuming these foods at least once over the 2-day survey period.	
^e	Estimates are less statistically reliable based on guidance published in the Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations (NCHS, 1993).

SUPPLEMENTAL TABLES

CODES AND DEFINITIONS USED TO DETERMINE THE VARIOUS COMMODITIES USED IN THE U.S. EPA ANALYSIS OF NATIONAL HEALTH AND NUTRITION EXAMINATION SURVEY (NHANES)-FOOD COMMODITY INTAKE DATABASE (FCID) DATA

The U.S. Environmental Protection Agency (EPA) analyses of the National Health and Nutrition Examination Survey (NHANES) 2005–2010 food consumption data analysis was performed using the NHANES-Food Commodity Intake Database (FCID) (<http://fcid.foodrisk.org/>), which converted the NHANES food items into FCID raw agricultural commodities using recipes developed by U.S. EPA. This supplement lists the FCID commodities used to generate statistics for corresponding foods and food categories as defined in the Exposure Factors Handbook (EFH). For example, “apples,” as defined here in the EFH, consists of the following seven FCID commodities: apple, dried (1100009000), apple, dried-baby food (1100009001), apple, fruit with peel (1100007000), apple, peeled fruit (1100008000), apple, peeled fruit-baby food (1100008001), apple sauce (1100011000) and apple, sauce-baby food (1100011001); apple juice is not included.

Chapter 10—Intake of Fish and Shellfish

10. INTAKE OF FISH AND SHELLFISH**10.1. INTRODUCTION**

Contaminated finfish and shellfish are potential sources of human exposure to toxic chemicals. Pollutants are carried in the surface waters but also may be stored and accumulated in the sediments as a result of complex physical and chemical processes. Finfish and shellfish are exposed to these pollutants and may become sources of contaminated food if the contaminants bioconcentrate in fish tissue or bioaccumulate through the food chain. Some chemicals (e.g., polychlorinated biphenyls and dioxins) are stored in fatty tissues, while others (e.g., mercury and arsenic) are typically found in the non-lipid components.

Accurately estimating exposure to toxic chemicals in fish requires information about the nature of the exposed population (i.e., general population, recreational fishermen, subsistence fishers) and their intake rates. For example, general population intake rates may be appropriate for assessing contaminants that are widely distributed in commercially caught fish. However, these data may not be suitable to estimate exposure to contaminants in a particular water source among recreational or subsistence fishers. Because the catch of recreational and subsistence fishermen is not "diluted" by fish from other water bodies, these individuals and their families represent the population that is most vulnerable to exposure by intake of contaminated fish from a specific location. Subsistence fishermen are those individuals who consume fresh caught fish as a major source of food. Their intake rates are generally higher than those of the general population. It should be noted that, depending on the study, the data presented in this chapter for Native American populations may or may not reflect subsistence fishing. Harper and Harris (2008), and Donatuto and Harper (2008) describe some difficulties associated with evaluating fish intake rates among Native American subsistence populations. For example, Donatuto and Harper (2008) suggest that contemporary Native American subsistence intake rates may be lower (i.e., suppressed) compared to heritage rates. Also, the intake rates among certain subsets of the Native American populations may be higher than the rate for the average Native American (Donatuto and Harper, 2008; Harper and Harris, 2008).

This chapter focuses on intake rates of fish. Note that in this section the term fish refers to both finfish and shellfish, unless otherwise noted. Intake rates for the general population, and recreational and Native American fishing populations are addressed, and data

are presented for intake rates for both marine and freshwater fish, when available. The general population studies in this chapter use the term consumer-only intake when referring to the quantity of fish and shellfish consumed by individuals during the survey period. These data are generated by averaging intake across only the individuals in the survey who consumed fish and shellfish. Per capita intake rates are generated by averaging consumer-only intakes over the entire survey population (including those individuals that reported no intake). In general, per capita intake rates are appropriate for use in exposure assessments for which average dose estimates are of interest because they represent both individuals who ate the foods during the survey period and individuals who may eat fish at some time but did not consume it during the survey period. Per capita intake, therefore, represents an average across the entire population of interest but does so at the expense of underestimating consumption for the population of fish consumers. Similarly, the discussions regarding recreationally caught fish consumption use the terms "all respondents" and "consuming anglers." "All respondents" represents both survey individuals/anglers who ate recreationally caught fish during the survey period and those that did not but may eat recreationally caught fish during other periods. "Consuming anglers" refers only to the individuals who ate fish during the survey period.

The determination to use consumer-only or per capita estimates of fish consumption in exposure assessments depends on the purpose of the assessment and on the source of the data. Both approaches can be a source of valuable insights on analyses of exposure and risk related to consumption of fish. This is because in the overall population, fish is not a frequently consumed item, and quantities may be relatively small, while in some populations, fish is consumed frequently and in large quantities. Nationwide surveys of food intake such as the Continuing Survey of Food Intake by Individuals (CSFII) or the National Health and Nutrition Examination Survey (NHANES) provide objective measures of food consumption that by design include overall, population-based estimates of fish consumption. The data from the CSFII or NHANES can be analyzed in terms of overall per capita consumption or consumers only. Although the CSFII and NHANES data are collected over short time periods, the large scale nature and design of such studies offer substantial advantages. In exposure analysis and risk assessment applications where fish intake is a concern, usually consumer-only data are of greater interest because of the relative infrequency of

Chapter 10—Intake of Fish and Shellfish

fish consumption. Both approaches are a source of valuable insights and help to provide context for the results from specialized surveys that typically focus on fish consumption. Specialized surveys are done for a variety of reasons using different methodologies that typically focus on relatively small, high-fish consuming groups. It may be important to know how results based on small, high consuming groups compare to overall estimates of consumption based on per capita data and consumer-only data. The data presented in this chapter come from a variety of sources and were collected using various methodologies. Some data come from creel surveys where fishermen are usually asked, among other things, how much they have caught and the number of family members with which they will share their catch. These data will not represent usual behavior because one cannot assume that the angler will have the same luck over time. In all likelihood, there will be variation in the amounts caught and consumed by anglers that should be considered. Other data come from mail surveys or personal or phone interviews where participants are asked to recall how much fish each family member eats over a certain period of time. In some cases, data are recorded by survey participants in a food diary. Some surveys may ask about frequency of consumption, but not the amount. Frequency of consumption data can be combined with information on amount consumed per eating occasion to estimate consumption. The recall period determines if the survey characterizes long-term (i.e., usual intake) or short-term consumption. Exposure assessors are generally interested in estimates of long-term behaviors, but longer recall periods are associated with generally higher reporting error that should be considered. If the data come from a survey where long-term or usual intake is characterized (i.e., how often does someone eat fish in a year?), then consumer-only estimates may capture day-to-day variability in consumption. On the other hand, if the survey instrument used to collect the data characterizes short-term consumption (e.g., how much was eaten in a week, how much was consumed on a particular day), then a per capita estimate may account for the fact that individuals who are not consumers during the survey period may consume fish at some point over a longer time period. Using consumer-only data from short-term surveys may tend to overestimate consumption over the long term, especially at the high end, because it would not include days where respondents do not consume fish. Overestimates of consumption could, however, be considered conservative with regard to intake of contaminants and, thus, provide the basis for measures protective of human health.

The U.S. Environmental Protection Agency (EPA) has prepared a review of and an evaluation of five different survey methods used for obtaining fish consumption data. They are

- Recall-Telephone Survey,
- Recall-Mail Survey,
- Recall-Personal Interview,
- Diary, and
- Creel Census.

Refer to U.S. EPA (1998) *Guidance for Conducting Fish and Wildlife Consumption Surveys* for more detail on these survey methods and their advantages and limitations. The type of survey used, its design, and any weighting factors used in estimating consumption should be considered when interpreting survey data for exposure assessment purposes. For surveys used in this handbook, respondents are typically adults who have reported on fish intake for themselves and for children living in their households.

Generally, surveys are either "creel" studies in which fishermen are interviewed while fishing, or broader population surveys using either mailed questionnaires or phone interviews. Both types of data can be useful for exposure assessment purposes, but somewhat different applications and interpretations are needed. In fact, results from creel studies have often been misinterpreted, due to inadequate knowledge of survey principles. Below, some basic facts about survey design are presented, followed by an analysis of the differences between creel and population-based studies.

Typical surveys seek to draw inferences about a larger population from a smaller sample of that population. This larger population, from which the survey sample is taken and to which the results of the survey are generalized, is denoted the target population of the survey. In order to generalize from the sample to the target population, the probability of being sampled must be known for each member of the target population. This probability is reflected in weights assigned to survey respondents, with weights being inversely proportional to sampling probability. When all members of the target population have the same probability of being sampled, all weights can be set to one and essentially ignored. For example, in a mail or phone study of licensed anglers, the target population is generally all licensed anglers in a particular area, and in the studies presented, the sampling probability is essentially equal for all target population members.

Chapter 10—Intake of Fish and Shellfish

In a creel study (i.e., a study in which fishermen are interviewed while fishing), the target population is anyone who fishes at the locations being studied. Generally, in a creel study, the probability of being sampled is not the same for all members of the target population. For instance, if the survey is conducted for 1 day at a site, then it will include all persons who fish there daily, but only about 1/7 of the people who fish there weekly, 1/30 of the people who fish there monthly, etc. In this example, the probability of being sampled (or inverse weight) is seen to be proportional to the frequency of fishing. However, if the survey involves interviewers revisiting the same site on multiple days, and persons are only interviewed once for the survey, then the probability of being in the survey is not proportional to frequency; in fact, it increases less than proportionally with frequency. At the extreme of surveying the same site every day over the survey period with no re-interviewing, all members of the target population would have the same probability of being sampled regardless of fishing frequency, implying that the survey weights should all equal one. On the other hand, if the survey protocol calls for individuals to be interviewed each time an interviewer encounters them (i.e., without regard to whether they were previously interviewed), then the inverse weights will again be proportional to fishing frequency, no matter how many times interviewers revisit the same site. Note that when individuals can be interviewed multiple times, the results of each interview are included as separate records in the database and the survey weights should be inversely proportional to the expected number of times that an individual's interviews are included in the database.

In the published analyses of most creel studies, there is no mention of sampling weights; by default, all weights are set to one, implying equal probability of sampling. However, because the sampling probabilities in a creel study, even with repeated interviewing at a site, are highly dependent on fishing frequency, the fish intake distributions reported for these surveys are not reflective of the corresponding target populations. Instead, those individuals with high fishing frequencies are given too big a weight, and the distribution is skewed to the right, i.e., it overestimates the target population distribution.

Price et al. (1994) explained this problem and set out to rectify it by adding weights to creel survey data; the authors used data from two creel studies (Puffer et al., 1982; Pierce et al., 1981) as examples. Price et al. (1994) used inverse fishing frequency as survey weights and produced revised estimates of median and 95th percentile intake for the above two studies. These revised estimates were

dramatically lower than the original estimates. The approach of Price et al. (1994) is discussed in more detail in Section 10.4 where the Puffer et al. (1982) and Pierce et al. (1981) studies are summarized.

When the correct weights are applied to survey data, the resulting percentiles reflect, on average, the distribution in the target population; thus, for example, an estimated 90% of the target population will have intake levels below the 90th percentile of the survey fish intake distribution. There is another way, however, of characterizing distributions in addition to the standard percentile approach; this approach is reflected in statements of the form “50% of the income is received by, for example, the top 10% of the population, which consists of individuals making more than \$100,000.” Note that the 50th percentile (median) of the income distribution is well below \$100,000. Here the \$100,000 level can be thought of as, not the 50th percentile of the population income distribution, but as the 50th percentile of the “resource utilization distribution” (see Appendix 10A for technical discussion of this distribution). Other percentiles of the resource utilization distribution have similar interpretations; e.g., the 90th percentile of the resource utilization distribution (for income) would be that level of income such that 90% of total income is received by individuals with incomes below this level and 10% by individuals with income above this level. This alternative approach to characterizing distributions is of particular interest when a relatively small fraction of individuals consumes a relatively large fraction of a resource, which is the case with regards to recreational fish consumption. In the studies of recreational anglers, this alternative approach, based on resource utilization, will be presented, where possible, in addition to the primary approach of presenting the standard percentiles of the fish intake distribution.

The recommendations for fish and shellfish ingestion rates are provided in the next section, along with summaries of the confidence ratings for these recommendations. The recommended values for the general population and for other subsets of the population are based on the key studies identified by U.S. EPA for this factor. Following the recommendations, the studies on fish ingestion among the general population (see Section 10.3), marine recreational angler populations (see Section 10.4), freshwater recreational populations (see Section 10.5), and Native American populations (see Section 10.6) are summarized. Information is provided on the key studies that form the basis for the fish and shellfish intake rate recommendations. Relevant data on ingestion of fish and shellfish are also provided. These studies are presented to provide

Chapter 10—Intake of Fish and Shellfish

the reader with added perspective on the current state-of-knowledge pertaining to ingestion of fish and shellfish among children and adults. Information on other population studies (see Section 10.7), serving size (see Section 10.8), and other factors to consider (see Section 10.9) are also presented.

10.2. RECOMMENDATIONS

Considerable variation exists in the mean and upper percentile fish consumption rates obtained from the studies presented in this chapter. This can be attributed largely to the type of water body (i.e., marine, estuarine, freshwater) and the characteristics of the survey population (i.e., general population, recreational, Native American), but other factors such as study design, method of data collection, and geographic location also play a role. Based on these study variations, fish consumption studies were classified into the following categories:

- General Population (finfish, shellfish, and total fish and shellfish combined);
- Recreational Marine Intake;
- Recreational Freshwater Intake; and
- Native American Populations

For exposure assessment purposes, the selection of intake rates for the appropriate category (or categories) will depend on the exposure scenario being evaluated.

10.2.1. Recommendations—General Population

Fish consumption rates are recommended for the general population, based on the key study presented in Section 10.3.1. The key study for estimating mean fish intake among the general population is the U.S. EPA analysis of data from the Centers for Disease Control and Prevention (CDC) NHANES 2003–2006.

Table 10-1 presents a summary of the recommended values for per capita and consumer-only intake of finfish, shellfish, and total finfish and shellfish combined. Table 10-2 provides confidence ratings for the fish intake recommendations for the general population. The U.S. EPA analysis of 2003–2006 NHANES data was conducted using childhood age groups that differed slightly from U.S. EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). However, for the purposes of the recommendations presented here, data were placed in

the standardized age categories closest to those used in the analysis.

Note that the fish intake values presented in Table 10-1 are reported as uncooked fish weights. Recipe files were used to convert, for each fish-containing food, the as-eaten fish weight consumed into an uncooked equivalent weight of fish. This is important because the concentrations of the contaminants in fish are generally measured in the uncooked samples. Assuming that cooking results in some reductions in weight (e.g., loss of moisture), and the mass of the contaminant in the fish tissue remains constant, then the contaminant concentration in the cooked fish tissue will increase.

In terms of calculating the dose (i.e., concentration times weight), actual consumption may be overestimated when intake is expressed on an uncooked basis, but the actual concentration may be underestimated when it is based on the uncooked sample. The net effect on the dose would depend on the magnitude of the opposing effects on these two exposure factors. On the other hand, if the "as-prepared" (i.e., as-consumed) intake rate and the uncooked concentration are used in the dose equation, dose may be underestimated because the concentration in the cooked fish is likely to be higher, if the mass of the contaminant remains constant after cooking. Reported weights are also more likely to reflect uncooked weight, and interpretation of advisories are likely to be in terms of uncooked weights. Although it is generally more conservative and appropriate to use uncooked fish intake rates, one should also be sure to use like measures. That is to say, avoid using raw fish concentrations and cooked weights to estimate the dose. For more information on cooking losses and conversions necessary to account for such losses, refer to Chapter 13 of this handbook.

If concentration data can be adjusted to account for changes after cooking, then the "as-prepared" (i.e., as-consumed) intake rates are appropriate. However, data on the effects of cooking on contaminant concentrations are limited, and assessors generally make the conservative assumption that cooking has no effect on the contaminant mass. The key study on fish ingestion provides intake data based on uncooked fish weights. However, relevant data on both "as-prepared" (i.e., as-consumed) and uncooked general population fish intake are also presented in this handbook. The assessor should choose the intake data that best matches the concentration data that are being used.

The NHANES data on which the general population recommendations are based, are short-term survey data and could not be used to

Chapter 10—Intake of Fish and Shellfish

estimate the distribution over the long term. Also, it is important to note that a limitation associated with these data is that the total amount of fish reported by respondents included fish from all sources (e.g., fresh, frozen, canned, domestic, international origin). The analysis of NHANES survey data used to develop the recommended intake rates in this handbook did not consider the source of the fish consumed. This type of information may be relevant for some assessments.

Recommended values should be selected that are relevant to the assessment, choosing the appropriate age groups and type of fish (i.e., finfish, shellfish, or total finfish, and shellfish). In some cases, a different study or studies may be particularly relevant to the needs of an assessment, in which case, results from that specific study or studies may be used instead of the recommended values provided here. For example, it may be advantageous to use estimates that target a particular region or geographical area, if relevant data are available. In addition, seasonal, sex, and fish species variations should be considered when appropriate, if data are available. Also, relevant data on general population fish intake in this chapter may be used if appropriate to the scenarios being assessed. For example, older data from the U.S. EPA's analysis of data from the 1994–1996 and 1998 CSFII provide intake rates for freshwater/estuarine fish and shellfish, marine fish and shellfish, and total fish and shellfish that are not available from the more recent NHANES analysis.

10.2.2. Recommendations—Recreational Marine Anglers

Table 10-3 presents the recommended values for recreational marine anglers. These values are based on the surveys of the National Marine Fisheries Service (NMFS, 1993). The values from NMFS (1993) are assumed to represent intake of marine fish among adult recreational fishers. Values represent both individuals who ate recreational fish during the survey period and those that did not, but may eat recreationally caught fish during other periods. Age-specific values were not available from this source. However, recommendations for children were estimated based on the ratios of marine fish intake for general population children to that of adults using data from U.S. EPA's analysis of CSFII data from 1994–1996 and 1998 (U.S. EPA, 2002) (see Section 10.3.2.6), multiplied by the adult recreational marine fish intake rates for the Atlantic, Gulf, and Pacific regions, using data from NMFS (1993) (see Section 10.4.1.1). The ratios of each age group to adults >18 years were calculated separately for the

means and 95th percentiles. Much of the other relevant data on recreational marine fish intake in this chapter are limited to certain geographic areas and cannot be generalized to the U.S. population as a whole. However, assessors may use the data from the relevant studies provided in this chapter if appropriate to the scenarios being assessed. Table 10-4 presents the confidence ratings for recommended recreational marine fish intake rates.

10.2.3. Recommendations—Recreational Freshwater Anglers

Recommended values are not provided for recreational freshwater fish intake because the available data are limited to certain geographic areas and cannot be readily generalized to the U.S. population of freshwater recreational anglers as a whole (see Figure 10-1). For example, factors associated with water body, climate, fishing regulations, availability of alternate fishable water bodies, and water body productivity may affect recreational fish intake rates. However, data from several relevant recreational freshwater studies are provided in this chapter. Table 10-5 summarizes data from these studies. Assessors may use these data, if appropriate to the scenarios and locations being assessed. Although recommendations are not provided, some general observations can be made. Most of the studies in Table 10-5 represent state-wide surveys of recreational anglers. These include Alabama, Connecticut, Indiana, Maine, Michigan, Minnesota, North Dakota, and Wisconsin. Consumption data from these states would include freshwater fish from rivers, lakes, and ponds. The average range of consumption for all respondents from these states varies from 5 g/day to 51 g/day. Another two studies represent consumption of fish from specific rivers. These included Savannah River in Georgia and The Clinch River in Tennessee. The consumption rates for all respondents from these two rivers ranged from 20 g/day to 70 g/day. One of the studies in Table 10-5 represents the consumption of fish from three lakes in Washington, and another represents consumption of fish from Lake Ontario. The average consumption rate for all responding adults was 10 g/day for the three Washington lakes. It can also be noted that a large percentage of recreational anglers consumed fish and shellfish during the survey period. Thus, values for all respondents and consuming anglers are fairly similar. For Lake Ontario, the average consumption rate for adults was 5 g/day.

10.2.4. Recommendations—Native American Populations

Recommended values are also not provided for Native American fish intake because the available data are limited to certain geographic areas and/or tribes and cannot be readily generalized to Native American tribes as a whole. However, data from several Native American studies are provided in this chapter and are summarized in Table 10-6. Assessors may use these data, if appropriate to the scenarios and populations being assessed. These studies were performed at various study locations among various tribes.

^a Analysis was conducted using slightly different childhood age groups than those recommended in *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). Data were placed in the standardized age categories closest to those used in the analysis.

^b Estimates are less statistically reliable based on guidance published in the *Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: NHIS/NCHS Analytical Working Group Recommendations* (NCHS, 1993).

Chapter 10—Intake of Fish and Shellfish

Table 10-2. Confidence in Recommendations for General Population Fish Intake

General Assessment Factors	Rationale	Rating
Soundness		High
<i>Adequacy of Approach</i>	The survey methodology and the analysis of the survey data were adequate. Primary data were collected and used in a secondary analysis of the data. The sample size was large.	
<i>Minimal (or Defined) Bias</i>	The response rate was adequate. The survey data were based on recent recall. Data were collected over a short duration (i.e., 2 days).	
Applicability and Utility		High
<i>Exposure Factor of Interest</i>	The key study focused on the exposure factor of interest.	
<i>Representativeness</i>	The survey was conducted nationwide and was representative of the general U.S. population.	
<i>Currency</i>	Data were derived from 2003–2006 NHANES.	
<i>Data Collection Period</i>	Data were collected for 2 non-consecutive days.	
Clarity and Completeness		High
<i>Accessibility</i>	The primary data are accessible through CDC.	
<i>Reproducibility</i>	The methodology was clearly presented; enough information was available to allow for reproduction of the results.	
<i>Quality Assurance</i>	Quality assurance of NHANES data was good; quality control of secondary analysis was good.	
Variability and Uncertainty		Medium to high for averages; low for long-term upper percentiles
<i>Variability in Population</i>	Full distributions were provided by the key study.	
<i>Uncertainty</i>	The survey was not designed to capture long-term intake and was based on recall.	
Evaluation and Review		Medium
<i>Peer Review</i>	The National Center for Health Statistics (NCHS) NHANES survey received a high level of peer review. The U.S. EPA analysis of these data has not been peer reviewed outside the Agency, but the methodology used has been peer reviewed in analysis of previous data.	
<i>Number and Agreement of Studies</i>	The number of studies is one.	
Overall Rating		Medium to High (mean) Medium (long-term upper percentiles)

Chapter 10—Intake of Fish and Shellfish

Table 10-3. Recommended Values for Recreational Marine Fish Intake

Age Group	Intake Rate ^a	
	Mean g/day ^b	95 th Percentile g/day ^b
<u>Atlantic</u>		
3 to <6 years	2.5	8.8
6 to <11 years	2.5	8.6
11 to <16 years	3.4	13
16 to <18 years	2.8	6.6
>18 years	5.6	18
<u>Gulf</u>		
3 to <6 years	3.2	13
6 to <11 years	3.3	12
11 to <16 years	4.4	18
16 to <18 years	3.5	9.5
>18 years	7.2	26
<u>Pacific</u>		
3 to <6 years	0.9	3.3
6 to <11 years	0.9	3.2
11 to <16 years	1.2	4.8
16 to <18 years	1.0	2.5
>18 years	2.0	6.8
^a	Represents intake for the recreational fishing population only. Data from U.S. EPA analysis of NMFS (1993) assumed to represent adults >18 years. Values represent both survey anglers who ate recreational fish during the survey period and those that did not, but may eat recreationally caught fish during other periods.	
^b	Recommendations for children were estimated based on the ratios of marine fish intake for general population children to that of adults using data from U.S. EPA's analysis of CSFII data (see Table 10-31), multiplied by the adult recreational marine fish intake rates for the Atlantic, Gulf, and Pacific regions, using data from NMFS (1993) (see Table 10-50). The ratios of each age group to adults >18 years were calculated separately for the means and 95 th percentiles.	

Chapter 10—Intake of Fish and Shellfish

Table 10-4. Confidence in Recommendations for Recreational Marine Fish Intake

General Assessment Factors	Rationale	Rating
Soundness		Medium
<i>Adequacy of Approach</i>	The survey methodology and the analysis of the survey data were adequate. Primary data were collected and used in a secondary analysis of the data. The sample size was large.	
<i>Minimal (or Defined) Bias</i>	The response rate was adequate. The survey data were based on recent recall.	
Applicability and Utility		Low to Medium
<i>Exposure Factor of Interest</i>	The key study was not designed to estimate individual consumption of fish. U.S. EPA obtained the raw data and estimated intake distributions by employing assumptions derived from other data sources.	
<i>Representativeness</i>	The survey was conducted in coastal states in the Atlantic, Pacific, and Gulf regions and was representative of fishing populations in these regions of the United States.	
<i>Currency</i>	The data are from a survey conducted in 1993.	
<i>Data Collection Period</i>	Data were collected in telephone interviews and direct interviews of fishermen in the field over a short time frame.	
Clarity and Completeness		Medium
<i>Accessibility</i>	The primary data are from NMFS.	
<i>Reproducibility</i>	The methodology was clearly presented; enough information was available to allow for reproduction of the results.	
<i>Quality Assurance</i>	Quality assurance of the primary data was not described. Quality assurance of the secondary analysis was good.	
Variability and Uncertainty		Low
<i>Variability in Population</i>	Mean and 95 th percentile values were provided.	
<i>Uncertainty</i>	The survey was specifically designed to estimate individual intake rates. U.S. EPA estimated intake based on an analysis of the raw data, using assumptions about the number of individuals consuming fish meals from the fish caught. Estimates for children are based on additional assumptions regarding the proportion of intake relative to the amount eaten by adults.	
Evaluation and Review		Medium
<i>Peer Review</i>	Data from NMFS (1993) were reviewed by NMFS and U.S. EPA. U.S. EPA's analysis was not peer reviewed outside of EPA.	
<i>Number and Agreement of Studies</i>	The number of studies is one.	
Overall Rating		Low to Medium (adults) Low (children)

Table 10-6. Summary of Relevant Studies on Native American Fish Intake (continued)

a	Results are reported in g/day or g/kg-day, depending on which was provided in the source material.
b	All respondents consumed fish caught in Northern Wisconsin lakes.
c	Value calculated by dividing all respondents by the percent consuming of 93%.
d	Based on uncooked fish weight.
e	Value represents consumption by Mohawk women >1 year before pregnancy. Value estimated by multiplying number of fish meals/year by the 90 th percentile meal size of 209 g/meal for general population females 20–39 years old from Smiciklas-Wright et al. (2002).
f	Based on 90 th percentile general population meal size, based on Pao et al. (1982).
g	Value represents the 90 th percentile.
-	Estimate not available.

Chapter 10—Intake of Fish and Shellfish

10.3. GENERAL POPULATION STUDIES**10.3.1. Key General Population Study****10.3.1.1. U.S. EPA Analysis of Consumption Data From 2003–2006 NHANES**

The key source of recent information on consumption rates of fish and shellfish is the U.S. CDC's NCHS' NHANES. Data from NHANES 2003–2006 have been used by the U.S. EPA, Office of Pesticide Programs (OPP) to generate per capita and consumer-only intake rates for finfish, shellfish, and total fish and shellfish combined.

NHANES is designed to assess the health and nutritional status of adults and children in the United States. In 1999, the survey became a continuous program that interviews a nationally representative sample of approximately 7,000 persons each year and examines a nationally representative sample of about 5,000 persons each year, located in counties across the country, 15 of which are visited each year. Data are released on a 2-year basis, thus, for example, the 2003 data are combined with the 2004 data to produce NHANES 2003–2004.

The dietary interview component of NHANES is called *What We Eat in America* and is conducted by the U.S. Department of Agriculture (USDA) and the U.S. Department of Health and Human Services (DHHS). DHHS' NCHS is responsible for the sample design and data collection, and USDA's Food Surveys Research Group is responsible for the dietary data collection methodology, maintenance of the databases used to code and process the data, and data review and processing. Beginning in 2003, 2 non-consecutive days of 24-hour intake data were collected. The first day is collected in-person, and the second day is collected by telephone 3 to 10 days later. These data are collected using USDA's dietary data collection instrument, the Automated Multiple Pass Method. This method provides an efficient and accurate means of collecting intakes for large-scale national surveys. It is fully computerized and uses a five-step interview. Details can be found at USDA's Agriculture Research Service (<http://www.ars.usda.gov/ba/bhnrc/fsrg>).

For NHANES 2003–2004, there were 12,761 persons selected; of these, 9,643 were considered respondents to the mobile examination center (MEC) for examination and data collection. However, only 9,034 of the MEC respondents provided complete dietary intakes for Day 1. Furthermore, of those providing the Day 1 data, only 8,354 provided complete dietary intakes for Day 2. For NHANES 2005–2006, there were 12,862 persons selected; of these, 9,950 were considered respondents

to the MEC examination and data collection. However, only 9,349 of the MEC respondents provided complete dietary intakes for Day 1. Furthermore, of those providing the Day 1 data, only 8,429 provided complete dietary intakes for Day 2.

The 2003–2006 NHANES surveys are stratified, multistage probability samples of the civilian non-institutionalized U.S. population. The sampling frame was organized using 2000 U.S. population census estimates. NHANES oversamples low-income persons, adolescents 12–19 years, persons 60 years and older, African Americans, and Mexican Americans. Several sets of sampling weights are available for use with the intake data. By using appropriate weights, data for all 4 years of the surveys can be combined. Additional information on NHANES can be obtained at <http://www.cdc.gov/nchs/nhanes.htm>.

In 2010, U.S. EPA's OPP used NHANES 2003–2006 data to update the Food Commodity Intake Database (FCID) that was developed in earlier analyses of data from the U.S. Department of Agriculture's (USDA's) CSFII (U.S. EPA, 2002; USDA, 2000). NHANES data on the foods people reported eating were converted to the quantities of agricultural commodities eaten. "Agricultural commodity" is a term used by U.S. EPA to mean plant (or animal) parts consumed by humans as food; when such items are raw or unprocessed, they are referred to as "raw agricultural commodities." For example, clam chowder may contain the commodities clams, vegetables, and spices. FCID contains approximately 553 unique commodity names and eight-digit codes. The FCID commodity names and codes were selected and defined by U.S. EPA and were based on the U.S. EPA Food Commodity Vocabulary (<http://www.epa.gov/pesticides/foodfeed/>).

Intake rates were generated for finfish, shellfish, and finfish and shellfish combined. These intake rates represent intake of all forms of the food (e.g., both self-caught and commercially caught) for individuals who provided data for 2 days of the survey. Individuals who did not provide information on body weight or for whom identifying information was unavailable were excluded from the analysis. Two-day average intake rates were calculated for all individuals in the database for each of the food items/groups. Note that if the person reported consuming fish on only one day of the survey, their 2-day average would be half the amount reported for the one day of consumption. These average daily intake rates were divided by each individual's reported body weight to generate intake rates in units of grams per kilogram of body weight per day (g/kg-

Chapter 10—Intake of Fish and Shellfish

day). The data were weighted according to the 4-year, 2-day sample weights provided in NHANES 2003–2006 to adjust the data for the sample population to reflect the national population.

Summary statistics were generated on a consumer-only and on a per capita basis. Summary statistics, including number of observations, percentage of the population consuming fish, mean intake rate, and standard error of the mean intake rate were calculated for finfish, shellfish, and finfish and shellfish combined, for both the entire population and consumers only (see Table 10-7 to Table 10-12). Data were provided for the following age groups: birth to <1 year, 1 to 2 years, 3 to 5 years, 6 to 12 years, 13 to 19 years, 20 to 49 years, and ≥ 50 years. Because these data were developed for use in U.S. EPA's pesticide registration program, the childhood age groups used are slightly different than those recommended in U.S. EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005).

The results are presented in units of g/kg-day (same as the CSFII data). Thus, use of these data in calculating potential dose does not require the body-weight factor to be included in the denominator of the average daily dose equation. It should be noted that converting these intake rates into units of g/day by multiplying by a single average body weight is inappropriate because individual intake rates were indexed to the reported body weights of the survey respondents. Also, it should be noted that the distribution of average daily intake rates generated using short-term data (e.g., 2-day) does not necessarily reflect the long-term distribution of average daily intake rates. The distributions generated from short-term and long-term data will differ to the extent that each individual's intake varies from day to day; the distributions will be similar to the extent that individuals' intakes are constant from day to day. Because of the increased variability of the short-term distribution, the short-term upper percentiles shown here may overestimate the corresponding percentiles of the long-term distribution.

The advantages of using the U.S. EPA's analysis of NHANES data are that it provides distributions of intake rates for various age groups of children and adults, normalized by body weight. The data set was designed to be representative of the U.S. population, and includes 4 years of intake data combined. Another advantage is the currency of the data. The NHANES data are from 2003–2006. However, short-term consumption data may not accurately reflect long-term eating patterns and may

under-represent infrequent consumers of a given fish species. This is particularly true for the tails (extremes) of the distribution of food intake. Because these are 2-day averages, consumption estimates at the upper end of the intake distribution may be underestimated if these consumption values are used to assess acute (i.e., short-term) exposures. Also, the analysis was conducted using slightly different childhood age groups than those recommended in U.S. EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). However, given the similarities in the age groups used, the data should provide suitable intake estimates for the age groups of interest.

10.3.2. Relevant General Population Studies

10.3.2.1. SRI (1980)—Seafood Consumption Study

SRI (1980) utilized data that were originally collected in a study funded by the Tuna Research Foundation (TRF) to estimate fish intake rates. The TRF study of fish consumption was performed by the National Purchase Diary during the period of September, 1973 to August, 1974. The data tapes from this survey were obtained by the NMFS, which later, along with the Food and Drug Administration, USDA and TRF, conducted an intensive effort to identify and correct errors in the database. SRI (1980) summarized the TRF survey methodology and used the corrected tape to generate fish intake distributions for various population groups.

The TRF survey sample included 9,590 families, of which 7,662 (25,162 individuals) completed the questionnaire, a response rate of 80%. The survey was weighted to represent the U.S. population.

The population of fish consumers represented 94% of the U.S. population. For this population of "fish consumers," SRI (1980) calculated means and percentiles of fish consumption by demographic variables (age, sex, race, census region, and community type) and overall (see Table 10-13). The overall mean fish intake rate among fish consumers was calculated at 14.3 g/day and the 95th percentile at 41.7 g/day.

Table 10-14 presents the distribution of fish consumption for females and males, by age; this table give the percentages of females/males in a given age bracket with intake rates within various ranges. Table 10-15 presents mean total fish consumption by fish species.

The TRF survey data were also utilized by Rupp et al. (1980) to generate fish intake distributions for three age groups (1 to 11, 12 to 18, and 18 to 98 years) within each of the 9 census regions and for

Chapter 10—Intake of Fish and Shellfish

the entire United States. Separate distributions were derived for freshwater finfish, saltwater finfish, and shellfish. Ruffle et al. (1994) used the percentiles data of Rupp et al. (1980) to estimate the best-fitting lognormal parameters for each distribution. Table 10-16 presents the optimal lognormal parameters, the mean (μ) and standard deviation (σ). These parameters can be used to determine percentiles of the corresponding distribution of average daily fish consumption rates through the relation $(p) = \exp[\mu + z(p)\sigma]$ where $DCR(p)$ is the p^{th} percentile of the distribution of average daily fish consumption rates and $z(p)$ is the z -score associated with the p^{th} percentile (e.g., $z(50) = 0$). The mean average daily fish consumption rate is given by $\exp[\mu + 0.5\sigma^2]$.

The advantages of the TRF data survey are that it was a large, nationally representative survey with a high response rate (80%) and was conducted over an entire year. In addition, consumption was recorded in a daily diary over a 1-month period; this format should be more reliable than one based on 1-month recall. The upper percentiles presented are derived from 1 month of data and are likely to overestimate the corresponding upper percentiles of the long-term (i.e., 1 year or more) average daily fish intake distribution. Similarly, the standard deviation of the fitted lognormal distribution probably overestimates the standard deviation of the long-term distribution. However, the period of this survey (1 month) is considerably longer than those of many other consumption studies, including the USDA National Food Consumption Surveys, CSFII, and NHANES, which report consumption over a 2-day to 1-week period. Another obvious limitation of this database is that it is now over 30 years out of date. Ruffle et al. (1994) considered this shortcoming and suggested that one may wish to shift the distribution upward to account for the recent increase in fish consumption, though CSFII has shown little change in g/day fish consumption from 1978 to 1996. Adding $\ln(1 + x/100)$ to the log mean μ will shift the distribution upward by $x\%$ (e.g., adding $0.22 = \ln(1.25)$ increases the distribution by 25%). Although the TRF survey distinguished between recreationally and commercially caught fish, SRI (1980), Rupp et al. (1980), and Ruffle et al. (1994) [which was based on Rupp et al. (1980)] did not present analyses by this variable.

10.3.2.2. Pao et al. (1982)—Foods Commonly Eaten by Individuals: Amount per Day and per Eating Occasion

The USDA 1977–1978 Nationwide Food Consumption Survey (NFCS) consisted of a household and individual component. For the individual component, all members of surveyed households were asked to provide three consecutive days of dietary data. For the first day's data, participants supplied dietary recall information to an in-home interviewer. Second and 3rd day dietary intakes were recorded by participants. A total of 15,000 households were included in the 1977–1978 NFCS, and about 38,000 individuals completed the 3-day diet records. Fish intake was estimated based on consumption of fish products identified in the NFCS database according to NFCS-defined food codes. These products included fresh, breaded, floured, canned, raw, and dried fish, but not fish mixtures or frozen plate meals.

Pao et al. (1982) used the data from this survey set to calculate per capita fish intake rates. However, because these data are now almost 30 years out of date, this analysis is not considered key with respect to assessing per capita intake (the average quantity of fish consumed per fish meal should be less subject to change over time than is per capita intake). In addition, fish mixtures and frozen plate meals were not included in the calculation of fish intake. The per capita fish intake rate reported by Pao et al. (1982) was 11.8 g/day. The 1977–1978 NFCS was a large and well-designed survey, and the data are representative of the U.S. population.

10.3.2.3. USDA (1993)—Food and Nutrient Intakes by Individuals in the United States, 1 Day, 1987–1988: Nationwide Food Consumption Survey 1987–1988

The USDA 1987–1988 (NFCS) also consisted of a household and individual component. For the individual component, each member of a surveyed household was interviewed (in person) and asked to recall all foods eaten the previous day; the information from this interview made up the “1-day data” for the survey. In addition, members were instructed to fill out a detailed dietary record for the day of the interview and the following day. The data for this entire 3-day period made up the “3-day diet records.” A statistical sampling design was used to ensure that all seasons, geographic regions of the United States, and demographic and socioeconomic groups were represented. Sampling weights were used to match the population distribution of

Chapter 10—Intake of Fish and Shellfish

13 demographic characteristics related to food intake (USDA, 1992).

Total fish intake was estimated based on consumption of fish products identified in the NFCS database according to NFCS-defined food codes. These products included fresh, breaded, floured, canned, raw, and dried fish but not fish mixtures or frozen plate meals.

A total of 4,500 households participated in the 1987–1988 survey; the household response rate was 38%. One-day data were obtained for 10,172 (81%) of the 12,522 individuals in participating households; 8,468 (68%) individuals completed 3-day diet records.

USDA (1992) used the 1-day data to derive per capita fish intake rate and intake rates for consumers of total fish. Table 10-17 shows these rates, calculated by sex and age group. Intake rates for consumers only were calculated by dividing the per capita intake rates by the fractions of the population consuming fish in 1 day.

An advantage of analyses based on the 1987–1988 USDA NFCS is that the data set is a large, geographically and seasonally balanced survey of a representative sample of the U.S. population. The survey response rate, however, was low, and an expert panel concluded that it was not possible to establish the presence or absence of non-response bias (USDA, 1992). In addition, the data from this survey have been superseded by more recent surveys.

**10.3.2.4. U.S. EPA (1996)—Descriptive Statistics
From a Detailed Analysis of the National
Human Activity Pattern Survey (NHAPS)
Responses**

The U.S. EPA collected information for the general population on the duration and frequency of time spent in selected activities and time spent in selected microenvironments via 24-hour diaries (U.S. EPA, 1996). Over 9,000 individuals from 48 contiguous states participated in NHAPS. Approximately 4,700 participants also provided information on seafood consumption. The survey was conducted between October 1992 and September 1994. Data were collected on (1) the number of people that ate seafood in the last month, (2) the number of servings of seafood consumed, and (3) whether the seafood consumed was caught or purchased (U.S. EPA, 1996). The participant responses were weighted according to selected demographics such as age, sex, and race to ensure that results were representative of the U.S. population. Of those 4,700 respondents, 2,980 (59.6%) ate seafood (including shellfish, eels,

or squid) in the last month (see Table 10-18). The number of servings per month was categorized in ranges of 1–2, 3–5, 6–10, 11–19, and 20+ servings per month (see Table 10-19). The highest percentage (35%) of the respondent population had an intake of 3–5 servings per month. Most (92%) of the respondents purchased the seafood they ate (see Table 10-20).

Intake data were not provided in the survey. However, intake of fish can be estimated using the information on the number of servings of fish eaten from this study and serving size data from other studies. Smiciklas-Wright et al. (2002) estimated that the mean value for fish serving size for all age groups combined is 114 g/serving based on the 1994–1996 CSFII survey (see Section 10.8). The CSFII serving size data are based on all finfish, except canned, dried, and raw, whether reported separately or as part of a sandwich or other mixed food. Using this mean value for serving size and assuming that the average individual eats 3–5 servings per month, the amount of seafood eaten per month would range from 340 to 570 g/month or 11.3 to 19.0 g/day for the highest percentage of the population. These values are within the range of per capita mean intake values for total fish (16.9 g/day, uncooked equivalent weight) calculated by U.S. EPA (2002) analysis of the USDA CSFII data. It should be noted that an all inclusive description for seafood was not presented in U.S. EPA (1996). It is not known if they included processed or canned seafood and seafood mixtures in the seafood category.

The advantages of NHAPS are that the data were collected for a large number of individuals and are representative of the U.S. general population. However, evaluation of seafood intake was not the primary purpose of the study, and the data do not reflect the actual amount of seafood that was eaten. However, using the assumption described above, the estimated seafood intake from this study is comparable to that observed in the U.S. EPA CSFII analysis.

**10.3.2.5. Stern et al. (1996)—Estimation of Fish
Consumption and Methylmercury Intake
in the New Jersey Population**

Stern et al. (1996) reported on a 7-day fish consumption recall survey that was conducted in 1993 as part of the New Jersey Household Fish Consumption Study. Households were contacted by telephone using the random-digit dialing technique, and the survey completion rate was 72% of households contacted. Respondents included 1 adult (i.e., ≥18 years) resident per household, for a total of

Chapter 10—Intake of Fish and Shellfish

1,000 residents. The sample was “stratified to provide equal numbers of men and women and proportional representation by county” (Stern et al., 1996). Survey respondents provided data on consumption of all seafood consumed within the previous 7 days, including the number of fish meals, fish type, amount eaten at each meal, frequency of consumption, and whether the consumption patterns during the recall period were typical of their intake throughout the year.

Stern et al. (1996) reported that “of the 1,000 respondents, 933 reported that they normally consume fish at least a few times per year and 686 reported that they consumed fish during the recall period” (Stern et al., 1996). Table 10-21 presents the distribution of the number of meals for the 7-day recall period. The average portion size was 168 grams. Approximately “4–5% of all fish meals consisted of fish obtained non-commercially, and only about 13% of these consisted of freshwater fish” (Stern et al., 1996). Tuna was consumed most frequently, followed by shrimp and flounder/fluke (see Table 10-22).

Table 10-23 provides the average daily consumption rates (g/day) for all fish for all adults and for women of childbearing age (i.e., 18–40 years). The mean fish intake rate for all adult consumers was 50 g/day, and the 90th percentile was 107 g/day. For women of childbearing age, the mean fish intake rate was 41 g/day, and the 90th percentile was 88 g/day. Table 10-24 provides information on the frequency of fish consumption.

The advantages of this study are that it is based on a 7-day recall period and that data were collected for the frequency of eating fish. However, the data are based on fish consumers in New Jersey and may not be representative of the general population of the United States.

10.3.2.6. U.S. EPA (2002)—Estimated Per Capita Fish Consumption in the United States

U.S. EPA’s Office of Water used data from the 1994–1996 CSFII and its 1998 Children’s Supplement (referred to collectively as CSFII 1994–1996, 1998) to generate fish intake estimates (U.S. EPA, 2002). Participants in the CSFII 1994–1996, 1998 provided 2 non-consecutive days of dietary data. The Day 2 interview occurred 3 to 10 days after the Day 1 interview but not on the same day of the week. Data collection for the CSFII started in April of the given year and was completed in March of the following year. Respondents estimated the weight of each food that they consumed. Information on the consumption of food was classified using 11,345

different food codes and stored in a database in units of grams consumed per day. A total of 831 of these food codes related to fish or shellfish; survey respondents reported consumption across 665 of these codes. The fish component (by weight) of the various foods was calculated using data from the recipe file for release seven of USDA’s Nutrient Data Base for Individual Food Intake Surveys.

The amount of fish consumed by each individual was then calculated by summing, over all fish containing foods, the product of the weight of food consumed and the fish component (i.e., the percentage fish by weight) of the food. The recipe file also contains cooking loss factors associated with each food. These were used to convert, for each fish-containing food, the as-eaten fish weight consumed into an uncooked equivalent weight of fish. Analyses of fish intake were performed on both an “as-prepared” (i.e., as-consumed) and uncooked basis.

Each fish-related food code was assigned, by U.S. EPA, to a habitat category. The habitat categories included freshwater/estuarine, or marine. Food codes were also designated as finfish or shellfish. Average daily individual consumption (g/day) was calculated, for a given fish type-by-habitat category (e.g., marine finfish), by summing the amount of fish consumed by the individual across the 2 reporting days for all fish-related food codes in the given fish-by-habitat category and then dividing by 2. Individual daily fish consumption (g/day) was calculated similarly except that total fish consumption was divided by the specific number of survey days the individual reported consuming fish; this was calculated for fish consumers only (i.e., those consuming fish on at least 1 of the 2 survey days). The reported body weight of the individual was used to convert consumption in g/day to consumption in g/kg-day.

There were a total of 20,607 respondents in the combined data set that had 2-day dietary intake data. Survey weights were assigned to this data set to make it representative of the U.S. population with respect to various demographic characteristics related to food intake. Survey weights were also adjusted for non-response.

U.S. EPA (2002) reported means, medians, and estimates of the 90th, 95th, and 99th percentiles of fish intake. The 90% interval estimates are non-parametric estimates from bootstrap techniques. The bootstrap estimates result from the percentile method, which calculates the lower and upper bounds for the interval estimate by the 100 α percentile and 100 (1– α) percentile estimates from the

Chapter 10—Intake of Fish and Shellfish

non-parametric distribution of the given point estimate (U.S. EPA, 2002).

Analyses of fish intake were performed on an as-prepared as well as on an uncooked equivalent basis and on a g/day and mg/kg-day basis. Table 10-25 gives the mean and various percentiles of the distribution of per capita finfish and shellfish intake rates (g/day), as prepared, by habitat and fish type, for the general population. Table 10-26 provides a list of the fish species categorized within each habitat. Table 10-26 also shows per capita consumption estimates by species. Table 10-27 displays the mean and various percentiles of the distribution of per capita finfish and shellfish intake rates (g/day) by habitat and fish type, on an uncooked equivalent basis. Table 10-28 shows per capita consumption estimates by species on an uncooked equivalent basis.

Table 10-29 through Table 10-36 present data for daily average fish consumption. These data are presented by selected age groupings (14 and under, 15-44, 45 and older, all ages, children ages 3 to 17, and ages 18 and older) and sex. It should be noted the analysis predated the age groups recommended by U.S. EPA *Guidelines on Selecting Age Groups for Monitoring and Assessing Childhood Exposure to Environmental Contaminants* (U.S. EPA, 2005). Table 10-29 through Table 10-32 present fish intake data (g/day and mg/kg-day; as prepared and uncooked) on a per capita basis, and Table 10-33 through Table 10-36 provide data for consumers only.

The advantages of this study are its large size and its representativeness. The survey was also designed and conducted to support unbiased estimation of food consumption across the population. In addition, through use of the USDA recipe files, the analysis identified all fish-related food codes and estimated the percent fish content of each of these codes. By contrast, some analyses of the USDA NFCSSs, which reported per capita fish intake rates [e.g., Pao et al. (1982); USDA (1993)], excluded certain fish-containing foods (e.g., fish mixtures, frozen plate meals) in their calculations.

10.3.2.7. Westat (2006)—Fish Consumption in Connecticut, Florida, Minnesota, and North Dakota

Westat (2006) analyzed the raw data from three fish consumption studies to derive fish consumption rates for various age, sex, and ethnic groups, and according to the source of fish consumed (i.e., bought or caught) and habitat (i.e., freshwater, estuarine, or marine). The studies represented data

from four states: Connecticut, Florida, Minnesota, and North Dakota.

The Connecticut data were collected in 1996/1997 by the University of Connecticut to obtain estimates of fish consumption for the general population, sport fishing households, commercial fishing households, minority and limited income households, women of child-bearing years, and children. Data were obtained from 810 households, representing 2,080 individuals, using a combination of a mail questionnaire that included a 10-day diary, and personal interviews. The response rate for this survey was low (i.e., 6% for the general population and 10% for anglers) but was considered to be adequate by the study authors (Balcom et al., 1999).

The Florida data were collected by telephone and in-person interviews by the University of Florida and represented a random sample of 8,000 households (telephone interviews) and 500 food stamp recipients (in-person interviews). The purpose of the survey was to obtain information on the quantity of fish and shellfish eaten, as well as the cooking method used. Additional information of the Florida survey can be found in Degner et al. (1994).

The Minnesota and North Dakota data were collected by the University of North Dakota in 2000 and represented 1,572 households and 4,273 individuals. Data on purchased and caught fish were collected for the general population, anglers, new mothers, and Native American tribes. The survey also collected information on the species of fish eaten. Additional information on this study can be found in Benson et al. (2001).

The primary difference in survey procedures among the three studies was the manner in which the fish consumption data were collected. In Connecticut, the survey requested information on how often each type of seafood was eaten, without a recall period specified. In Minnesota and North Dakota, the survey requested information on the rate of fish or shellfish consumption during the previous 12 months. In Florida, the survey requested information on fish consumption during the last 7 days prior to the telephone interview. In addition, for the Florida survey, information on away-from-home fish consumption was collected from a randomly selected adult from each participating household. Because this information was not collected from all household members, the study may tend to underestimate away-from-home consumption. The study notes that estimates of fish consumption using a shorter recall period will decrease the proportion of respondents that report eating fish or shellfish. This trend was observed in the Florida study (in which approximately half of respondents reported eating

Chapter 10—Intake of Fish and Shellfish

fish/shellfish), compared with Connecticut, Minnesota, and North Dakota (in which approximately 90% of respondents reported eating fish or shellfish).

Table 10-37 through Table 10-46 present key findings of the Westat (2006) consumption study. The tables show the fish and shellfish consumption rates for various groups classified by demographic characteristics and by the source of the fish and shellfish consumed (i.e., freshwater versus marine, and bought versus self-caught). Consumption rates are presented in grams per kilogram of body weight per day for the entire population (i.e., consumption per capita) and for just those that reported consuming fish and shellfish (consumption for consumers only).

An advantage of this study is that it focused on individuals within the general population that may consume more fish and shellfish and, thus, may be at higher risk from exposure to contaminants in fish than other members of the population. Also, it provides distributions of fish consumption for different age cohorts, ethnic groups, socioeconomic status, types of fish (i.e., freshwater, marine, estuarine), and sources of fish (i.e., store-bought versus self-caught). However, the data were collected in four states and may not be representative of the U.S. population as a whole.

10.3.2.8. Moya et al. (2008)—Estimates of Fish Consumption Rates for Consumers of Bought and Self-Caught Fish in Connecticut, Florida, Minnesota, and North Dakota

Moya et al. (2008) summarized the analysis conducted by Westat (2006) described in Section 10.3.2.7. Moya et al. (2008) utilized the data to generate intake rates for 3 age groups of children (i.e., 1 to <6 years, 6 to <11 years, and 11 to <16 years) and 3 age groups of adults (16 to <30 years, 30 to <50 years, and >50 years), which are also listed by sex. These data represented the general population and angler population in the four states. Recreational fish intake rates were not provided for children, and data were not provided for children according to the source of intake (i.e., bought or caught) or habitat (i.e., freshwater, estuarine, or marine). Table 10-47 presents the intake rates for the general population who consumed fish and shellfish in g/kg-day, as-consumed. Table 10-47 also provides information on the fish intake among the sample populations from the four states, based on the source of the fish (i.e., caught or bought) and provides estimated fish intake rates among the general

populations and angler populations from Connecticut, Minnesota, and North Dakota.

This analysis is based on the data from Westat (2006). Therefore, the advantages and limitations are the same as those of the Westat (2006) study. Also, while data were provided for individuals who ate self-caught fish, it is not possible from this analysis to determine the proportion of self-caught fish represented by marine or freshwater habitats.

10.3.2.9. Mahaffey et al. (2009)—Adult Women's Blood Mercury Concentrations Vary Regionally in the United States: Association With Patterns of Fish Consumption (NHANES 1999–2004)

Mahaffey et al. (2009) used NHANES 1999–2004 data to evaluate relationships between fish intake and blood mercury levels. Mercury intake via fish ingestion was evaluated for four coastal populations (i.e., Atlantic, Pacific, Gulf of Mexico, and Great Lakes), and four non-coastal populations defined by U.S. census regions (i.e., Northeast, South, Midwest, and West) (Mahaffey et al., 2009). Serving size data, based on 24-hour dietary recall, were used with 30-day food frequency data to estimate mercury intake from consumption of fish over a 30-day period. The frequency data used in the study indicated that people living on the Atlantic coast consumed fish most frequently (averaging 6 meals/month), followed closely by those of the Gulf and Pacific coasts. People living in non-coastal areas or on the coasts of the Great Lakes consumed fish least often (averaging ≤ 4 meals/month). Figure 10-2 illustrates these regional differences.

The advantage of this study is that it is based on relatively recent NHANES data (i.e., 1999–2004), it uses data from the 30-day food frequency questionnaire, and it provides regional data that are not available elsewhere. However, because the study focused on mercury exposure, it did not provide non-chemical specific fish intake data (in g/day or g/kg-day) that can be used to support risk assessments for other chemicals (i.e., only frequency data were provided). It does, however, provide useful information on the relative differences in frequency of fish intake for regional populations.

10.4. MARINE RECREATIONAL STUDIES

10.4.1. Key Marine Recreational Study

10.4.1.1. National Marine Fisheries Service (1993, 1986a, b, c)

The NMFS conducts systematic surveys, on a continuing basis, of marine recreational fishing.

Chapter 10—Intake of Fish and Shellfish

These surveys are designed to estimate the size of the recreational marine finfish catch by location, species, and fishing mode. In addition, the surveys provide estimates for the total number of participants in marine recreational finfishing and the total number of fishing trips.

The NMFS surveys involve two components: telephone surveys and direct interviewing of fishermen in the field. The telephone survey randomly samples residents of coastal regions, defined generally as counties within 25 miles of the nearest seacoast, and inquires about participation in marine recreational fishing in the resident's home state in the past year, and more specifically, in the past 2 months. This component of the survey is used to estimate, for each coastal state, the total number of coastal region residents who participate in marine recreational fishing (for finfish) within the state, as well as the total number of (within state) fishing trips these residents take. To estimate the total number of participants and fishing trips in the state, by coastal residents and others, a ratio approach, based on the field interview data, was used. Thus, if the field survey data found that there was a 4:1 ratio of fishing trips taken by coastal residents as compared to trips taken by non-coastal and out-of-state residents, then an additional 25% would be added to the number of trips taken by coastal residents to generate an estimate of the total number of within-state trips.

The surveys are not designed to estimate individual consumption of fish from marine recreational sources, primarily because they do not attempt to estimate the number of individuals consuming the recreational catch. Intake rates for marine recreational anglers can be estimated, however, by employing assumptions derived from other data sources about the number of consumers.

The field intercept survey is essentially a creel type survey. The survey utilizes a national site register that details marine fishing locations in each state. Sites for field interviews are chosen in proportion to fishing frequency at the site. Anglers fishing on shore, private boat, and charter/party boat modes who had completed their fishing were interviewed. The field survey included questions about frequency of fishing, area of fishing, age, and place of residence. The fish catch was classified by the interviewer as either type A, type B1, or type B2 catch. The type A catch denoted fish that were taken whole from the fishing site and were available for inspection. The type B1 and B2 catch were not available for inspection; the former consisted of fish used as bait, filleted, or discarded dead, while the latter was fish released alive. The type A catch was identified by species and weighed, with the weight

reflecting total fish weight, including inedible parts. The type B1 catch was not weighed, but weights were estimated using the average weight derived from the type A catch for the given species, state, fishing mode, and season of the year. For both the type A and B1 catch, the intended disposition of the catch (e.g., plan to eat, plan to throw away, etc.) was ascertained.

U.S. EPA obtained the raw data tapes from NMFS in order to generate intake distributions and other specialized analyses. Fish intake distributions were generated using the field survey tapes. Weights proportional to the inverse of the angler's reported fishing frequency were employed to correct for the unequal probabilities of sampling; this was the same approach used by NMFS in deriving their estimates. Note that in the field survey, anglers were interviewed regardless of past interviewing experience; thus, the use of inverse fishing frequency as weights was justified (see Section 10.1).

For each angler interviewed in the field survey, the yearly amount of fish caught that was intended to be eaten by the angler and his/her family or friends was estimated by U.S. EPA as follows:

$$Y = [(wt\ of\ A\ catch) \times I_A + (wt\ of\ B1\ catch) \times I_B] \times [Fishing\ frequency] \quad (Eqn.\ 10-1)$$

where I_A (I_B) are indicator variables equal to one if the type A (B1) catch was intended to be eaten, and equal to 0 otherwise. To convert Y to a daily fish intake rate by the angler, it was necessary to convert amount of fish caught to edible amount of fish, divide by the number of intended consumers, and convert from yearly to daily rate.

Although theoretically possible, U.S. EPA chose not to use species-specific edible fractions to convert overall weight to edible fish weight because edible fraction estimates were not readily available for many marine species. Instead, an average value of 0.5 was employed. For the number of intended consumers, U.S. EPA used an average value of 2.5, which was an average derived from the results of several studies of recreational fish consumption (ChemRisk, 1992; West et al., 1989; Puffer et al., 1982). Thus, the average daily intake rate (ADI) for each angler was calculated as

$$ADI = Y \times (0.5) / [2.5 \times 365] \quad (Eqn.\ 10-2)$$

Chapter 10—Intake of Fish and Shellfish

Note that ADI will be 0 for those anglers who either did not intend to eat their catch or who did not catch any fish. The distribution of ADI among anglers was calculated by region and coastal status (i.e., coastal versus non-coastal counties).

The results presented in Table 10-48 and Table 10-49 are based on the results of the 1993 survey. Sample sizes were 200,000 for the telephone survey and 120,000 for the field surveys. All coastal states in the continental United States were included in the survey except Texas and Washington.

Table 10-48 presents the estimated number of coastal, non-coastal, and out-of-state fishing participants by state and region of fishing. Florida had the greatest number of both Atlantic and Gulf participants. The total number of coastal residents who participated in marine finfishing in their home state was eight million; an additional 750,000 non-coastal residents participated in marine finfishing in their home state.

Table 10-49 presents the estimated total weight of the type A and B1 catch by region and time of year. For each region, the greatest catches were during the 6-month period from May through October. This period accounted for about 90% of the North and Mid-Atlantic catch, about 80% of the Northern California and Oregon catch, about 70% of the Southern Atlantic and Southern California catch, and 62% of the Gulf catch. Note that in the North and Mid-Atlantic regions, field surveys were not done in January and February due to very low fishing activity. For all regions, over half the catch occurred within 3 miles of the shore or in inland waterways.

Table 10-50 presents the mean and 95th percentile of average daily intake (ADI) of recreationally caught marine finfish among anglers by region. The mean ADI values among all anglers were 5.6, 7.2, and 2.0 g/day for the Atlantic, Gulf, and Pacific regions, respectively. Table 10-51 gives the distribution of catch, by species, for the Atlantic, Gulf, and Pacific regions.

The NMFS surveys provide a large, geographically representative sample of marine angler activity in the United States. The major limitation of this database in terms of estimating fish intake is the lack of information regarding the intended number of consumers of each angler's catch. In this analysis, it was assumed that every angler's catch was consumed by the same number (2.5) of people; this number was derived from averaging the results of other studies. This assumption introduces a relatively low level of uncertainty in the estimated mean intake rates among anglers, but a somewhat higher level of uncertainty in the estimated intake distributions.

Under the above assumption, the distributions shown here pertain not only to the population of anglers, but also to the entire population of recreational fish consumers, which is 2.5 times the number of anglers. If the number of consumers was changed, to, for instance, 2.0, then the distribution would be increased by a factor of 1.25 (2.5/2.0), but the estimated population of recreational fish consumers to which the distribution would apply, would decrease by a factor of 0.8 (2.0/2.5).

Another uncertainty involves the use of 0.5 as an (average) edible fraction. This figure is assumed to be somewhat conservative (i.e., the true average edible fraction is probably lower); thus, the intake rates calculated here may be biased upward somewhat.

The recreational fish intake distributions given refer only to marine finfish. In addition, the intake rates calculated are based only on the catch of anglers in their home state. Marine fishing performed out-of-state would not be included in these distributions. Therefore, these distributions give an estimate of consumption of locally caught marine fish. These data are approximately 2 decades old and may not be entirely representative of current intake rates. Also, data were not available for children.

10.4.2. Relevant Marine Recreational Studies

10.4.2.1. *Pierce et al. (1981)—Commencement Bay Seafood Consumption Study*

Pierce et al. (1981) performed a local creel survey to examine seafood consumption patterns and demographics of sport fishermen in Commencement Bay, WA. The objectives of this survey included determining (1) the seafood consumption habits and demographics of non-commercial anglers catching seafood; (2) the extent to which resident fish were used as food; and (3) the method of preparation of the fish to be consumed. Salmon were excluded from the survey because it was believed that they had little potential for contamination. The first half of this survey was conducted from early July to mid-September, 1980 and the second half from mid-September through most of November. During the summer months, interviewers visited each of four sub-areas of Commencement Bay on five mornings and five evenings; in the fall, the areas were sampled on four complete survey days. Interviews were conducted only with persons who had caught fish. The anglers were interviewed only once during the survey period. Data were recorded for species, wet weight, size of the living group (family), place of residence, fishing frequency, planned uses of the fish, age, sex, and race (Pierce et al., 1981). The analysis

Chapter 10—Intake of Fish and Shellfish

of Pierce et al. (1981) did not employ explicit sampling weights (i.e., all weights were set to one).

There were 304 interviews in the summer and 204 in the fall. About 60% of anglers were White, 20% Black, and 19% Asian, and the rest were Hispanic or Native American. Table 10-52 gives the distribution of fishing frequency calculated by Pierce et al. (1981); for both the summer and fall, more than half of the fishermen caught and consumed fish weekly. The dominant (by weight) species caught were Pacific hake and walleye pollock. Pierce et al. (1981) did not present a distribution of fish intake or a mean fish intake rate.

Price et al. (1994) obtained the raw data from this survey and performed a re-analysis using sampling weights proportional to inverse fishing frequency. The rationale for these weights is explained in Section 10.1 and in the discussion of the Puffer et al. (1982) study (see Section 10.4.2.2). In the re-analysis, Price et al. (1994) calculated a median intake rate of 1.0 g/day and a 90th percentile rate of 13 g/day. The distribution of fishing frequency generated by Pierce et al. (1981) is shown in Table 10-52. Note that when equal weights were used, Price et al. (1994) found a median rate of 19 g/day (Table 10-53).

The same limitations apply to interpreting the results presented here to those presented in the discussion of Puffer et al. (1982) (see Section 10.4.2.2). As with the Puffer et al. (1982) data described in the following section, these values (1.0 g/day and 19 g/day) are both probably underestimates because the sampling probabilities are less than proportional to fishing frequency; thus, the true target population median is probably somewhat above 1.0 g/day, and the true 50th percentile of the resource utilization distribution is probably somewhat higher than 19 g/day. The data from this survey provide an indication of consumption patterns for the time period around 1980 in the Commencement Bay area. However, the data may not reflect current consumption patterns because fishing advisories were instituted due to local contamination. Another limitation of these data is that fish consumption rates were estimated indirectly from a series of assumptions.

10.4.2.2. Puffer et al. (1982)—Intake Rates of Potentially Hazardous Marine Fish Caught in the Metropolitan Los Angeles Area

Puffer et al. (1982) conducted a creel survey with sport fishermen in the Los Angeles area in 1980. The survey was conducted at 12 sites in the harbor and

coastal areas to evaluate intake rates of potentially hazardous marine fish and shellfish by local, non-professional fishermen. It was conducted for the full 1980 calendar year, although inclement weather in January, February, and March limited the interview days. Each site was surveyed an average of three times per month, on different days, and at a different time of the day. The survey questionnaire was designed to collect information on demographic characteristics, fishing patterns, species, number of fish caught, and fish consumption patterns. Scales were used to obtain fish weights. Interviews were conducted only with anglers who had caught fish, and the anglers were interviewed only once during the entire survey period.

Puffer et al. (1982) estimated daily consumption rates (g/day) for each angler using the following equation:

$$K \times N \times W \times F / [E \times 365] \quad (\text{Eqn. 10-3})$$

where:

- K = edible fraction of fish (0.25 to 0.5 depending on species),
- N = number of fish in catch,
- W = average weight of (grams) fish in catch,
- F = frequency of fishing/year, and
- E = number of fish eaters in family/living group.

No explicit survey weights were used in analyzing this survey; thus, each respondent's data were given equal weight.

A total of 1,059 anglers were interviewed for the survey. Table 10-54 shows the ethnic and age distribution of respondents; 88% of respondents were male. The median intake rate was higher for Asian/Samoan anglers (median 70.6 g/day) than for other ethnic groups and higher for those ages over 65 years (median 113.0 g/day) than for other age groups. Puffer et al. (1982) found similar median intake rates for seasons: 36.3 g/day for November through March and 37.7 g/day for April through October. Puffer et al. (1982) also evaluated fish preparation methods; Appendix 10B presents these data. Table 10-55 presents the cumulative distribution of recreational fish (finfish and shellfish) consumption by survey respondents; this distribution was calculated only for those fishermen who indicated they eat the fish they catch. The median fish consumption rate was 37 g/day, and the

Chapter 10—Intake of Fish and Shellfish

90th percentile rate was 225 g/day (Puffer et al., 1982). Table 10-56 presents a description of catch patterns for primary fish species kept.

As mentioned in the introduction to this chapter, intake distributions derived from analyses of creel surveys that did not employ weights reflective of sampling probabilities will overestimate the target population intake distribution and will, in fact, be more reflective of the “resource utilization distribution.” Therefore, the reported median level of 37.3 g/day does not reflect the fact that 50% of the target population has intake above this level; instead, 50% of recreational fish consumption is by individuals consuming at or above 37 g/day. In order to generate an intake distribution reflective of that in the target population, weights inversely proportional to sampling probability need to be employed. Price et al. (1994) made this attempt with the Puffer et al. (1982) survey data, using inverse fishing frequencies as the sampling weights. Price et al. (1994) was unable to get the raw data for this survey, but through the use of frequency tables and the average level of fish consumption per fishing trip provided in Puffer et al. (1982), generated an approximate revised intake distribution. This distribution was dramatically lower than that obtained by Puffer et al. (1982); the median was estimated at 2.9 g/day [compared with 37 from Puffer et al. (1982)] and the 90th percentile at 35 g/day [compared to 225 g/day from Puffer et al. (1982)].

There are several limitations to the interpretation of the percentiles presented by both Puffer et al. (1982) and Price et al. (1994). As described in Appendix 10A, the interpretation of percentiles reported from creel surveys in terms of percentiles of the “resource utilization distribution” is approximate and depends on several assumptions. One of these assumptions is that sampling probability is proportional to inverse fishing frequency. In this survey, where interviewers revisited sites numerous times and anglers were not interviewed more than once, this assumption is not valid, though it is likely that the sampling probability is still highly dependent on fishing frequency, so that the assumption does hold in an approximate sense. The validity of this assumption also impacts the interpretation of percentiles reported by Price et al. (1994) because inverse frequency was used as sampling weights. It is likely that the value (2.9 g/day) of Price et al. (1994) underestimates somewhat the median intake in the target population but is much closer to the actual value than the Puffer et al. (1982) estimate of 37.3 g/day. Similar statements would apply about the 90th percentile. Similarly, the 37.3-g/day median value, if interpreted as the 50th percentile of the

“resource utilization distribution,” is also somewhat of an underestimate.

The fish intake distribution generated by Puffer et al. (1982) [and by Price et al. (1994)] was based only on fishermen who caught fish and ate the fish they caught. If all anglers were included, intake estimates would be somewhat lower. In contrast, the survey assumed that the number of fish caught at the time of the interview was all that would be caught that day. If it were possible to interview fishermen at the conclusion of their fishing day, intake estimates could be potentially higher. An additional factor potentially affecting intake rates is that fishing quarantines were imposed in early spring due to heavy sewage overflow (Puffer et al., 1982). These data are also over 20 years old and may not reflect current behaviors.

10.4.2.3. Burger and Gochfeld (1991)—Fishing a Superfund Site: Dissonance and Risk Perception of Environmental Hazards by Fishermen in Puerto Rico

Burger and Gochfeld (1991) examined fishing behavior, consumption patterns, and risk perceptions of fishermen and crabbers engaged in recreational and subsistence fishing in the Humacao Lagoons located in eastern Puerto Rico. For a 20-day period in February and March 1988, all persons encountered fishing and crabbing at the Humacao lagoons and at control sites were interviewed on fishing patterns, consumption patterns, cooking patterns, fishing and crabbing techniques, and consumption warnings. The control interviews were conducted at sites that were ecologically similar to the Humacao lagoons and contained the same species of fish and crabs. A total of 45 groups of people (3 to 4 people per group) fishing at the Humacao Lagoons and 17 control groups (3 to 4 people per group) were interviewed.

Most people fished in the late afternoon or evenings, and on weekends. Eighty percent of the fishing groups from the lagoons were male. The breakdown according to age is as follows: 27% were younger than 20 years, 49% were 21–40 years old, 24% were 41–60 years old, and 2% were over 60. The age groups for fishing were generally lower than the groups for crabbing. Caught fish were primarily tilapia and some tarpon. All crabs caught were blue crabs.

On average, people at Humacao ate about 7 fish ($N=25$) or 13 crabs ($N=20$) each week, while people fishing at the control site ate about 2 fish ($N=9$) and 14 crabs ($N=9$) a week (see Table 10-57). All of the crabbers (100%) and 96% of the

Chapter 10—Intake of Fish and Shellfish

fisherman at the lagoons had heard of a contamination problem.

All the interviewees that knew of a contamination problem knew that the contaminant was mercury. Most fisherman and crabbers believed that the water was clean and the catch was safe (fisherman—96% and crabbers—100%), and all fisherman and crabbers ate their catch. Seventy-two percent of the fisherman and crabbers from the lagoons lived within 3 km, 18% lived 17–30 km away, and 1 group came from 66 km away. Because many of the people interviewed had cars, researchers concluded that they were not impoverished and did not need the fish as a protein substitute.

Burger and Gochfeld (1991) noted that fisherman and crabbers did not know of anyone who had gotten sick from eating catches from the lagoons, and the potential of chronic health effects did not enter into their consideration. The study concluded that fisherman and crabbers experienced an incompatibility between their own experiences, and the risk driven by media reports of pollution and the lack of governmental prohibition of fishing.

One limitation of the study is that consumption rates were based on groups not individuals. In addition, rates were given in terms of fish per week and not mass consumed per time or body weight.

10.4.2.4. Burger et al. (1992)—Exposure Assessment for Heavy Metal Ingestion From Sport Fish in Puerto Rico: Estimating Risk for Local Fishermen

Burger et al. (1992) conducted another study in conjunction with the Burger and Gochfeld (1991) study. The study interviewed 45 groups of fishermen at Humacao and 14 groups at Boqueron in Puerto Rico. The respondents were 80% male, 50% were 21 to 40 years old, most fished with pole or cast, and most fished for 1.5 hours. In Humacao, 96% claimed that they ate the entire fish besides the head. The fish were either fried or boiled in stews or soups.

In February and March, 64% of the group caught only tilapia, but respondents stated that in June they caught mostly robalo and tarpon. Generally, the fisherman stated that they ate 2.1 fish (maximum of 11 fish) from Boqueron and 6.8 fish (maximum of 23) from Humacao per week. The study reported that adults ate 374 grams of fish per day, while children ate 127 grams per day. In order to calculate the daily mass intake of fish, the study assumed that an adult ate 4.4 robalos, each weighing 595 grams over a 7-day period, and a child ate 1.5 robalos, each weighing 595 grams over a 7-day period. The study

used a maximum consumption value of 200 g/day for fishermen to create various hazard indices.

One limitation of this study is that the consumption rates were based on groups not individuals. In addition, consumption rates were calculated using the average fish weight and the number of meals per week reported by the respondents.

10.4.2.5. Moya and Phillips (2001)—Analysis of Consumption of Home-Produced Foods

The 1987–1988 NFCS was also utilized to estimate consumption of home-produced (i.e., self-caught) fish (as well as home-produced fruits, vegetables, meats, and dairy products) in the general U.S. population. The methodology for estimating home-produced intake rates was rather complex and involved combining the household and individual components of the NFCS; the methodology, as well as the estimated intake rates, are described in detail in Chapter 13. Some of the data on fish consumption from households who consumed self-caught fish are also provided in Moya and Phillips (2001). A total of 2.1% of the total survey population reported self-caught fish consumption during the survey week. Among consumers, the mean intake rate was 2.07 g/kg-day, and the 95th percentile was 7.83 g/kg-day; the mean per capita intake rate was 0.04 g/kg-day. Note that intake rates for home-produced foods were indexed to the weight of the survey respondent and reported in g/kg-day.

The NFCS household component contains the question “Does anyone in your household fish?” For the population answering yes to this question (21% of households), the NFCS data show that 9% consumed home-produced fish in the week of the survey; the mean intake rate for fish consumers from fishing households was 2.2 g/kg-day (all ages combined, see Table 13-20) for the fishing population. Note that 92% of individuals reporting home-produced fish consumption for the week of the survey indicated that a household member fishes; the overall mean intake rate among home-produced fish consumers, regardless of fishing status, was the above reported 2.07 g/kg-day). The mean per capita intake rate among all those living in fishing household is then calculated as 0.2 g/kg-day (2.2×0.09). Using the estimated average weight of survey participants of 59 kg, this translates into an average national per capita self-caught fish consumption rate of 11.8 g/day among the population of individuals who fish. However, this intake rate represents intake of both freshwater and saltwater fish combined. According to the data in Chapter 13 (see Table 13-68),

Chapter 10—Intake of Fish and Shellfish

home-produced fish consumption accounted for 32.5% of total fish consumption among households who fish.

As discussed in Chapter 13 of this handbook, intake rates for home-produced foods, including fish, are based on the results of the household survey, and as such, reflect the weight of fish taken into the household. In most of the recreational fish surveys discussed later in this section, the weight of the fish catch (which generally corresponds to the weight taken into the household) is multiplied by an edible fraction to convert to an uncooked equivalent of the amount consumed. This fraction may be species specific, but some studies used an average value; these average values ranged from 0.3 to 0.5. Using a factor of 0.5 would convert the above 11.8 g/day rate to 5.9 g/day.

The advantage of this study is that it provides a national perspective on the consumption of self-caught fish. A limitation of this study is that these values include both freshwater and saltwater fish. The proportion of freshwater to saltwater is unknown and will vary depending on geographical location. Intake data cannot be presented for various age groups due to sample size limitations. The unweighted number of households, who responded positively to the survey question “do you fish?” was also low (i.e., 220 households).

10.4.2.6. KCA Research Division (1994)—Fish Consumption of Delaware Recreational Fishermen and Their Households

In support of the Delaware Estuary Program, the State of Delaware’s Department of Natural Resources and Environmental Control conducted a survey of marine recreational fishermen along the coastal areas of Delaware between July 1992 and June 1993 (KCA Research Division, 1994). There were two components of the study: (1) a field survey of fishermen as they returned from their fishing trips, and (2) a telephone follow-up call.

The purpose of the first component was to obtain information on their fishing trips and on their household composition. This information included the method and location of fishing, number of fish caught and kept by species, and weight of each fish kept. Household information included race, age, sex, and number of persons in the household. Information was also recorded as to the location of the angler intercept (i.e., where the angler was interviewed) and the location of the household.

The purpose of the second component was to obtain information on the amount of fish caught and kept from the fishing trip and then eaten by the

household. The methods used for preparing and cooking the fish were also documented.

The field portion of the study was designed to interview 2,000 anglers. Data were obtained from 1,901 anglers, representing 6,204 household members (KCA Research Division, 1994). While the primary goal of the study was to collect data on marine recreational fishing practices, the survey included some freshwater fishing and crabbing sites. Follow-up phone interviews typically occurred 2 weeks after the field interview and were used to gather information about consumption. Interviewers aided respondents in their estimation of fish intake by describing the weight of ordinary products, for the purpose of comparison to the quantity of fish eaten. Information on the number of fishing trips a respondent had taken during the month was used to estimate average annual consumption rates.

For all respondents, the average consumption was 17.5 g/day. Males were found to have consumed more fish than women, and Caucasians consumed more fish per day than the other races surveyed (see Table 10-58). More than half of the study respondents reported that they skinned the fish that they ate (i.e., 450 out of 807 who reported whether they skinned their catch); the majority ate filleted fish (i.e., 617 out of 794 who reported the preparation method used), and over half fried their fish (i.e., 506 out of 875 who reported the cooking method). Information on consumption relative to preparation method indicated a higher consumption level for skinned fish (0.627 oz/day) than for un-skinned fish (0.517 oz/day). Although most respondents fried their catch (0.553 oz/day), baking and broiling were also common (0.484 and 0.541 oz/day, respectively).

One limitation of this study is that information on fish consumption is based on anglers’ recall of amount of fish eaten. While this study provides information on fish consumption of various ethnic groups, another limitation of this study is that the sample size for ethnic groups was very small. Also, the study was limited to one geographic area and may not be representative of the U.S. population.

10.4.2.7. Santa Monica Bay Restoration Project (SMBRP) (1995)—Seafood Consumption Habits of Recreational Anglers in Santa Monica Bay, Los Angeles, CA

The Santa Monica Bay Restoration Project (SMBRP) conducted a study on the seafood consumption habits of recreational anglers in Santa Monica Bay, CA. The study was conducted between September 1991 and August 1992. Surveys were conducted at 11 piers and jetties, three private boat

Chapter 10—Intake of Fish and Shellfish

launches and hoists, 11 beach and intertidal sites, and five party boat landings. Information requested in the survey included fishing history, types of fish eaten, consumption habits, methods of preparing fish, and demographics. Consumption rates were calculated based on the anglers' estimates of meal size relative to a model fish fillet that represented a 150-gram meal. Interviewers identified 67 species of fish, 2 species of crustaceans, 2 species of mollusks, and 1 species of echinoderms that had been caught from the study area by recreational anglers during the study period. The most abundant species caught were chub mackerel, barred sand bass, kelp bass, white croaker, Pacific barracuda, and Pacific bonito.

A total of 2,376 anglers were censused during 113 separate surveys. Of those anglers, 1,243 were successfully interviewed, and 554 provided sufficient information for calculation of consumption rates. The socio-demographics of the sample population were as follows: most anglers were male (93%), 21 to 40 years old (54%), White (43%), and had an annual household income of \$25,000 to \$50,000 (39%).

The results of the survey showed that the mean consumption rate was 50 g/day, while the 90th percentile was over two times higher at 107 g/day (see Table 10-59). Of the identified ethnic groups, Asians had the highest mean consumption rate (51 g/day) and the highest 90th percentile value for consumption rate (116 g/day). Anglers with annual household incomes greater than \$50,000 had the highest mean consumption rate (59 g/day) and the highest 90th percentile consumption rate (129 g/day). Species of fish that were consumed in larger amounts than other species included barred sand bass, Pacific barracuda, kelp bass, rockfish species, Pacific bonito, and California halibut.

About 77% of all anglers were aware of health warnings about consumption of fish from Santa Monica Bay. Of these anglers, 50% had altered their seafood consumption habits as a result of the warnings (46% stopped consuming some species, 25% ate less of all species, 19% stopped consuming all fish, and 10% ate less of some species). Most anglers in the ethnic groups surveyed were aware of the health-risk warnings, but Asian and White anglers were more likely to alter their consumption behavior based on these warnings.

One limitation of this study is the low numbers of anglers younger than 21 years of age. In this study, if several anglers from the same household were fishing, only the head of the household was interviewed. Hence, young individuals were frequently not interviewed and, therefore, are under-represented in this study.

It should also be noted that this study was not adjusted for avidity bias, but the California Office of Environmental Health Hazard Assessment has adjusted the distribution of fish consumption for avidity bias and other factors in the Air Toxics Hot Spots Program Risk Assessment Guidelines Part IV: Exposure Assessment and Stochastic Analysis Technical Support (see http://www.oehha.ca.gov/air/hot_spots/finalStoc.html).

10.4.2.8. Florida State Department of Health and Rehabilitative Services (1995)—Health Study to Assess the Human Health Effects of Mercury Exposure to Fish Consumed From the Everglades

A health study was conducted in two phases in the Everglades, Florida for the U.S. Department of Health and Human Services (Florida State Department of Health and Rehabilitative Services, 1995). The objectives of the first phase were to (a) describe the human populations at risk for mercury exposure through their consumption of fish and other contaminated animals from the Everglades and (b) evaluate the extent of mercury exposure in those persons consuming contaminated food and their compliance with the voluntary health advisory. The second phase of the study involved neurologic testing of all study participants who had total mercury levels in hair greater than 7.5 µg/g.

Study participants were identified by using special targeted screenings, mailings to residents, postings and multi-media advertisements of the study throughout the Everglades region, and direct discussions with people fishing along the canals and waterways in the contaminated areas. The contaminated areas were identified by the interviewers and long-term Everglade residents. Of a total of 1,794 individuals sampled, 405 individuals were eligible to participate in the study because they had consumed fish or wildlife from the Everglades at least once per month in the last 3 months of the study period. The majority of the eligible participants (>93%) were either subsistence fishermen, Everglade residents, or both. Subsistence fishermen were defined in the survey as "people who rely on fish and the wildlife of the Everglades as a source of dietary protein for themselves and their families." Of the total eligible participants, 55 individuals refused to participate in the survey. Useable data were obtained from 330 respondents ranging in age from 10–81 years of age (mean age 39 years ± 18.8) (Florida State Department of Health and Rehabilitative Services, 1995). Respondents were administered a three-page questionnaire from which demographic

Chapter 10—Intake of Fish and Shellfish

information, fishing and eating habits, and other variables were obtained (Florida State Department of Health and Rehabilitative Services, 1995).

Table 10-60 shows the ranges, means, and standard deviations of selected characteristics by various groups of the survey population. Sixty-two percent of the respondents were male with a slight preponderance of Black individuals (43% White, 46% Black non-Hispanic, and 11% Hispanic). Most of the respondents reported earning an annual income of \$15,000 or less per family before taxes (Florida State Department of Health and Rehabilitative Services, 1995). The mean number of years fished along the canals by the respondents was 15.8 years with a standard deviation of 15.8. The mean number of times per week fish consumers reported eating fish over the last 6 months and last month of the survey period were 1.8 and 1.5 per week with standard deviations of 2.5 and 1.4, respectively. Table 10-60 also indicates that 71% of the respondents reported knowing about the mercury health advisories. Of those who were aware, 26% reported that they had lowered their consumption of fish caught in the Everglades, while the rest (74%) reported no change in consumption patterns (Florida State Department of Health and Rehabilitative Services, 1995).

A limitation of this study is that fish intake rates (g/day) were not reported. Another limitation is that the survey was site limited and, therefore, not representative of the U.S. population. An advantage of this study is that it is one of the few studies targeting populations expected to have higher consumption rates.

**10.4.2.9. Alcoa (1998)—Draft Report for the
Finfish/Shellfish Consumption Study—
Alcoa (Point Comfort)/Lavaca Bay
Superfund Site**

The Texas Saltwater Angler Survey was conducted in 1996/1997 to evaluate the quantity and species of finfish and shellfish consumed by individuals who fish at Lavaca Bay (Alcoa, 1998). The target population for this study was residents of three Texas counties: Calhoun, Victoria, and Jackson (over 70% of the anglers who fish Lavaca Bay are from these three counties). The random sample design specified that the population percentages for the counties should be as follows: 50% from Calhoun, 30% from Victoria, and 20% from Jackson.

Each individual in the sample population was sent an introductory note describing the study and then was contacted by telephone. People who agreed to participate and had taken fewer than six fishing trips

to Lavaca Bay were interviewed by telephone. Persons who agreed to participate and had taken more than five fishing trips to Lavaca Bay were sent a mail survey with the same questions. A total of 1,979 anglers participated in this survey, representing a response rate greater than 68%. Data were collected from the households for men, women, and children.

The information collected as part of the survey included recreational fishing trip information for November 1996 (i.e., fishing site, site facilities, distance traveled, number and species caught), self-caught fish consumption (by the respondent, spouse and child, if applicable), opinions on different types of fishing experiences, and socio-demographics. Portion size for shellfish was determined by utilizing the number of shrimp, crabs, oysters, etc. that an individual consumed during a meal and the assumed tissue weight of the particular species of shellfish.

Table 10-61 presents the results of the study. Adult men consumed 25 grams of self-caught finfish per day while women consumed an average of 18 grams daily. Women of childbearing age consumed 19 grams per day, on average. Small children were found to consume 11 g/day, and youths consumed 16 g/day, on average. Less shellfish was consumed by all individuals than finfish. Men consumed an average of 2 g/day, women and youths an average of 1 g/day, and small children consumed less than 1 g/day of shellfish.

The study results also showed the number of average meals and portion sizes for the respondents, (see Table 10-62). On average, members of each cohort consumed slightly more than 3 meals per month of finfish, although small children and youths consumed slightly less than 3 meals per month of finfish and less than 1 meal per month of shellfish. For finfish, adult men consumed an average, per meal, portion size of 8 ounces, while women and youths consumed 7 ounces, and small children consumed less than 5 ounces per meal. The average number of shellfish meals consumed per month for all cohorts was less than one. Adult men consumed an average shellfish portion size of 4 ounces, women and youth 3 ounces, and small children consumed 2 ounces per meal.

The study also discussed the species composition of self-caught fish consumed by source. Four different sources of fish were included: fish consumed from the closure area, fish consumed from Lavaca Bay, fish consumed from all waters, and all self-caught finfish and shellfish consumed, including preserved (i.e., frozen or smoked) fish where the location of the catch is not known. Red drum comprised the bulk of total finfish grams consumed

Chapter 10—Intake of Fish and Shellfish

from any area, while black drum represented the smallest amount of finfish grams consumed. Overall, almost 40% of all self-caught finfish consumed were red drum, followed by speckled sea trout, flounder, all other finfish (all species were not specifically examined in this study), and black drum. Out of all self-caught shellfish, oysters accounted for 37%, blue crabs for 35%, and shrimp for 29% of the total.

The study authors noted that because the survey relied on the anglers' recall of meal frequency and portion, fish consumption may have been overestimated. There was evidence of overestimation when the data were validated, and approximately 10% of anglers reported consuming more fish than what they caught and kept. Also, the study was conducted at one geographic location and may not be representative of the U.S. population.

10.4.2.10. Burger et al. (1998)—Fishing, Consumption, and Risk Perception in Fisherfolk Along an East Coast Estuary

Burger et al. (1998) examined fishing behavior, consumption patterns, and risk perceptions of 515 people that were fishing and crabbing in Barnegat Bay, NJ. This research also tested the null hypotheses that there are no sex differences in fishing behavior and consumption patterns and no sex differences in the perception of fish and crab safety.

The researchers interviewed 515 people who were fishing or crabbing on Barnegat Bay and Great Bay. Interviews were conducted from June 22 until September 27, 1996. Fifteen percent of the fishermen approached refused to be interviewed, usually because they did not have the time to participate. The questionnaire that researchers used to conduct the interviews contained questions about fishing behavior, consumption patterns, cooking patterns, warnings, and safety associated with the seafood, environmental problems, and changes in the Bay, and personal demographics.

Eighty-four percent of those who were interviewed were men, 95% were White, and the rest were evenly divided between African American, Hispanic, and Asian. The age of interviewees ranged from 13 to 92 years. The subjects fished an average of seven times per month and crabbed three times per month (see Table 10-63). Bluefish (*Pomatomus saltatrix*), fluke or summer flounder (*Paralichthys dentatus*), and weakfish (*Cynoscion regalis*) were the most frequently caught fish. The researchers found that the average consumption rate for people fishing along the Barnegat Bay was 5 fish meals per month (eating just under 10 ounces per meal) for an approximate total of 1,450 grams of fish per month

(48.3 g/day). Most of the subjects (80%) ate the fish they caught.

The study found that there were significant differences in fishing behavior and consumption as a function of sex. Women had more children with them when fishing, and more women fished on foot along the Bay. The consumption by women included a significantly lower proportion of self-caught fish than men. Men ate significantly larger portions of fish per meal than did women, and men ate the whole fish more often. The study results showed that there were no sex differences with regard to the average number of fish caught or in fish size. Nearly 90% of the subjects believed the fish and crabs from Barnegat Bay were safe to eat, although approximately 40% of the subjects had heard warnings about their safety. The subjects generally did not have a clear understanding of the relationships between contaminants and fish size or trophic level. The researchers suggested that reducing the risk from contaminants does not necessarily involve a decrease in consumption rates but rather a change in the fish species and sizes consumed.

While the study provides some useful information on sex difference in fishing behavior and consumption, the study is limited in that the majority of the people surveyed were White males. There were low numbers for women and ethnic groups.

10.4.2.11. Chiang (1998)—A Seafood Consumption Survey of the Laotian Community of West Contra Costa County, CA

A survey of members of the Laotian community of West Contra Costa, CA, was conducted to obtain data on the fishing and fish consumption activities of this community. A questionnaire was developed and translated by the survey staff into the many ethnic languages spoken by the members of the Laotian community. The survey questions covered the following topics: demographics, fishing and fish consumption habits back home, current fishing and fish consumption habits, fish preparation methods, fish species commonly caught, fishing locations, and awareness of the health advisory for this area. A total of 229 people were surveyed.

Most respondents reported eating fish a few times per month, and the most common portion size was about 3 ounces. The mean amount of fish eaten per day was reported as 18.3 g/day, with a maximum of 182.3 g/day (see Table 10-64). "Fish consumers" were considered to be people who ate fish at least once a month, and this group made up 86.9% of the people surveyed. The mean fish consumption rate for this group ("fish consumers") averaged 21.4 g/day.

Chapter 10—Intake of Fish and Shellfish

Catfish was most often mentioned when respondents were asked to name the fish they caught, but striped bass was the species reported caught most often by respondents. Soups/stews were reported as the most common preparation method of fish (86.4%) followed by frying (78.4%), and baking (63.6%).

Of all survey respondents, 48.5% reported having heard of the health advisory about eating fish and shellfish from San Francisco Bay. Of those that had heard the advisory, 59.5% reported recalling its contents, and 60.3% said that it had influenced their fishing and fish consumption patterns.

Some sectors of the Laotian community were not included in the survey such as the Lue, Hmong, and Lahu groups. However, it was noted that the groups excluded from the survey do not differ greatly from the sample population in terms of seafood consumption and fishing practices. The study authors also indicated that participants may have under-reported fishing and fish consumption practices due to recent publicity about contamination of the Bay, fear of losing disability benefits, and fear that the survey was linked to law enforcement actions about fishing from the Bay. Another limitation of the study involved the use of a 3-ounce fish fillet model to estimate portion size of fish consumed. The use of this small model may have biased respondents to choose a smaller portion size than what they actually eat. In addition, the study authors noted that the fillet model may not have been appropriate for estimating fish portions eaten by those respondents who eat “family style” meals.

**10.4.2.12. San Francisco Estuary Institute (SFEI)
(2000)—Technical Report: San Francisco
Bay Seafood Consumption Report**

A comprehensive study of 1,331 anglers was conducted by the California Department of Health Services between July 1998 and June 1999 at various recreational fishing locations in the San Francisco Bay area. The catching and consumption of 13 finned fish species and 3 shellfish species were investigated to determine the number of meals eaten from recreational and other sources such as restaurants and grocery stores. The method of fish preparation, including the parts of the fish eaten, was also documented. Information was gathered on the amount of fish consumed per meal, as well as respondents’ ethnicity, age, income level, education, and the mode of fishing (e.g., pier, boat, and beach). Questions were also asked to ascertain the anglers’ knowledge and response to local fish advisories. Respondents were asked to recall their fishing/consumption experiences within the previous

4 weeks. Anglers were not asked about the consumption habits of other members of their families.

About 15% of the anglers reported that they do not eat San Francisco Bay fish (whether self-caught or commercial). Of those who did consume Bay fish, 80% consumed about 1 fish meal per month or less; 10% ate about 2 fish meals per month; and 10% ate more than 2 fish meals per month, which is above the advisory level for fish. (The advisory level was 16 grams per day, or about two 8-ounce meals per 4 weeks.) Two-thirds of those consuming fish at levels above the advisory limit consumed more than twice the advisory limit. Difference in income, education, or fishing mode did not markedly change anglers’ likelihood of eating in excess of the advisory limit. African Americans and Filipino anglers reported higher consumption levels than Caucasians (see Table 10-65). The overall mean consumption rate was 23 g/day.

More than 50% of the finfish caught by anglers were striped bass, and about 25% were halibut. Approximately 15% of the anglers caught each of the following fish: jacksmelt, sturgeon, and white croaker. All other species were caught by less than 10% of the anglers. For white croaker fish consumption: (1) lower income anglers consumed statistically more fish than mid- and upper-level income anglers, (2) anglers who did not have a high school education consumed more than those anglers with higher education levels, and (3) anglers of Asian descent consumed significantly more than anglers of other ethnic backgrounds. Asian anglers were more likely to eat fish skin, cooking juices, and raw fish than other anglers. These portions of the fish are believed to be more likely to contain higher levels of contamination. Likewise, skin consumption was higher for lower income and shore-based anglers. Anglers who had eaten Bay fish in the previous 4 weeks indicated, in general, that they were likely to have eaten 1 fish meal from another source in the same time period.

More than 60% of the anglers interviewed reported having knowledge of the health advisories. Of that 60%, only about one-third reported changing their fish-consumption behavior.

A limitation of this study is that the sample size for ethnic groups was very small. Data are also specific to the San Francisco Bay area and may not be representative of anglers in other locations.

Chapter 10—Intake of Fish and Shellfish

10.4.2.13. Burger (2002a)—Consumption Patterns and Why People Eat Fish

Burger (2002a) evaluated fishing behavior and consumption patterns among 267 anglers who were interviewed at locations around Newark Bay and the New York-New Jersey Harbor estuary in 1999. Among the 267 study respondents, 13% were Asian, 21% were Hispanic, 23% were Black, and 43% were White. Survey participants provided demographic information as well as information on their fish and crab consumption, knowledge of fishing advisories, and reasons for angling. Individual monthly fish consumption was estimated by multiplying the reported number of fish meals eaten per month by an average portion size, based on comparisons to a three-dimensional model of an 8-ounce fish fillet. Individual monthly crab consumption was estimated by multiplying the reported number of crabs eaten per month by the edible portion of crab, which was assumed to weigh 70 grams. Yearly fish and crab consumption was estimated by multiplying the monthly consumption rates by the number of months in a year over which the survey respondents reported eating self-caught fish or crabs. Intake rates were provided separately for those who fished only (44%), for those who crabbed only (44%), and for respondents who reported both fishing and crabbing (12%) (Burger, 2002a). Burger (2002a) also reported that more than 30% of the respondents reported that they did not eat the fish or crabs that they caught. Table 10-66 provides the average daily intake rates of fish and crab. U.S. EPA calculated these average daily intake rates by dividing the yearly intake rates provided by Burger (2002a) by 365 days/year.

Burger (2002a) also evaluated potential differences in consumption based on age, income, and race/ethnicity. Consumption was found to be negatively correlated with mean income and positively correlated with age for fish, but not crabs. An evaluation of differences based on ethnicity indicated that Whites were the least likely to eat their catch than other groups; 49% of Whites, 40% of Hispanics, 24% of Asians, and 22% of Blacks reported that they did not eat the fish or crabs that they caught. Among all ethnicities most people indicated that they fished (63%) or crabbed (68%) for recreational purposes, and very few (4%) reported that they angled to obtain food.

The advantages of this study are that it provides information for both fish and crab intake, and that it provides data on intake over a longer period of time than many of the other studies summarized in this chapter. However, the data are for individuals living in the Newark Bay area and may not be

representative of the U.S. population as a whole. Also, there may be uncertainties in long-term intake estimates that are based on recall.

10.4.2.14. Mayfield et al. (2007)—Survey of Fish Consumption Patterns of King County (Washington) Recreational Anglers

Mayfield et al. (2007) conducted a series of fish consumption surveys among recreational anglers at marine and freshwater sites in King County, WA. The marine surveys were conducted between 1997 and 2002 at public parks and boat launches throughout Elliot Bay and the Duwamish River, and at North King County marine locations. The numbers of individuals interviewed at these three locations were 807, 152, and 228, respectively. The majority of participants were male, 15 years and older, and were either Caucasian or Asian and Pacific Islander. Data were collected on fishing location preferences, fishing frequency, consumption amounts, species preferences, cooking methods, and whether family members would also consume the catch. Respondent demographic data were also collected. Consumption rates were estimated using information on fishing frequency, weight of the catch, a cleaning factor, and the number of individuals consuming the catch. Mean recreational marine fish and shellfish consumption rates were 53 g/day and 25 g/day, respectively (see Table 10-67). Mayfield et al. (2007) also reported differences in intake according to ethnicity. Mean marine fish intake rates were 73, 60, 50, 43, and 35 g/day for Native American, Caucasian, Asian and Pacific Islander, African American, and Hispanic/Latino respondents, respectively.

The advantages of this study are that it provides additional perspective on recreational marine fish intake. However, the data are limited to a specific area of the United States and may not be representative of anglers in other locations.

10.5. FRESHWATER RECREATIONAL STUDIES**10.5.1. Fiore et al. (1989)—Sport Fish Consumption and Body Burden Levels of Chlorinated Hydrocarbons: A Study of Wisconsin Anglers**

This survey, reported by Fiore et al. (1989), was conducted to assess socio-demographic factors and sport-fishing habits of anglers, to evaluate anglers' comprehension of and compliance with the Wisconsin Fish Consumption Advisory, to measure body burden levels of polychlorinated biphenyls (PCBs) and Dichlorodiphenyldichloroethylene

Chapter 10—Intake of Fish and Shellfish

(DDE) through analysis of blood serum samples, and to examine the relationship between body burden levels and consumption of sport-caught fish. The survey targeted all Wisconsin residents who had purchased fishing or sporting licenses in 1984 in any of 10 pre-selected study counties. These counties were chosen in part based on their proximity to water bodies identified in Wisconsin fish advisories. A total of 1,600 anglers were sent survey questionnaires during the summer of 1985.

The survey questionnaire included questions about fishing history, locations fished, species targeted, kilograms caught for consumption, overall fish consumption (including commercially caught), and knowledge of fish advisories. The recall period was 1 year.

A total of 801 surveys were returned (50% response rate). Of these, 601 (75%) were from males and 200 from females; the mean age was 37 years. Fiore et al. (1989) reported that the mean number of fish meals for 1984 for all respondents was 18 for sport-caught meals and 24 for non-sport-caught meals. Fiore et al. (1989) assumed that each fish meal consisted of 8 ounces (227 grams) of fish to generate means and percentiles of fish intake. The reported mean and 95th percentile intake rate of sport-caught fish for all respondents were 11.2 g/day and 37.3 g/day, respectively. Among consumers, who comprised 91% of all respondents, the mean sport-caught fish intake rate was 12.3 g/day, and the 95th percentile was 37.3 g/day. The mean daily fish intake from all sources (both sport-caught and commercial) was 26.1 g/day, with a 95th percentile of 63.4 g/day. The 95th percentile of 37.3 g/day of sport caught fish represents 60 fish meals per year; the 95th percentile of 63.4 g/day of total fish intake represents 102 fish meals per year.

U.S. EPA obtained the raw data from this study and calculated the distribution of the number of sport-caught fish meals and the distribution of fish intake rates using the same meal size (227 g/meal) used by Fiore et al. (1989). This meal size is higher than the mean meal size of 114 g/meal, but similar to the 90th percentile meal size for general population adults (age 20–39 years) reported in a study by Smiciklas-Wright et al. (2002). However, because data for the general population may underestimate meal size for anglers, use of an upper percentile general population value may reflect higher intake among anglers. This is supported by data from other studies in the literature that have shown that the average meal size for sport fishing populations is higher than those of the general population. For example, Balcom et al. (1999) reported an average meal size for sport-caught fish for the angler

population of 7.3 ounces (i.e., 207 grams), while the average meal size for the general population was 5 ounces (142 grams). Other studies reported similar meal sizes for sport-caught fish. West et al. (1989) stated that the meal size most often reported in their survey was 8 ounces (i.e., 227 grams), and Connelly et al. (1996) estimated an average meal size of 216 grams. Another study reported an average meal size of 376 grams (Burger et al., 1999). Therefore, the meal size used by Fiore et al. (1989) was deemed reasonable to represent a mean value for the population of sport anglers. Table 10-68 presents distributions of fish consumption using a meal size of 227 grams.

This study is limited in its ability to accurately estimate intake rates because of the absence of data on weight of fish consumed. Another limitation of this study is that the results are based on 1-year recall, which may tend to over-estimate the number of fishing trips (Ebert et al., 1993). In addition, the response rate was rather low (50%).

10.5.2. West et al. (1989)—Michigan Sport Anglers Fish Consumption Survey

The Michigan Sport Anglers Fish Consumption Survey (West et al., 1989) surveyed a stratified random sample of Michigan residents with fishing licenses. The sample was divided into 18 cohorts, with one cohort receiving a mail questionnaire each week between January and May 1989. The survey included both a short-term recall component, and a usual frequency component. For the short-term recall component, respondents were asked to identify all household members and list all fish meals consumed by each household member during the past 7 days. Information on the source of the fish for each meal was also requested (self-caught, gift, market, or restaurant). Respondents were asked to categorize serving size by comparison with pictures of 8-ounce fish portions; serving sizes could be designated as either “about the same size,” “less,” or “more” than the size pictured. Data on fish species, locations of self-caught fish, and methods of preparation and cooking were also obtained.

The usual frequency component of the survey asked about the frequency of fish meals during each of the four seasons and requested respondents give the overall percentage of household fish meals that came from recreational sources. A sample of 2,600 individuals was selected from state records to receive survey questionnaires. A total of 2,334 survey questionnaires were deliverable, and 1,104 were completed and returned, giving a response rate of 47.3%.

Chapter 10—Intake of Fish and Shellfish

In the analysis of the survey data by West et al. (1989), the authors did not attempt to generate the distribution of recreationally caught fish intake in the survey population. U.S. EPA obtained the raw data of this survey for the purpose of generating fish intake distributions and other specialized analyses.

As described elsewhere in this handbook, percentiles of the distribution of average daily intake reflective of long-term consumption patterns cannot, in general, be estimated using short-term (e.g., 1 week) data. Such data can be used to adequately estimate mean average daily intake rates (reflective of short- or long-term consumption); in addition, short-term data can serve to validate estimates of usual intake based on longer recall.

U.S. EPA first analyzed the short-term data with the intent of estimating mean fish intake rates. In order to compare these results with those based on usual intake, only respondents with information on both short-term and usual intake were included in this analysis. For the analysis of the short-term data, U.S. EPA modified the serving size weights used by West et al. (1989), which were 5, 8, and 10-ounces, respectively, for portions that were less, about the same, and more than the 8-ounce picture. U.S. EPA examined the percentiles of the distribution of fish meal sizes reported in Pao et al. (1982) derived from the 1977–1978 USDA National Food Consumption Survey and observed that a lognormal distribution provided a good visual fit to the percentile data. Using this lognormal distribution, the mean values for serving sizes greater than 8 ounces and for serving sizes at least 10% greater than 8 ounces were determined. In both cases, a serving size of 12 ounces was consistent with the Pao et al. (1982) distribution. The weights used in the U.S. EPA analysis then were 5, 8, and 12 ounces for fish meals described as less, about the same, and more than the 8-ounces picture, respectively. The mean serving size from Pao et al. (1982) was about 5 ounces, well below the value of 8 ounces most commonly reported by respondents in the West et al. (1989) survey.

Table 10-69 displays the mean number of total and recreational fish meals for each household member based on the 7-day recall data. Also shown are mean fish intake rates derived by applying the weights described above to each fish meal. Intake was calculated on both g/day and g/kg body weight-day bases. This analysis was restricted to individuals who eat fish and who reside in households reporting some recreational fish consumption during the previous year. About 75% of survey respondents (i.e., licensed anglers) and about 84% of respondents who fished in the prior year reported some household recreational fish consumption.

The U.S. EPA analysis next attempted to use the short-term data to validate the usual intake data. West et al. (1989) asked the main respondent in each household to provide estimates of their usual frequency of fishing and eating fish, by season, during the previous year. The survey provides a series of frequency categories for each season, and the respondent was asked to check the appropriate range. The ranges used for all questions were almost daily, 2–4 times a week, once a week, 2–3 times a month, once a month, less often, none, and don't know. For quantitative analysis of the data, it is necessary to convert this categorical information into numerical frequency values. As some of the ranges are relatively broad, the choice of conversion values can have some effect on intake estimates. In order to obtain optimal values, the usual fish eating frequency reported by respondents for the season during which the questionnaire was completed was compared to the number of fish meals reportedly consumed by respondents over the 7-day short-term recall period.

The results of these comparisons are displayed in Table 10-70; it shows that, on average, there is general agreement between estimates made using 1-year recall and estimates based on 7-day recall. The average number of meals (1.96/week) was at the bottom of the range for the most frequent consumption group with data (2–4 meals/week). In contrast, for the lower usual frequency categories, the average number of meals was at the top, or exceeded the top of category range. This suggests some tendency for relatively infrequent fish eaters to underestimate their usual frequency of fish consumption. The last column of the table shows the estimated fish eating frequency per week that was selected for use in making quantitative estimates of usual fish intake. These values were guided by the values in the second column, except that frequency values that were inconsistent with the ranges provided to respondents in the survey were avoided.

Using the four seasonal fish-eating frequencies provided by respondents and the above conversions for reported intake frequency, U.S. EPA estimated the average number of fish meals per week for each respondent. This estimate, as well as the analysis above, pertains to the total number of fish meals eaten (in Michigan) regardless of the source of the fish. Respondents were not asked to provide a seasonal breakdown for eating frequency of recreationally caught fish; rather, they provided an overall estimate for the past year of the percent of fish they ate that was obtained from different sources. U.S. EPA estimated the annual frequency of recreationally caught fish meals by multiplying the estimated total number of fish meals by the reported

Chapter 10—Intake of Fish and Shellfish

percent of fish meals obtained from recreational sources; recreational sources were defined as either self-caught or a gift from family or friends.

The usual intake component of the survey did not include questions about the usual portion size for fish meals. In order to estimate usual fish intake, a portion size of 8 ounces was applied (the majority of respondents reported this meal size in the 7-day recall data). Individual body-weight data were used to estimate intake on a g/kg-day basis. Table 10-71 displays the fish intake distribution estimated by U.S. EPA.

The distribution shown in Table 10-71 is based on respondents who consumed recreational caught fish. As mentioned above, these represent 75% of all respondents and 84% of respondents who reported having fished in the prior year. Among this latter population, the mean recreational fish intake rate is $14.4 \times 0.84 = 12.1$ g/day; the value of 38.7 g/day (95th percentile among consumers) corresponds to the 95.8th percentile of the fish intake distribution in this (fishing) population.

The advantages of this data set and analysis are that the survey was relatively large and contained both short-term and usual intake data. The presence of short-term data allowed validation of the usual intake data, which were based on long-term recall; thus, some of the problems associated with surveys relying on long-term recall are mitigated here.

The response rate of this survey, 47%, was relatively low. In addition, the usual fish intake distribution generated here employed a constant fish meal size, 8 ounces. Although use of this value as an average meal size was validated by the short-term recall results, the use of a constant meal size, even if correct on average, may seriously reduce the variation in the estimated fish intake distribution.

This study was conducted in the winter and spring months of 1988. This period does not include the summer months, when peak fishing activity can be anticipated, leading to the possibility that intake results based on the 7-day recall data may understate individuals' usual (annual average) fish consumption. A second survey by West et al. (1993) gathered diary data on fish intake for respondents spaced over a full year. However, this later survey did not include questions about usual fish intake and has not been re-analyzed here. The mean recreational fish intake rates derived from the short-term and usual components were quite similar, however, 14.0 versus 14.4 g/day.

10.5.3. ChemRisk (1992)—Consumption of Freshwater Fish by Maine Anglers

ChemRisk conducted a study to characterize the rates of freshwater fish consumption among Maine residents (Ebert et al., 1993; ChemRisk, 1992). Because the only dietary source of local freshwater fish is recreational fish, the anglers in Maine were chosen as the survey population. The survey was designed to gather information on the consumption of fish caught by anglers from flowing (rivers and streams) and standing (lakes and ponds) water bodies. Respondents were asked to recall the frequency of fishing trips during the 1989–1990 ice-fishing season, and the 1990 open water season, the number of fish species caught during both seasons, and to estimate the number of fish consumed from 15 fish species. The respondents were also asked to describe the number, species, and average length of each sport-caught fish consumed that had been gifts from other members of their households or other households. The weight of fish consumed by anglers was calculated by first multiplying the estimated weight of the fish by the edible fraction and then dividing this product by the number of intended consumers. Species-specific regression equations were utilized to estimate weight from the reported fish length. The edible fractions used were 0.4 for salmon, 0.78 for Atlantic smelt, and 0.3 for all other species (Ebert et al., 1993).

A total of 2,500 prospective survey participants were randomly selected from a list of anglers licensed in Maine. The surveys were mailed in during October 1990. Because this was before the end of the open fishing season, respondents were also asked to predict how many more open water fishing trips they would undertake in 1990.

ChemRisk (1992) and Ebert et al. (1993) calculated distributions of freshwater fish intake for two populations, “all anglers” and “consuming anglers.” All anglers were defined as licensed anglers who fished during either the 1989–1990 ice-fishing season or the 1990 open-water season (consumers and non-consumers) and licensed anglers who did not fish but consumed freshwater fish caught in Maine during these seasons. “Consuming anglers” were defined as those anglers who consumed freshwater fish obtained from Maine sources during the 1989–1990 ice fishing or 1990 open water fishing season. In addition, the distribution of fish intake from rivers and streams was also calculated for two populations, those fishing on rivers and streams (“river anglers”), and those consuming fish from rivers and streams (“consuming river anglers”).

Chapter 10—Intake of Fish and Shellfish

A total of 1,612 surveys were returned, giving a response rate of 64%; 1,369 (85%) of the 1,612 respondents were included in the “all angler” population, and 1,053 (65%) were included in the “consuming angler” population. Table 10-72 presents freshwater fish intake distributions. The mean and 95th percentile were 5.0 g/day and 21.0 g/day, respectively, for “all anglers,” and 6.4 g/day and 26.0 g/day, respectively, for “consuming anglers.” Table 10-72 also presents intake distributions for fish caught from rivers and streams. Among “river anglers,” the mean and 95th percentile were 1.9 g/day and 6.2 g/day, respectively, while among “consuming river anglers,” the mean and the 95th percentile were 3.7 g/day and 12.0 g/day, respectively. Table 10-73 presents fish intake distributions by ethnic group for consuming anglers. The highest mean intake rates reported are for Native Americans (10 g/day) and French Canadians (7.4 g/day). Because there was a low number of respondents for Hispanics, Asian/Pacific Islanders, and African Americans, intake rates within these groups were not calculated (ChemRisk, 1992).

Table 10-74 presents the consumption, by species, of freshwater fish caught. The largest species consumption was salmon from ice fishing (~292,000 grams); white perch (380,000 grams) for lakes and ponds; and Brook trout (420,000 grams) for rivers and streams (ChemRisk, 1992).

U.S. EPA obtained the raw data tapes from the marine anglers survey and performed some specialized analyses. One analysis involved examining the percentiles of the “resource utilization distribution” (this distribution was defined in Section 10.1). The 50th, or more generally, the p^{th} percentile of the resource utilization distribution, is defined as the consumption level such that p percent of the resource is consumed by individuals with consumptions below this level and $100-p$ percent by individuals with consumptions above this level. U.S. EPA found that 90% of recreational fish consumption was by individuals with intake rates above 3.1 g/day, and 50% was by individuals with intakes above 20 g/day. Those above 3.1 g/day make up about 30% of the “all angler” population, and those above 20 g/day make up about 5% of this population; thus, the top 5% of the angler population consumed 50% of the recreational fish catch.

U.S. EPA also performed an analysis of fish consumption among anglers and their families. This analysis was possible because the survey included questions on the number, sex, and age of each individual in the household and whether the individual consumed recreationally caught fish. The total population of licensed anglers in this survey and

their household members was 4,872; the average household size for the 1,612 anglers in the survey was thus 3.0 persons. Fifty-six percent of the population was male, and 30% was 18 or under.

A total of 55% of this population was reported to consume freshwater recreationally caught fish in the year of the survey. The sex and ethnic distribution of the consumers was similar to that of the overall population. The distribution of fish intake among the overall household population, or among consumers in the household, can be calculated under the assumption that recreationally caught fish was shared equally among all members of the household reporting consumption of such fish (note this assumption was used above to calculate intake rates for anglers). With this assumption, the mean intake rate among consumers was 5.9 g/day, with a median of 1.8 g/day, and a 95th percentile of 23.1 g/day; for the overall population, the mean was 3.2 g/day and the 95th percentile was 14.1 g/day.

The results of this survey can be put into the context of the overall Maine population. The 1,612 anglers surveyed represent about 0.7% of the estimated 225,000 licensed anglers in Maine. It is reasonable to assume that licensed anglers and their families will have the highest exposure to recreationally caught freshwater fish. Thus, to estimate the number of persons in Maine with recreationally caught freshwater fish intake above, for instance, 6.5 g/day (the 80th percentile among household consumers in this survey), one can assume that virtually all persons came from the population of licensed anglers and their families. The number of persons above 6.5 g/day in the household survey population is calculated by taking 20% (i.e., 100–80%) of the consuming population in the survey; this number then is $0.2 \times (0.55 \times 4,872) = 536$. Dividing this number by the sampling fraction of 0.007 (0.7%), gives about 77,000 persons above 6.5 g/day of recreational freshwater fish consumption statewide. The 1990 census showed the population of Maine to be 1.2 million people; thus, the 77,000 persons above 6.5 g/day represent about 6% of the state’s population.

ChemRisk (1992) reported that the fish consumption estimates were based upon the following assumptions: a 40% estimate as the edible portion of landlocked and Atlantic salmon; inclusion of the intended number of future fishing trips and an assumption that the average success and consumption rates for the individual angler during the trips already taken would continue through future trips. The data collected for this study were based on recall and self-reporting, which may have resulted in a biased estimate. The social desirability of the sport and

Chapter 10—Intake of Fish and Shellfish

frequency of fishing are also bias-contributing factors; successful anglers are among the highest consumers of freshwater fish (ChemRisk, 1992). Additionally, fish advisories are in place in these areas and may affect the rate of fish consumption among anglers. The survey results showed that in 1990, 23% of all anglers consumed no freshwater fish, and 55% of the river anglers ate no freshwater fish. An advantage of this study is that the sample size is rather large.

10.5.4. Connelly et al. (1992)—Effects of Health Advisory and Advisory Changes on Fishing Habits and Fish Consumption in New York Sport Fisheries

Connelly et al. (1992) conducted a study to assess the awareness and knowledge of New York anglers about fishing advisories and contaminants found in fish and their fishing and fish consuming behaviors. The survey sample consisted of 2,000 anglers with New York State fishing licenses for the year beginning October 1, 1990, through September 30, 1991. A questionnaire was mailed to the survey sample in January 1992. The questionnaire was designed to measure catch and consumption of fish, as well as methods of fish preparation and knowledge of and attitudes towards health advisories (Connelly et al., 1992). The survey-adjusted response rate was 52.8% (1,030 questionnaires were completed, and 51 were not deliverable).

The average and median number of fishing days per year were 27 and 15 days, respectively (Connelly et al., 1992). The mean number of sport-caught fish meals was 11 meals/year. The maximum number of meals consumed was 757 meals/year. About 25% of anglers reported that they did not consume sport-caught fish.

Connelly et al. (1992) found that 80% of anglers statewide did not eat listed species or ate them within advisory limits and followed the 1 sport-caught fish meal per week recommended maximum. The other 20% of anglers exceeded the advisory recommendations in some way; 15% ate listed species above the limit, and 5% ate more than one sport-caught meal per week.

Connelly et al. (1992) found that respondents eating more than 1 sport-caught meal per week were just as likely as those eating less than one meal per week to know the recommended level of sport-caught fish consumption, although less than 1/3 in each group knew the level. An estimated 85% of anglers were aware of the health advisory. Over 50% of respondents said that they made changes in their

fishing or fish consumption behaviors in response to health advisories.

The advisory included a section on methods that can be used to reduce contaminant exposure. Respondents were asked what methods they used for fish cleaning and cooking.

A limitation of this study with respect to estimating fish intake rates is that only the number of sport-caught meals was ascertained, not the weight of fish consumed. The fish meal data can be converted to a mean intake rate (g/day) by assuming a meal size of 227 g/meal (i.e., 8 ounces). This value corresponds to the adult general population 90th percentile meal size derived from Smiciklas-Wright et al. (2002). The resulting mean intake rate among the angler population would be 6.8 g/day. However, about 25% of this population reported no sport-caught fish consumption. Therefore, the mean consumption rate among consuming anglers would be 27.4 g/day (i.e., 6.8 g/day divided by 0.25).

The major focus of this study was not on consumption, per se, but on the knowledge of and impact of fish health advisories; Connelly et al. (1992) provides important information on these issues.

10.5.5. Hudson River Sloop Clearwater, Inc. (1993)—Hudson River Angler Survey

Hudson River Sloop Clearwater, Inc. (1993) conducted a survey of adherence to fish consumption health advisories among Hudson River anglers. All fishing has been banned on the upper Hudson River where high levels of PCB contamination are well documented; while voluntary recreational fish consumption advisories have been issued for areas south of the Troy Dam (Hudson River Sloop Clearwater, 1993).

The survey consisted of direct interviews with 336 shore-based anglers between the months of June and November 1991, and April and July 1992. Table 10-75 presents socio-demographic characteristics of the respondents. The survey sites were selected based on observations of use by anglers, and legal accessibility. The selected sites included upper-, mid-, and lower- Hudson River sites located in both rural and urban settings. The interviews were conducted on weekends and weekdays during morning, midday, and evening periods. The anglers were asked specific questions concerning: fishing and fish consumption habits; perceptions of presence of contaminants in fish; perceptions of risks associated with consumption of recreationally caught fish; and awareness of, attitude toward, and response to fish consumption advisories or fishing bans.

Chapter 10—Intake of Fish and Shellfish

Approximately 92% of the survey respondents were male. The following statistics were provided by Hudson River Sloop Clearwater, Inc. (1993). The most common reason given for fishing was for recreation or enjoyment. Over 58% of those surveyed indicated that they eat their catch. Of those anglers who eat their catch, 48% reported being aware of advisories. Approximately 24% of those who said they currently do not eat their catch have done so in the past. Anglers were more likely to eat their catch from the lower Hudson areas where health advisories, rather than fishing bans, have been issued. Approximately 94% of Hispanic Americans were likely to eat their catch, while 77% of African Americans and 47% of Caucasian Americans intended to eat their catch. Of those who eat their catch, 87% were likely to share their meal with others (including women of childbearing age, and children under the age of 15).

For subsistence anglers, more low-income than upper-income anglers eat their catch (Hudson River Sloop Clearwater, 1993). Approximately 10% of the respondents stated that food was their primary reason for fishing; this group is more likely to be in the lowest per capita income group (Hudson River Sloop Clearwater, 1993).

The average frequency of fish consumption reported was just under 1 (0.9) meal over the previous week, and 3 meals over the previous month. Approximately 35% of all anglers who eat their catch exceeded the amounts recommended by the New York State health advisories. Less than half (48%) of all the anglers interviewed were aware of the State health advisories or fishing bans. Only 42% of those anglers aware of the advisories have changed their fishing habits as a result.

The advantages of this study include in-person interviews with 95% of all anglers approached; field-tested questions designed to minimize interviewer bias; and candid responses concerning consumption of fish from contaminated waters. The limitations of this study are that specific intake amounts are not indicated, and that only shore-based anglers were interviewed.

10.5.6. West et al. (1993)—Michigan Sport Anglers Fish Consumption Study, 1991–1992

West et al. (1993) conducted a survey financed by the Michigan Great Lakes Protection Fund, as a follow-up to the earlier 1989 Michigan survey described previously. The major purpose of 1991–1992 survey was to provide short-term recall data of recreational fish consumption over a full year period;

the 1989 survey, in contrast, was conducted over only a half year period (West et al., 1993).

This survey was similar in design to the 1989 Michigan survey. A sample of 7,000 persons with Michigan fishing licenses was drawn, and surveys were mailed in 2-week cohorts over the period January 1991 to January 1992. Respondents were asked to report detailed fish consumption patterns during the preceding 7 days, as well as demographic information; they were also asked if they currently eat fish. Enclosed with the survey were pictures of about a half pound of fish. Respondents were asked to indicate whether reported consumption at each meal was more, less, or about the same as the picture. Based on responses to this question, respondents were assumed to have consumed ten, 5- or 8-ounce portions of fish, respectively.

A total of 2,681 surveys were returned. West et al. (1993) calculated a response rate for the survey of 46.8%; this was derived by removing from the sample those respondents who could not be located or who did not reside in Michigan for at least 6 months.

Of these 2,681 respondents, 2,475 (93%) reported that they currently eat fish; all subsequent analyses were restricted to the current fish eaters. The mean fish consumption rates were found to be 16.7 g/day for sport fish and 26.5 g/day for total fish (West et al., 1993). Table 10-76 shows mean sport-fish consumption rates by demographic categories. Rates were higher among minorities, people with low income, and people residing in smaller communities. Consumption rates in g/day were also higher in males than in females; however, this difference would likely disappear if rates were computed on a g/kg-day basis.

West et al. (1993) estimated the 80th percentile of the survey fish consumption distribution. More extensive percentile calculations were performed by U.S. EPA (1995) using the raw data from the West et al. (1993) survey. However, because this survey only measured fish consumption over a short (1 week) interval, the resulting distribution will not be indicative of the long-term fish consumption distribution, and the upper percentiles reported from the U.S. EPA analysis will likely considerably overestimate the corresponding long-term percentiles. The overall 95th percentile calculated by U.S. EPA (1995) was 77.9; this is about double the 95th percentile estimated using yearlong consumption data from the 1989 Michigan survey.

The limitations of this survey are the relatively low response rate and the fact that only three categories were used to assign fish portion size. The main study strengths were its relatively large size and its reliance on short-term recall.

Chapter 10—Intake of Fish and Shellfish

**10.5.7. Alabama Dept. of Environmental Management (ADEM) (1994)—
Estimation of Daily Per Capita
Freshwater Fish Consumption of
Alabama Anglers**

The Alabama Department of Environmental Management (1994) conducted a fish consumption survey of sport-fishing Alabama anglers during the time period from August 1992 to August 1993. The target population included all anglers who were Alabama residents. The survey design consisted of personal interviews given to sport fishermen at the end of their fishing trips at 23 sampling sites. Each sampling site was surveyed once during each season (summer, fall, winter, and spring). The survey was conducted for 2 consecutive days, either a Friday and Saturday or a Sunday and Monday. This approach minimized single-day-type bias and maximized surveying the largest number of anglers because a large amount of fishing occurs on weekends. Anglers were asked about consumption of fish caught at the sampling site as well as consumption of fish caught from other lakes and rivers in Alabama.

A total of 1,586 anglers were interviewed during the entire study period, of which, 83% reported eating fish they caught from the sampling sites (1,313 anglers). The number of anglers interviewed during each season was as follows: 488 during the summer, 363 during the fall, 224 during the winter, and 511 during the spring. Fish consumption rates were estimated using two methods: the 4-ounce Serving Method and the Harvest Method. The 4-ounce Serving Method estimated consumption based on a typical 4-ounce serving size. The Harvest Method used the actual harvest of fish and dressing method reported. All of the 1,313 anglers were used in the mean estimates of daily consumption based on the 4-ounce Serving Method, while only 563 anglers were utilized in the calculations of mean estimates of daily consumption, based on the Harvest Method.

Table 10-77 shows the results of the survey. Adults consumed an annual average of 32.6 g/day using the Harvest Method, calculated from study sites, and an annual average of 43.1 g/day using the Harvest Method, calculated from study sites plus other Alabama lakes and rivers. The survey also showed that adults consumed an annual average of 30.3 g/day using the 4-ounce Serving Method, calculated from study sites, and an annual average of 45.8 g/day using the 4-ounce Serving Method, calculated from study sites plus other Alabama lakes and rivers. When the entire sample was pooled, and a mean was taken over all respondents for the 4-ounce

Serving Method, the average annual consumption was 44.8 g/day.

The study also examined fish consumption in conjunction with socio-demographic factors. It was noted that fish consumption tended to increase with age. Anglers below the age of 20 years were not well represented in this study. However, based on estimates of consumption rates using the 4-ounce Serving Method, the study found that anglers between 20 and 30 years of age consumed an average of 16 g/day, anglers between 30 and 50 years old consumed 39 g/day, and anglers over 50 years old consumed 76 g/day. Trends also emerged when ethnic groups and income levels were examined together. Using the 4-ounce Serving Method, estimates of fish consumption for Blacks dropped from 60 g/day for poverty-level families to 15 g/day for upper-income families. For Whites, fish consumption rates dropped slightly from 41 g/day for poverty-level families to 35 g/day for upper-income families. Similar trends were observed with the Harvest Method estimates. Averaging the results from the two estimation methods, there was a tendency for upper-income White anglers to eat roughly 30% less fish than poverty-level White anglers, while upper-income Black anglers ate about 80% less fish as poverty-level Black anglers. The analysis of seasonal intake showed that the highest consumption rates were consistently found to occur in the summer (see Table 10-77). It was also found the lowest fish consumption rate occurred in the spring.

The advantages of this study are that it compares estimates of intake using two different methods and provides some perspective on seasonal differences in intake. Data are not provided for children, and the number of observations for some race/ethnic groups is very small.

**10.5.8. Connelly et al. (1996)—Sportfish
Consumption Patterns of Lake Ontario
Anglers and the Relationship to Health
Advisories, 1992**

The objectives of the Connelly et al. (1996) study were to provide accurate estimates of fish consumption (overall and sport caught) among Lake Ontario anglers and to evaluate the effect of Lake Ontario health advisory recommendations (Connelly et al., 1996). To target Lake Ontario anglers, a sample of 2,500 names was randomly drawn from 1990–1991 New York fishing license records for licenses purchased in six counties bordering Lake Ontario. Participation in the study was solicited by mail with potential participants encouraged to enroll in the study even if they fished infrequently or consumed

Chapter 10—Intake of Fish and Shellfish

little or no sport-caught fish. The survey design involved three survey techniques including a mail questionnaire asking for 12-month recall of 1991 fishing trips and fish consumption, self-recording information in a diary for 1992 fishing trips and fish consumption, periodic telephone interviews to gather information recorded in the diary, and a final telephone interview to determine awareness of health advisories (Connelly et al., 1996).

Participants were instructed to record in the diary the species of fish eaten, meal size, method by which fish was acquired (sport-caught or other), fish preparation and cooking techniques used, and the number of household members eating the meal. Fish meals were defined as finfish only. Meal size was estimated by participants by comparing their meal size to pictures of 8-ounce fish steaks and fillets on dinner plates. An 8-ounce size was assumed unless participants noted their meal size was smaller than 8 ounces, in which case, a 4-ounce size was assumed, or they noted it was larger than 8 ounces, in which case, a 12-ounce size was assumed. Participants were also asked to record information on fishing trips to Lake Ontario and species and length of any fish caught.

From the initial sample of 2,500 license buyers, 1,993 (80%) were reachable by phone or mail, and 1,410 of these were eligible for the study, in that they intended to fish Lake Ontario in 1992. A total of 1,202 of these 1,410, or 85%, agreed to participate in the study. Of the 1,202 participants, 853 either returned the diary or provided diary information by telephone. Due to changes in health advisories for Lake Ontario, which resulted in less Lake Ontario fishing in 1992, only 43%, or 366 of these 853 persons indicated that they fished Lake Ontario during 1992. The study analyses summarized below concerning fish consumption and Lake Ontario fishing participation are based on these 366 persons.

Anglers who fished Lake Ontario reported an average of 30.3 (standard error = 2.3) fish meals per person from all sources in 1992; of these meals, 28% were sport caught (Connelly et al., 1996). Less than 1% ate no fish for the year, and 16% ate no sport-caught fish. The mean fish intake rate from all sources was 17.9 g/day, and from sport-caught sources was 4.9 g/day. Table 10-78 gives the distribution of fish intake rates from all sources and from sport-caught fish. The median rates were 14.1 g/day for all sources and 2.2 g/day for sport caught; the 95th percentiles were 42.3 g/day and 17.9 g/day for all sources and sport caught, respectively. As seen in Table 10-79, statistically significant differences in intake rates were seen across age and residence groups, with residents of

large cities and younger people having lower intake rates, on average.

The main advantage of this study is the diary format. This format provides more accurate information on fishing participation and fish consumption, than studies based on 1-year recall (Ebert et al., 1993). However, a considerable portion of diary respondents participated in the study for only a portion of the year, and some errors may have been generated in extrapolating these respondents' results to the entire year (Connelly et al., 1996). In addition, the response rate for this study was relatively low—853 of 1,410 eligible respondents, or 60%—which may have engendered some non-response bias.

The presence of health advisories should be taken into account when evaluating the intake rates observed in this study. Nearly all respondents (>95%) were aware of the Lake Ontario health advisory. This advisory counseled to eat none of nine fish species from Lake Ontario and to eat no more than one meal per month of another four species. In addition, New York State issues a general advisory to eat no more than 52 sport-caught fish meals per year. Among participants who fished Lake Ontario in 1992, 32% said they would eat more fish if health advisories did not exist. A significant fraction of respondents did not totally adhere to the fish advisory; however, 36% of respondents, and 72% of respondents reporting Lake Ontario fish consumption, ate at least one species of fish over the advisory limit. Interestingly, 90% of those violating the advisory reported that they believed they were eating within advisory limits.

10.5.9. Balcom et al. (1999)—Quantification of Seafood Consumption Rates for Connecticut

Balcom et al. (1999) conducted a seafood consumption study in Connecticut, utilizing a food frequency questionnaire along with portion size models. Follow-up telephone calls were made to encourage participation 7–10 days after mailing the questionnaires to improve response rates. Information requested in the survey included frequency of fish consumption, types of fish/seafood eaten, portion size, parts eaten, and the source of the fish/seafood eaten. A diary was also given to the sample populations to record fish and seafood consumption over a 10-day period, and to document where the fish/seafood was obtained and how it was prepared.

The sample population size for this study was 2,354 individuals (1,048 households). The study authors divided this overall population into various population groups including the general population (460 individuals/216 households), commercial

Chapter 10—Intake of Fish and Shellfish

fishing population (178 individuals/73 households), sport fishing and cultural/subsistence fishing population (514 individuals/348 households), minority population (860 individuals/245 households), Southeast Asian (329 individuals/89 households), non-Southeast Asian (531 individuals/156 households), limited income population (937 individuals/276 households), women of childbearing age population (493 individuals/420 households), and children population (559 individuals/305 households).

It is important to note that the nine population groups used in this study are not mutually exclusive. Many individuals were included in more than one population. For this reason, the authors did not attempt to make any statistical comparisons between the population groups.

The survey showed that over 33% of the respondents ate 1–2 meals of fish or seafood per week, including 39% of the general population, 35% of the sport fishing population, 38% of the commercial and minority populations, and 39% of the limited income population. A total of 36% of the Southeast Asian population consumed 2–3 meals per week with 2.1% consuming 5 or more meals per week, while 43% of non-Southeast Asians consumed 1–2 meals of seafood per week. The general population consumed, on average, 4.2 ounces of fish per meal of purchased fish and 5.0 ounces per meal of caught fish. Individuals in the sport fishing population showed a marked difference, consuming 4.7 ounces per meal of bought fish and 7.3 ounces per meal of caught fish. Southeast Asians consumed smaller portions of fish per meal, and children consumed the smallest portions of fish per meal.

On average, the general population consumed 27.7 g/day of fish and seafood while the sport fishing population consumed 51.1 g/day (see Table 10-80). The consumption of sport fish among consuming anglers can be estimated by dividing the consumption for all respondents by the percentage of consuming anglers reported by Balcom et al. (1999) of 97% to yield 52.7 g/day. The commercial fishing population had an average consumption rate of 47.4 g/day, while the limited income population's rate was 43.1 g/day. The overall minority population consumption rate was 50.3 g/day, with Southeast Asians consuming an average of 59.2 g/day (the highest overall rate) and non-Southeast Asians consuming an average of 45.0 g/day. Child-bearing age women consumed an average of 45.0 g/day, and children consumed an average of 18.3 g/day.

The study also examined fish preparations and cooking practices for each population group. It was found that the sport fishing population was most

likely to perform risk-reducing preparation methods compared to the other populations, while the minority population was least likely to use the same risk-reducing methods. Cooking information by specie was only available for the Southeast Asian population, but the most common cooking methods were boiling, poaching-boiling-steaming, sauté/stir fry, and deep frying.

The authors noted that there were some limitations to this study. First, there was some association among household members in terms of the tendency to eat fish and seafood, but there was no dependence between households. Second, the study had a very low percent return rate for the general population mail survey, and it is questionable whether or not the responses accurately reflect the total population's behavior. In addition, the proportion of intake that can be attributed to freshwater fish is not known.

10.5.10. Burger et al. (1999)—Factors in Exposure Assessment: Ethnic and Socioeconomic Differences in Fishing and Consumption of Fish Caught Along the Savannah River

Burger et al. (1999) examined the differences in fishing rates and fish consumption of people fishing along the Savannah River as a function of age, education, ethnicity, employment history, and income. A total of 258 people who were fishing on the Savannah River were interviewed. The interviews were conducted both on land and by boat from April to November 1997. Anglers were asked about fishing behavior, consumption patterns, cooking patterns, knowledge of warnings and safety of fish, and personal demographics. The authors used multiple regression procedures to examine the relative contribution of ethnicity, income, age, and education to parameters such as years fished, serving size, meals/month, and total ounces of fish consumed per year.

Eighty-nine percent of people interviewed were men, 70% were White, 28% were African American, and 2% were of other ethnicity not specified in the study. The age of the interviewees ranged from 16 to 82 years (mean = 43 ± 1 years). The study authors reported that the average fish intake for all survey respondents was 1.46 kg of fish per month (48.7 g/day). Although most of the respondents were men, they indicated that their wives and children consumed fish as often as they did, and children began to eat fish at 3 to 5 years of age.

There were significant differences in fishing behavior and consumption as a function of ethnicity (see Table 10-81). African Americans fished more

Chapter 10—Intake of Fish and Shellfish

often, consumed fish more frequently, and ate larger portions of fish than did Whites. Given the higher level of consumption by African Americans compared to consumption by Whites, the study authors suggested that the potential for exposure is higher for African Americans than for Whites, although the risks depend on the levels of contaminants in the fish. Income and education also contributed to variations in fishing and consumption behavior. Anglers with low incomes (less than or equal to \$20,000) ate fish more often than those with higher incomes. Anglers who had not graduated from high school consumed fish more frequently, ate more fish per month and per year, and deep fried fish more often than anglers with more education. At all levels of education, African Americans consumed more fish than Whites.

The authors acknowledged that there may have been sampling bias in the study because they only interviewed people who were fishing on the river and were, therefore, limited to those people they found. To reduce the bias, the authors conducted the survey at all times of the day, on all days of the week, and along different sections of the river. Another limitation noted by the study authors is that the survey asked questions about consumption of fish from two general sources: self-caught and bought. The study authors indicated that it would have been useful to distinguish between fish obtained directly from the wild by the anglers, their friends or family, and store-bought or restaurant fish.

10.5.11. Williams et al. (1999)—Consumption of Indiana Sport-Caught Fish: Mail Survey of Resident License Holders

In 1997, sport-caught fish consumption among licensed Indiana anglers was assessed using a mail survey (Williams et al., 1999). Anglers were asked about their consumption patterns during a 3-month recall, their fishing rates, species of fish consumed, awareness of advisory warnings, and associated behaviors.

Average meal size among respondents was 9.3 ounces per meal. Consumers indicated that, on average, they ate between 1 and 2 meals per month. The survey population was divided into active consumers (those who actively engage in consuming sport fish meals) and potential consumers (those who eat fish during other times of the year). The average consumption rate for active consumers was reported as 19.8 g/day. For both active and potential consumers, the rate was 16.4 g/day (see Table 10-82).

The statewide mail survey of licensed Indiana anglers did not specifically address lower-income and

minority anglers. The respondents to the mail survey were predominately White (94.5%). The recall period for this survey extended from the summer through the end of fall and early winter. No information was collected on consumption during spring or winter. Another limitation of the study was that only sport-caught fish consumption was measured among anglers.

10.5.12. Burger (2000)—Gender Differences in Meal Patterns: Role of Self-Caught Fish and Wild Game in Meat and Fish Diets

Burger (2000) used the hypothesis that there are sex differences in consumption patterns of self-caught fish and wild game in a meat and fish diet. A total of 457 people were randomly selected and interviewed while attending the Palmetto Sportsmen's Classic in Columbia, SC in March 1998. The mean age of the respondents was 40 years and ranged from 15 to 74. The questionnaire requested information on two different categories: socio-demographics and number of meals consumed that included several types of fish and wild game. The demographics section contained questions dealing with ethnicity, sex, age, location of residence, occupation, and income. The section on consumption of wild game and fish included specific questions about the number of meals eaten and the source (i.e., self-caught fish, store-bought fish, and restaurant fish).

The results of this study indicated that there were no sex differences in the percentage of people who ate commercial protein sources, but there were significant sex differences for the consumption of most wild-caught game and fish. A higher proportion of men (81.5%) ate wild-caught species than women (73.2%). There were also sex differences in mean monthly meals and mean serving sizes for wild-caught fish. Men ate more meals of wild-caught fish than woman, and men also ate larger portions than women. The mean number of wild-caught fish meals eaten per month was 2.24 for men and 1.52 for women. The mean serving size was 373 grams for men and 232 for women. The study authors also found that individuals who consumed a large number of fish meals per month consumed a higher percentage of wild-caught fish meals than individuals who consumed a small number of fish meals per month.

This study provides information on sex differences with regard to consumption of wild-caught fish. Information on the number of monthly meals and meal size is provided. However, the study did not distinguish between marine and

Chapter 10—Intake of Fish and Shellfish

freshwater fish. In addition, all subjects interviewed were White.

10.5.13. Williams et al. (2000)—An Examination of Fish Consumption by Indiana Recreational Anglers: An Onsite Survey

An on-site survey of Indiana anglers was conducted in the summer of 1998 (Williams et al., 2000). A total of 946 surveys were completed. Minority anglers accounted for 31.8% of those surveyed, with African American anglers accounting for the majority of this group (25.1% of all respondents). Respondents reporting household incomes below \$25,000 comprised 30.9% of the respondents. Anglers were asked to report their Indiana sport-caught fish consumption frequency for a 3-month recall period. Using the meal frequency and portion size reported by the anglers, the amount of fish consumed was calculated into a daily amount called grams per day consumption. Consumption rates were weighted to correct for participation bias.

Consumption was reported as 27.2 g/day among minority consumers and 20.0 g/day among White consumers (see Table 10-83). Of the anglers surveyed, 75.4% of White active consumers reported being aware of the fish consumption advisory, while 70.0% of the minority consumers reported awareness. The study authors also examined angler consumption rate based on the level of awareness of Indiana fish consumption advisories reported by the anglers. The consumption rate for those consumers who were very aware of the advisory was 35.2 g/day. For those with a general awareness of the advisory, the consumption rate was 14.1 g/day, and for those who were not aware of the advisory, the consumption rate was 21.3 g/day. In terms of income, the study authors found that there was a significant difference in grams of Indiana sport-caught fish consumed per day. Anglers reporting a household income below \$25,000 had an average consumption rate of 18.9 g/day. Anglers with incomes between \$25,000 and \$34,999 averaged 18.8 g/day, and anglers with incomes between \$35,000 and \$49,999 averaged 15.2 g/day. The highest income—those reporting an income \$50,000 or above—consumed an average of 48.9 g/day.

The advantages of this study are that it was designed to determine the consumption rates of Indiana anglers, particularly those in minority and low-income groups, during a portion of the year. However, information was not collected for the period of September through January, so calculation of year-round consumption was not possible.

10.5.14. Benson et al. (2001)—Fish Consumption Survey: Minnesota and North Dakota

Benson et al. (2001) conducted a fish consumption survey among Minnesota and North Dakota residents. The target population included the general population, licensed anglers, and members of Native American tribes. The survey focused on obtaining the most recent year's fish intake from all sources, including locally caught fish. Survey questionnaires were mailed to potential respondent households. Groups of interest were selected and allotted a portion of the total number of surveys to be distributed to each group as follows: a group categorized as the general population and anglers received 37.5% of the surveys, and new mothers and Native Americans each received 12.5% of the total surveys distributed. The survey distribution was split 60/40 between Minnesota and North Dakota. For the entire survey population, a total of 1,565 surveys were returned completed (out of 7,835 that were mailed out), resulting in a total of 4,273 respondents. A target of 100 completed telephone interviews of non-respondents was set in order to characterize the non-respondent population. However, this target was not met.

The Minnesota survey showed median total fish and sport fish consumption rates for the general population (2,312 respondents) of 12.3 and 2.8 g/day, respectively (see Table 10-84). The total number of Minnesota Bois Forte Tribe respondents was 232, and median total fish and sport fish consumption rates in g/day were 9.3 and 2.8, respectively. For Minnesota residents with fishing licenses (2,020 respondents), median total fish and sport fish consumption rates in g/day were 13.2 and 3.9, respectively. For Minnesota respondents without fishing licenses, median total fish and sport fish consumption rates in g/day were 7.5 and 0, respectively. Table 10-84 also shows median intake rates for purchased fish, upper percentile intake rates for total fish, sport fish and purchased fish for various age groups.

The North Dakota survey showed median total fish and sport fish consumption rates for the general population (1,406 respondents) of 12.6 and 3.0 g/day, respectively (see Table 10-84). The total number of North Dakota Spirit Lake Nation and Three Affiliated Tribes respondents was 105, and the median total fish and sport fish consumption rates in g/day were 1.4 and 0, respectively. For North Dakota residents with fishing licenses (1,101 respondents), median total fish and sport fish consumption rates in g/day were 14.0 and 4.5, respectively. For North Dakota respondents without fishing licenses, median total fish and sport fish consumption rates in g/day were

Chapter 10—Intake of Fish and Shellfish

7.2 and 0, respectively. Table 10-84 also shows median intake rates for purchased fish, upper percentile intake rates for total fish, sport fish and purchased fish for various age groups.

Westat (2006) analyzed the raw data from Benson et al. (2001) to derive fish consumption rates for various age, sex, and ethnic groups, and according to the source of fish consumed (i.e., bought or caught) and habitat (i.e., freshwater, estuarine, or marine). Westat (2006) calculated consumption rates of freshwater fish for consuming anglers. For Minnesota and North Dakota, these values are identical to the consumption rates estimated by Westat (2006) for consuming anglers of all self-caught fish (i.e., freshwater and saltwater). From this observation, it can be concluded that all the consumption of self-caught fish comes from freshwater. The mean and 95th percentile consumption rate for consuming anglers of freshwater fish reported by Westat (2006) are 14 g/day and 37 g/day, respectively, for Minnesota and 12 g/day and 43 g/day, respectively, for North Dakota.

The authors noted that 80% of respondents in Minnesota and 72% of respondents in North Dakota lived in a household that included a licensed angler. They stated that this was a result of a direct intent to oversample the angling population in both states by sending 37.5% of surveys distributed to persons who purchased a fishing license in either Minnesota or North Dakota. The data were adjusted to incorporate overall licensed angler rates in both states (47.3% of households in Minnesota and 40.0% of households in North Dakota).

An advantage of this study is its large overall sample size. A limitation of the study is the low numbers of Native Americans surveyed; thus, the survey may not be representative of overall Native American populations in Minnesota. In addition, the study did not include Asian Immigrants, African Americans, African immigrants, or Latino populations, and was limited to two states. Therefore, the results may not be representative of the U.S. population as a whole.

10.5.15. Moya and Phillips (2001)—Analysis of Consumption of Home-Produced Foods

As discussed in Section 10.4.2.5, some data on fish consumption from households who fish are provided in Chapter 13 and in Moya and Phillips (2001). This information is based on an analysis of data from the household component of the USDA's 1987–1988 NFCS. This analysis shows a mean consumer-only fish consumption of 2.2 g/kg-day (all ages combined, see Table 13-20) for the fishing

population. This value can be converted to a per capita value by multiplying by the number of consumers and dividing by the total number of positive responses to the survey question “do you fish?” Assuming an average body weight of 59 kg for the survey population results in an average national per capita self-caught fish consumption rate of 12 g/day among the population of individuals who fish. However, this mean intake rate represents intake of both freshwater and saltwater fish combined. Converting this number into the edible portion by multiplying by 0.5 as described in Section 10.4.2.5, the mean national per capita self-caught fish consumption rate is about 6 g/day.

The advantage of this study is that it provides a national perspective on the consumption of self-caught fish. A limitation of this study is that these values include both freshwater and saltwater fish. The proportion of freshwater to saltwater is unknown and will vary depending on geographical location. Intake data cannot be presented for various age groups due to sample size limitations. The unweighted number of households, who responded positively to the survey question “do you fish?” was also low (i.e., 220 households).

10.5.16. Rouse Campbell et al. (2002)—Fishing Along the Clinch River Arm of Watts Bar Reservoir Adjacent to the Oak Ridge Reservation, Tennessee: Behavior, Knowledge, and Risk Perception

Rouse Campbell et al. (2002) examined consumption habits of anglers fishing along the Clinch River arm of Watts Bar Reservoir, adjacent to the U.S. Department of Energy's Oak Ridge Reservation in East Tennessee. A total of 202 anglers were interviewed on 65 sampling days, which included 48 weekdays and 17 weekend days. Eighty-six percent of fishermen interviewed were fishing from the shore, while 14% were fishing from a boat. The questionnaire utilized in the study included questions on demographics, fishing behavior, perceptions, cooking patterns, consumption patterns, and consumption warnings. Interviews were conducted by two people who were local to the area in order to promote participation in the study.

Out of all anglers interviewed, approximately 35% did not eat fish. Of the 65% who ate fish, only 38% ate fish from the study area. This 38% (77 people) was considered useful to the study and, thus, were the main focus of the data analysis. These anglers averaged 2 meals of fish per month, with an average consumption rate of 37 grams per day or 13.7 kilograms per year (see Table 10-85). They

Chapter 10—Intake of Fish and Shellfish

caught almost 90% of the fish they ate, had a mean age of 42 years, and a mean income of \$28,800. The species of fish most often mentioned by anglers who caught and ate fish from the study area were crappie, striped bass, white bass, sauger, and catfish.

A limitation of this study is that the small size of the population does not allow for statistically significant analysis of the data.

10.5.17. Burger (2002b)—Daily Consumption of Wild Fish and Game: Exposure of High-End Recreationists

Burger (2002b) determined consumption patterns for a range of wild-caught fish and game in South Carolina. The population selected for dietary surveys were attendees at the Palmetto Sportsman's Classic in Columbia, South Carolina. Individual dietary surveys were conducted at the show in March, 1998, on 458 participants who were randomly selected from an attending population of approximately 60,000 people. Of the survey participants, 15% were Black, 85% were White, and 33% were women. The age composition was similar for black and white respondents; however, Black participants had significantly lower mean incomes than White participants.

The dietary survey took about 20 minutes to complete and was divided into three parts: a section on demographics; one on the number of meals consumed of different types of fish and meat for each of the past 12 months, and a section collecting information on serving size and cooking methods. The types of fish and meat inquired about included wild-caught fish, store-bought fish, restaurant fish, deer, wild-caught quail, restaurant quail, dove, duck, rabbit, squirrel, raccoon, wild turkey, beef, chicken, pork, and any wild game not listed in the questionnaire. Respondents were asked to provide information regarding serving/portion size and what percent of their meals they consumed as meat as opposed to stews. The average number of meals eaten as meat and stew were separately determined for each of the 12 months, then multiplied by the average serving size. Yearly consumption rates were then determined by summing across months for each type of fish or meat. Means and percentiles were computed using SAS.

Mean daily consumption of wild-caught fish ranged from 32.6 g/kg-day for respondents less than 32 years of age to 171.0 g/kg-day for Black respondents (see Table 10-86). The disparity in mean consumption was the greatest for ethnicity and income level, with black and low income respondents eating more than twice as much wild-caught fish as

Whites or higher income respondents. Male fish consumption (mean of 55.2 g/kg-day) was higher than that of females (mean of 39.1 g/kg-day), while by age, fish consumption was highest among the 33–45 year olds (mean intake of 71.3 g/kg-day). The author suggested that although the high consumption of wild-caught fish for this age group may reflect a more active lifestyle, it may also reflect exposure of women of child-bearing age. As shown in Table 10-86, the differences between mean consumption rates and 99th percentile values were very large. For some population groups at the higher end of the distribution, fish consumption was ten times greater than that of the mean.

This study provides useful comparisons on wild-caught fish intake among populations with differing ethnicity, sex, age, and income level. Data on fish consumption at the higher end of the distribution were also provided. A limitation of the study includes the fact that the study was based on dietary recall which is less reliable over time and may have recall bias. In addition, although the methodology indicated that information was collected and/or calculated for serving/portion size, the percent of meals consumed as meat versus stews, and yearly consumption rates, no data were provided for these parameters in the study.

10.5.18. Mayfield et al. (2007)—Survey of Fish Consumption Patterns of King County (Washington) Recreational Anglers

Mayfield et al. (2007) conducted a series of fish consumption surveys among recreational anglers at marine and freshwater sites in King County, WA. The freshwater surveys were conducted between 2002 and 2003 at “freshwater locations around Lake Sammamish, Lake Washington, and Lake Union” (Mayfield et al., 2007). A total of 212 individuals were interviewed at these locations. The majority of participants were male, 18 years and older, and were either Caucasian or Asian and Pacific Islander. Data were collected on fishing location preferences, fishing frequency, consumption amounts, species preferences, cooking methods, and whether family members would also consume the catch. Respondent demographic data were also collected. Consumption rates were estimated using information on fish meal frequency and meal size. The mean recreational freshwater fish consumption rates were 10 g/day for all respondents and 7 g/day for the children of survey respondents (see Table 10-87). Mayfield et al. (2007) also reported differences in intake according to ethnicity. Mean freshwater fish intake rates were 40, 38, 20, 19, and 2 g/day for Native American, African

Chapter 10—Intake of Fish and Shellfish

American, Asian and Pacific Islander, Caucasian, and Hispanic/Latino respondents, respectively.

The advantage of this study is that it provides additional perspective on recreational freshwater fish intake. However, the data are limited to a specific area of the United States and may not be representative of anglers in other locations.

10.6. NATIVE AMERICAN STUDIES

10.6.1. Wolfe and Walker (1987)—Subsistence Economies in Alaska: Productivity, Geography, and Development Impacts

Wolfe and Walker (1987) analyzed a data set from 98 communities for harvests of fish, land mammals, marine mammals, and other wild resources. The analysis was performed to evaluate the distribution and productivity of subsistence harvests in Alaska during the 1980s. Harvest levels were used as a measure of productivity. Wolfe and Walker (1987) defined harvest to represent a single year's production from a complete seasonal round. The harvest levels were derived primarily from a compilation of data from subsistence studies conducted between 1980 and 1985 by various researchers in the Alaska Department of Fish and Game, Division of Subsistence.

Of the 98 communities studied, four were large urban population centers, and 94 were small communities. The harvests for these latter 94 communities were documented through detailed retrospective interviews with harvesters from a sample of households (Wolfe and Walker, 1987). Harvesters were asked to estimate the quantities of a particular species that were harvested and used by members of that household during the previous 12-month period. Wolfe and Walker (1987) converted harvests to a common unit for comparison, pounds dressed weight per capita per year, by multiplying the harvests of households within each community by standard factors, converting total pounds to dressed weight, summing across households, and then dividing by the total number of household members in the household sample. Note average consumption by household member can be misleading because households include both children and adults whose intake rates may be very different. Dressed weight varied by species and community but, in general, was 70% to 75% of total fish weight; dressed weight for fish represents that portion brought into the kitchen for use (Wolfe and Walker, 1987).

Harvests for the four urban populations were developed from a statewide data set gathered by the Alaska Department of Fish and Game Divisions of Game and Sports Fish. Urban sport-fish harvest

estimates were derived from a survey that was mailed to a randomly selected statewide sample of anglers (Wolfe and Walker, 1987). Sport-fish harvests were disaggregated by urban residency, and the data set was analyzed by converting the harvests into pounds and dividing by the 1983 urban population.

For the overall analysis, each of the 98 communities was treated as a single unit of analysis, and the entire group of communities was assumed to be a sample of all communities in Alaska (Wolfe and Walker, 1987). Each community was given equal weight, regardless of population size. Annual per capita harvests were calculated for each community. For the four urban centers, fish harvests ranged from 5 to 21 pounds per capita per year (6.2 g/day to 26.2 g/day).

The range for the 94 small communities was 25 to 1,239 pounds per capita per year (31 g/day to 1,541 g/day). For these 94 communities, the median per capita fish harvest was 130 pounds per year (162 g/day). In most (68%) of the 98 communities analyzed, resource harvests for fish were greater than the harvests of the other wildlife categories (land mammal, marine mammal, and other) combined.

The communities in this study were not made up entirely of Alaska Natives. For roughly half the communities, Alaska Natives comprised 80% or more of the population, but for about 40% of the communities, they comprised less than 50% of the population. Wolfe and Walker (1987) performed a regression analysis, which showed that the per capita harvest of a community tended to increase as a function of the percentage of Alaska Natives in the community. Although this analysis was done for total harvest (i.e., fish, land mammal, marine mammal, and others), the same result should hold for fish harvest because it is highly correlated with total harvest.

A limitation of this report is that it presents per capita harvest rates as opposed to individual intake rates. Wolfe and Walker (1987) compared the per capita harvest rates reported to the results for the household component of the 1977–1978 USDA NFCS. The NFCS showed that about 222 pounds of meat, fish, and poultry were purchased and brought into the household kitchen for each person each year in the western region of the United States. This contrasts with a median total resource harvest of 260 lbs/year in the 94 communities studied. This comparison, and the fact that Wolfe and Walker (1987) state that “harvests represent that portion brought into the kitchen for use,” suggest that the same factors used to convert household consumption rates in the NFCS to individual intake rates can be used to convert per capita harvest rates to individual

Chapter 10—Intake of Fish and Shellfish

intake rates. In Section 10.3, a factor of 0.5 was used to convert fish consumption from household to individual intake rates. Applying this factor, the median per capita individual fish intake in the 94 communities would be 81 g/day and the range 15.5 to 770 g/day.

A limitation of this study is that the data were based on 1-year recall from a mailed survey. An advantage of the study is that it is one of the few studies that present fish harvest patterns for subsistence populations.

10.6.2. Columbia River Inter-Tribal Fish Commission (CRITFC) (1994)—A Fish Consumption Survey of the Umatilla, Nez Perce, Yakama, and Warm Springs Tribes of the Columbia River Basin

The Columbia River Inter-Tribal Fish Commission (CRITFC) (1994) conducted a fish consumption survey among four Columbia River Basin Native American tribes during the fall and winter of 1991–1992. The target population included all adult tribal members who lived on or near the Yakama, Warm Springs, Umatilla, or Nez Perce reservations. The survey was based on a stratified random sampling design where respondents were selected from patient registration files at the Indian Health Service. Interviews were performed in person at a central location on the member's reservation.

The overall response rate was 69%, yielding a sample size of 513 tribal members, 18 years old and above. Of these, 58% were female, and 59% were under 40 years old. Each participating adult was asked if there were any children 5 years old or younger in his or her household. Those responding affirmatively were asked a set of survey questions about the fish consumption patterns of the youngest child in the household (CRITFC, 1994). Information for 204 children, 5 years old and younger, was provided by participating adult respondents. Consumption data were available for 194 of these children.

Participants were asked to describe and quantify all food and drink consumed during the previous day. They were then asked to identify the months in which they ate the most and the least fish, and the number of fish meals consumed per week during each of those periods and an average value for the whole year. The typical portion size (in ounces) was determined with the aid of food models provided by the questioner. The next set of questions identified specific species of fish and addressed the number of times per month each was eaten, as well as what parts (e.g., fillet, skin, head, eggs, bones, other) were eaten.

Respondents were then asked to identify the frequency with which they used various preparation methods, expressed as a percentage. Respondents sharing a household with a child, aged 5 years or less, were asked to repeat the serving size, eating frequency, and species questions for the child's consumption behavior. All respondents were asked about the geographic origin of any fish they personally caught and consumed, and to identify the major sources of fish in their diet (e.g., self-caught, grocery store, tribe, etc.). Fish intake rates were calculated by multiplying the annual frequency of fish meals by the average serving size per fish meal.

The population sizes of the four tribes were highly unequal, ranging from 818 to 3,872 individuals (CRITFC, 1994). Nearly equal sample sizes were collected from each tribe. Weighting factors were applied to the pooled data (in proportion to tribal population size) so that the survey results would be representative of the overall population of the four tribes for adults only. Because the sample size for children was considered small, only an unweighted analysis was performed for this population. Based on a desired sample size of approximately 500 and an expected response rate of 70%, 744 individuals were selected at random from lists of eligible patients; the numbers from each tribe were approximately equal.

The results of the survey showed that adults consumed an average of 1.71 fish meals/week and had an average intake of 58.7 g/day (CRITFC, 1994). Table 10-88 shows the adult fish intake distribution; the median was between 29 and 32 g/day, and the 95th percentile about 170 g/day. A small percentage (7%) of respondents indicated that they were not fish consumers. Table 10-89 shows that mean intake was slightly higher in males than females (63 g/day versus 56 g/day) and was higher in the over 60 years age group (74.4 g/day) than in the 18–39 years (57.6 g/day) or 40–59 years (55.8 g/day) age groups. Intake also tended to be higher among those living on the reservation. The mean intake for nursing mothers—59.1 g/day—was similar to the overall mean intake. Intake rates were calculated for children for which both the number of fish meals per week and serving size information were available. Appendix 10B presents the weighted percentage of adults consuming specific fish parts.

A total of 49% of respondents of the total survey population reported that they caught fish from the Columbia River basin and its tributaries for personal use or for tribal ceremonies and distributions to other tribe members, and 88% reported that they obtained fish from either self-harvesting, family, or friends; at tribal ceremonies; or from tribal distributions. Of all

Chapter 10—Intake of Fish and Shellfish

fish consumed, 41% came from self- or family harvesting, 11% from the harvest of friends, 35% from tribal ceremonies or distribution, 9% from stores, and 4% from other sources (CRITFC, 1994).

Of the 204 children, the total number of respondents used in the analysis varied from 167 to 202, depending on the topic (amount and species consumed, fish meals consumed/week, age consumption began, serving size, consumption of fish parts) of the analysis. The unweighted mean for the age when children begin eating fish was 13.1 months of age ($N = 167$). The unweighted mean number of fish meals consumed per week by children was 1.2 meals per week ($N = 195$), and the unweighted mean serving size of fish for children aged 5 years old and less was 95 grams (i.e., 3.36 ounces) ($N = 201$). The unweighted percent of fish consumed by children by species was 82.7% for salmon, followed by 46.5% ($N = 202$) for trout.

The analysis of seasonal intake showed that May and June tended to be high-consumption months and December and January, low consumption months. The mean adult intake rate for May and June was 108 g/day, while the mean intake rate for December and January was 30.7 g/day. Salmon was the species eaten by the highest number of respondents (92%) followed by trout (70%), lamprey (54%), and smelt (52%). Table 10-90 gives the fish intake distribution for children under 5 years of age. The mean intake rate was 19.6 g/day, and the 95th percentile was approximately 70 g/day. These mean intake rates include both consumers and non-consumers. These values are based on survey questions involving estimated behavior throughout the year, which survey participants answered in terms of meals per week or per month and typical serving size per meal. Table 10-91 presents consumption rates for children, who were reported to consume particular species of fish.

The authors noted that some non-response bias may have occurred in the survey because respondents were more likely to be female and live near the reservation than non-respondents. In addition, they hypothesized that non-consumers may have been more likely to be non-respondents than fish consumers because non-consumers may have thought their contribution to the survey would be meaningless. If such were the case, this study would overestimate the mean per capita intake rate. It was also noted that the timing of the survey, which was conducted during low fish consumption months, may have led to underestimation of actual fish consumption. The authors conjectured that an individual may have reported higher annual consumption if interviewed during a relatively high consumption month and lower annual consumption if

interviewed during a relatively low consumption month. Finally, with respect to children's intake, it was observed that some of the respondents provided the same information for their children as for themselves; thereby, the reliability of some of these data is questioned (CRITFC, 1994). The combination of four different tribes' survey responses into a single pooled data set is somewhat problematic. The data presented are unweighted and, therefore, contain a bias toward the smaller tribes, who were oversampled compared to the larger tribes.

The limitations of this study, particularly with regard to the estimates of children's consumption, result in a high degree of uncertainty in the estimated rates of consumption. Although the authors have noted these limitations, this study does present information on fish consumption patterns and habits for a Native American population.

10.6.3. Peterson et al. (1994)—Fish Consumption Patterns and Blood Mercury Levels in Wisconsin Chippewa Indians

Peterson et al. (1994) investigated the extent of exposure to methylmercury by Chippewa Indians living on a Northern Wisconsin reservation who consume fish caught in Northern Wisconsin lakes. Chippewa have a reputation for high fish consumption (Peterson et al., 1994). The Chippewa Indians fish by the traditional method of spearfishing. Spearfishing (for walleye) occurs for about 2 weeks each spring after the ice breaks, and although only a small number of tribal members participate in it, the spearfishing harvest is distributed widely within the tribe by an informal distribution network of family and friends and through traditional tribal feasts (Peterson et al., 1994).

Potential survey participants, 465 adults, 18 years of age and older, were randomly selected from the tribal registries (Peterson et al., 1994). Participants were asked to complete a questionnaire describing their routine fish consumption and, more extensively, their fish consumption during the 2 previous months. The survey was carried out in May 1990. A follow-up survey was conducted for a random sample of 75 non-respondents (80% were reachable), and their demographic and fish consumption patterns were obtained. Peterson et al. (1994) reported that the non-respondents' socioeconomic information and fish consumption were similar to the respondents.

A total of 175 of the original random sample (38%) participated in the study. In addition, 152 non-randomly selected participants were surveyed and included in the data analysis; these participants were reported by Peterson et al. (1994) to

Chapter 10—Intake of Fish and Shellfish

have fish consumption rates similar to those of the randomly selected participants. Results from the survey showed that fish consumption varied seasonally, with 50% of the respondents reporting April and May (spearfishing season) as the highest fish consumption months (Peterson et al., 1994). Table 10-92 shows the number of fish meals consumed per week during the last 2 months (recent consumption) before the survey was conducted and during the respondents' peak consumption months grouped by sex, age, education, and employment level. During peak consumption months, males consumed more fish (1.9 meals per week) than females (1.5 meals per week), respondents under 35 years of age consumed more fish (1.8 meals per week) than respondents 35 years of age and over (1.6 meals per week), and the unemployed consumed more fish (1.9 meals per week) than the employed (1.6 meals per week). During the highest fish consumption season (April and May), 50% of respondents reported eating 1 or less fish meals per week, and only 2% reported daily fish consumption. A total of 72% of respondents reported Walleye consumption in the previous 2 months. Peterson et al. (1994) also reported that the mean number of fish meals usually consumed per week by the respondents was 1.2.

The mean fish consumption rate reported (1.2 fish meals per week, or 62.4 meals per year) in this survey was compared with the rate reported in a previous survey of Wisconsin anglers (Fiore et al., 1989) of 42 fish meals per year. These results indicate that the Chippewa Indians do not consume much more fish than the general Wisconsin angler population (Peterson et al., 1994). The differences in the two values may be attributed to differences in study methodology (Peterson et al., 1994). Note that this number (1.2 fish meals per week) includes fish from all sources. Peterson et al. (1994) noted that subsistence fishing, defined as fishing as a major food source, appears rare among the Chippewa. Using a meal size of 227 g/meal, the rate reported here of 1.2 fish meals per week translates into a mean fish intake rate of 39 g/day in this population. This meal size is similar to an adult general population 90th percentile meal size derived from Smiciklas-Wright et al. (2002) (see Section 10.8.2).

The advantages of this study are that it targeted a specific Native American population and provides some perspective on peak consumption and species of fish consumed. However, the data are more than 2 decades old and may not be entirely representative of current intake patterns.

10.6.4. Fitzgerald et al. (1995)—Fish PCB Concentrations and Consumption Patterns Among Mohawk Women at Akwesasne

Akwesasne is a Native American community of 10,000 plus persons located along the St. Lawrence River (Fitzgerald et al., 1995). Fitzgerald et al. (1995) conducted a recall study from 1986 to 1992 to determine the fish consumption patterns among nursing Mohawk women residing near three industrial sites. The study sample consisted of 97 Mohawk women living on the Akwesasne Reservation and 154 nursing Caucasian controls living in Warren and Schoharie counties, which are primary rural like the Akwesasne. The Mohawk mothers were significantly younger (mean age: 24.9) than the controls (mean age: 26.4) and had significantly more years of education (mean: 13.1 for Mohawks versus 12.4 for controls). A total of 97 out of 119 Mohawk nursing women responded, a response rate of 78%; 154 out of 287 control nursing Caucasian women responded, a response rate of 54%. Statistical analysis focused upon socio-demographic, physical, reproductive, lifestyle, and dietary and consumption differences between the Mohawk and control women.

Potential participants were identified prior to, or shortly after, delivery. The interviews were conducted at home within 1 month postpartum and were structured to collect information for socio-demographics, vital statistics, use of medications, occupational and residential histories, behavioral patterns (cigarette smoking and alcohol consumption), drinking water source, diet, and fish preparation methods (Fitzgerald et al., 1995). The dietary data collected were based on recall for food intake during the index pregnancy, the year before the pregnancy, and more than 1 year before the pregnancy.

The dietary assessment involved the report by each participant on the consumption of various foods with emphasis on local species of fish and game (Fitzgerald et al., 1995). This method combined food frequency and dietary histories to estimate usual intake. Food frequency was evaluated with a checklist of foods for indicating the amount of consumption of a participant per week, month, or year. Information gathered for the dietary history included duration of consumption, changes in the diet, and food preparation method.

Table 10-93 presents the number of local fish meals per year for both the Mohawk and control participants. The highest percentage of participants reported consuming between 1 and 9 local fish meals

Chapter 10—Intake of Fish and Shellfish

per year. Table 10-93 indicates that Mohawk respondents consumed statistically significantly more local fish than did control respondents during the two time periods prior to pregnancy; for the time period during pregnancy, there was no significant difference in fish consumption between the two groups. Table 10-94 presents the mean number of local fish meals consumed per year by time period for all respondents and for those ever consuming (consumers only). A total of 82 (85%) Mohawk mothers and 72 (47%) control mothers reported ever consuming local fish. The mean number of local fish meals consumed per year by Mohawk respondents declined over time, from 23.4 (over 1 year before pregnancy) to 9.2 (less than 1 year before pregnancy) to 3.9 (during pregnancy); a similar decline was seen among consuming Mohawks only. There was also a decreasing trend over time in consumption among controls, though it was much less pronounced.

Table 10-95 presents the mean number of fish meals consumed per year for all participants by time period and selected characteristics (age, education, cigarette smoking, and alcohol consumption). Pairwise contrasts indicated that control participants over 34 years of age had the highest fish consumption of local fish meals (22.1) (see Table 10-95). However, neither the overall nor pairwise differences by age among the Mohawk women over 34 years old were statistically significant, which may be due to the small sample size ($N = 6$) (Fitzgerald et al., 1995). The most common fish consumed by Mohawk mothers was yellow perch; for controls, the most common fish consumed was trout.

An advantage of this study is that it presents data for fish consumption patterns for Native Americans as compared to a demographically similar group of Caucasians. Although the data are based on nursing mothers as participants, the study also captures consumption patterns prior to pregnancy (up to 1 year before and more than 1 year before). Fitzgerald et al. (1995) noted that dietary recall for a period more than 1 year before pregnancy may be inaccurate, but these data were the best available measure of the more distant past. They also noted that the observed decrease in fish consumption among Mohawks from 1 year before pregnancy to the period of pregnancy is due to a secular trend of declining fish consumption over time in Mohawks. This decrease, which was more pronounced than that seen in controls, may be due to health advisories promulgated by tribal, as well as state, officials. The authors noted that this decreasing secular trend in Mohawks is consistent with a survey from 1979–1980 that found an overall mean of 40 fish meals per year among male and female Mohawk adults.

The data are presented as number of fish meals per year; the authors did not assign an average weight to fish meals. If assessors wanted to estimate the weight of fish consumed, some value of weight per fish meal would have to be assumed. Smiciklas-Wright et al. (2002) reported 209 grams as the 90th percentile weight of fish consumed per eating occasion for general population females 20–39 years old. Using this value, the rate reported of 27.6 fish meals per year for consumers only (over 1 year before pregnancy) translates into a mean fish intake rate of 15.8 g/day.

A limitation of this study is that information on meal size was not available. It is not known whether the 90th percentile meal size from the general population is representative of the population of Mohawk women.

10.6.5. Forti et al. (1995)—Health Risk Assessment for the Akwesasne Mohawk Population From Exposure to Chemical Contaminants in Fish and Wildlife

Forti et al. (1995) estimated the potential exposure of residents of the Mohawk Nation at Akwesasne to PCBs through the ingestion of locally caught fish and wildlife, and human milk. The study was part of a remedial investigation/feasibility study (RI/FS) for a National Priorities List site near Massena, NY and the St. Lawrence River. Forti et al. (1995) used data collected in 1979–1980 on the source (store bought or locally caught), species, and frequency of fish consumption among 1,092 adult Mohawk Native Americans. The information on frequency of fish consumption was combined with an assumed meal size of 227 grams to estimate intake among the adult population. This meal size represents the 90th percentile meal size for fish consumers in the U.S. population as reported by Pao et al. (1982). Children were assumed to eat fish at the same frequency as adults but were assumed to have a meal size of 93 grams.

Table 10-96 presents the mean and 95th percentile fish intake estimates for the Mohawk population, as reported by Forti et al. (1995). Mean intake of local fish was estimated to be 25 g/day for all adult fish consumers and 29 g/day for adult consumers only; 95th percentile rates for these groups were 131 and 135 g/day, respectively. Mean intake of local fish was estimated to be 10 g/day among all Mohawk children and 13 g/day among children consumers only; 95th percentile estimates for these groups were 54 and 58 g/day, respectively.

The advantage of this study is that it provides additional perspective on intake among Native

Chapter 10—Intake of Fish and Shellfish

American populations, especially those in the St. Lawrence River area. However, the fish intake survey data used in this analysis were collected more than 3 decades ago and may not represent current intake patterns for this population. Also, the Forti et al. (1995) report provides limited details about the survey methodology and data used to estimate intake. It should also be noted that fish intake rates were estimated using a 90th percentile meal size. It is not known whether the 90th percentile meal size from the general population is representative of this population of Native Americans.

10.6.6. Toy et al. (1996)—A Fish Consumption Survey of the Tulalip and Squaxin Island Tribes of the Puget Sound Region

Toy et al. (1996) conducted a study to determine fish and shellfish consumption rates of the Tulalip and Squaxin Island tribes living in the Puget Sound region. These two Indian tribes were selected on the basis of judgment that they would be representative of the expected range of fishing and fish consumption activities of the 14 tribes in the region. Commercial fishing is a major source of income for members of both tribes; some members of the Squaxin Island tribe also participate in commercial shellfishing. Both tribes participate in subsistence fishing and shellfishing.

A survey was conducted to describe fish consumption for Puget Sound tribal members over the age of 18 years, and their dependents, aged 5 years and under, in terms of their consumption rate of anadromous, pelagic, bottom fish, and shellfish in grams per kilogram of body weight per day. The survey focused on the frequency of fish and shellfish consumption (number of fish meals eaten per day, per week, per month, or per year) over a 1-year period, and the portion size of each meal. Data were also collected on fish parts consumed, preparation methods, patterns of acquisition for all fish and shellfish consumption (including seasonal variations in consumption), and children's consumption rates. Interviews were conducted between February 25 and May 15, 1994. A total of 190 tribal members, aged 18 years old and older, and 69 children between birth and 5 years old, were surveyed on consumption of 52 species. The response rate was 77% for the Squaxin Island tribe and 76% for the Tulalip tribes.

The appropriate sample size was calculated based on the enrolled population of each tribe and a desired confidence interval of $\pm 20\%$ from the mean, with an additional 25% added to the total to allow for non-response or unusable data. The target population, derived from lists of enrolled tribal members

provided by the tribes, consisted of enrolled tribal members aged 18 years and older and children aged 5 years and younger living in the same household as an enrolled member. Only members living on or within 50 miles of the reservation were considered for the survey. Each eligible enrolled tribal member was assigned a number, and computer-generated random numbers were used to identify the survey participants. Children were not sampled directly but through adult members of their household; if one adult had more than one eligible child in his or her household, one of the children was selected at random. This indirect sampling method was necessitated by the available tribal records but may have introduced sampling bias to the process of selecting children for the study. A total of 190 adult tribal members (ages 18 years old and older) and 69 children between birth and 5 years old (i.e., 0 to <6 years) were surveyed about their consumption of 52 fish species in six categories: anadromous, pelagic, bottom, shellfish, canned tuna, and miscellaneous.

Respondents described their consumption behavior for the past year in terms of frequency of fish meals eaten per week or per month, including seasonal variations in consumption rates. Portion sizes (in ounces) were estimated with the aid of model portions provided by the questioner. Data were also collected on fish parts consumed, preparation methods, patterns of acquisition for all fish and shellfish consumption, and children's consumption rates.

The adult mean and median consumption rates for all forms of fish combined were 0.89 and 0.55 g/kg-day for the Tulalip tribes, and 0.89 and 0.52 g/kg-day for the Squaxin Island tribe, respectively (see Table 10-97). As shown in Table 10-98, consumption per body weight varied by sex (males consumed more as indicated by mean and median consumption). The median rates for the Tulalip Tribes were 53 g/day for males and 34 g/day for females, while the rates were 66 g/day for males and 25 g/day for females for the Squaxin Island tribe (see Table 10-99). Among adults, consumption generally followed a curvilinear pattern, with greater median consumption in the age range of 35 to 64 years old, and lower consumption in the age range of 18 to 34 years old and 65 years old and over (see Table 10-100). No consistent pattern of consumption by income was found for either tribe (see Table 10-101).

The mean and median consumption rates for children 5 years and younger for both tribes combined, were 0.53 and 0.17 g/kg-day, respectively. These values were significantly lower than those of

Chapter 10—Intake of Fish and Shellfish

adults, even when the consumption rate was adjusted for body weight (see Table 10-102). Squaxin Island children tended to consume more fish than Tulalip children (mean: 0.825 g/kg-day vs. 0.239 g/kg-day). The data were insufficient to allow re-analysis to fit the data to the standard U.S. EPA age categories used elsewhere in this handbook. A minority of consumers ate fish parts that are considered to have a higher concentration of toxins: skin, head, bones, eggs, and organs, and for the majority of consumers, fish were prepared (baking, boiling, broiling, roasting, and poaching) and eaten in a manner that tends to reduce intake of contaminants. Most anadromous fish and shellfish were obtained by harvesting in the Puget Sound area rather than by purchasing, though sources of harvesting varied between the tribes.

The advantage of this study is that the data can be used to improve how exposure assessments are conducted for populations that include high consumers of fish and shellfish and to identify cultural characteristics that may place tribal members at disproportionate risk to chemical contamination. One limitation associated with this study is that although data from the Tulalip and Squaxin Island tribes may be representative of consumption rates of these specific tribes, fish consumption rates, habits, and patterns can vary among tribes and other population groups. As a result, the consumption rates of these two tribes may not be useful as a surrogate for consumption rates of other Native American tribes. There might also be a possible bias due to the time the survey was conducted; many species in the survey are seasonal, and although the survey was designed to solicit annual consumption rates, respondents may have weighted their responses toward the interview period. For example, because of the timing of the survey, respondents may have overestimated their annual consumption of shellfish and underestimated their annual consumption of salmon. Furthermore, there were differences in consumption patterns between the two tribes included in this study; the study provided data for each tribe and for the pooled data from both tribes, but the latter may not be a statistically valid measure for tribes in the region.

10.6.7. Duncan (2000)—Fish Consumption Survey of the Suquamish Indian Tribe of the Port Madison Indian Reservation, Puget Sound Region

The Suquamish Tribal Council conducted a study of the Suquamish tribal members living on and near the Port Madison Indian Reservation in the Puget Sound region (Duncan, 2000). The study was funded

by the Agency for Toxic Substances and Disease Registry (ATSDR) through a grant to the Washington State Department of Health. The purpose of the study was to determine seafood consumption rates, patterns, and habits of the members of the Suquamish Tribe. The second objective was to identify cultural practices and attributes that affect consumption rates, patterns, and habits of members of the Suquamish Tribe.

Adults, 16 years and older, were selected randomly from a Tribal enrollment roster. The study had a participation rate of 64.8%, which was calculated on the basis of 92 respondents out of a total of 142 potentially eligible adults on the list of those selected into the sample. Consumption data for children under 6 years of age were gathered through adult respondents who had children in this age group living in the household at the time of the survey. Data were collected for 31 children under 6 years old.

A survey questionnaire was administered by personal interview. The survey included four parts: (1) 24-hour dietary recall; (2) identification, portions, frequency of consumption, preparation, harvest location of fish; (3) shellfish consumption, preparation, harvest location; and (4) changes in consumption over time, cultural information, physical information, and socioeconomic information. A display booklet was used to assist respondents in providing consumption data and identifying harvest locations of seafood consumed. Physical models of finfish and shellfish were constructed to assist respondents in determining typical food portions. Finfish and shellfish were grouped into categories based on similarities in life history as well as practices of Tribal members who fish for subsistence, ceremonial, and commercial purposes.

Adult respondents reported a mean consumption rate of all finfish and all shellfish of 2.71 g/kg-day (see Table 10-103). Table 10-104, Table 10-105, and Table 10-106 provide consumption rates for adults by species, sex, and age, respectively. For children under 6 years of age, the mean consumption rate of all finfish and shellfish was 1.48 g/kg-day (see Table 10-107 and Table 10-108). The Suquamish Tribe's seafood consumption rates for adults and children under 6 years of age were higher than seafood consumption rates reported in studies conducted among the CRITFC, Tulalip Tribes, Squaxin Island Tribe, and the Asian Pacific Island population of King County (Duncan, 2000). This disparity illustrates the high degree of variability found between tribes even within a small geographic region (Puget Sound) and indicates that exposure and risk assessors should exercise care when imputing fish

Chapter 10—Intake of Fish and Shellfish

consumption rates to a population of interest using data from tribal studies.

An important attribute of this survey is that it provides consumption rates by individual type of fish and shellfish. It is important to note that the report indicates that increased levels of development as well as pollutants from residential, industrial, and commercial uses have resulted in degraded habitats and harvesting restrictions. Despite degraded water quality and habitat, tribal members continue to rely on fish and shellfish as a significant part of their diet. A limitation of this study is that the sample size for children was fairly small (31 children).

10.6.8. Westat (2006)—Fish Consumption in Connecticut, Florida, Minnesota, and North Dakota

As discussed in Section 10.3.2.7, Westat (2006) analyzed the raw data from three fish consumption studies to derive fish consumption rates for various age, sex, and ethnic groups, and according to the source of fish consumed (i.e., bought or caught) and habitat (i.e., freshwater, estuarine, or marine). The studies represented data from four states: Connecticut, Florida, Minnesota, and North Dakota. Consumption rates for individuals of Native American heritage were available for the states of Florida, Minnesota, and North Dakota. Fish intake distributions for these populations are presented in Table 10-41 for all respondents and Table 10-42 for consuming individuals. The mean and 95th percentile for all Native American respondents were 0.8 g/kg-day and 4.5 g/kg-day for Florida, respectively. The mean fish intake rate for all Native American respondents for Minnesota was 2.8 g/kg-day. The mean and 90th percentile fish intake rate for all Native American respondents for North Dakota were 0.4 g/kg-day and 0.9 g/kg-day, respectively. The mean and 95th percentile intake rate for Native American consumers only for Florida were 1.5 g/kg-day and 5.7 g/kg-day, respectively. The mean fish intake rate for Native American consumers only for Minnesota was 2.8 g/kg-day. The mean and 90th percentile fish intake rate for Native American consumers only for North Dakota were 0.4 g/kg-day and 0.8 g/kg-day, respectively (Westat, 2006).

A limitation of this study is that sample sizes for these populations were small. Intake rates represent consumption of fish from all sources. Also, the study did not specifically target Native Americans, and it is not known whether the Native Americans included in the survey lived on reservations.

10.6.9. Polissar et al. (2006)—A Fish Consumption Survey of the Tulalip and Squaxin Island Tribes of the Puget Sound Region—Consumption Rates for Fish Consumers Only

Using fish consumption data from the Toy et al. (1996) survey of the Tulalip and Squaxin Island tribes of Puget Sound, Polissar et al. (2006) calculated consumption rates for various fish species groups, considering only the consumers of fish within each group. Weight-adjusted consumption rates were calculated by tribe, age, sex, and species groups. Species groups (anadromous, bottom, pelagic, and shellfish) were defined by life history and distribution in the water column. Data were available for 69 children, birth to <6 years of age; 18 of these children had no reported fish consumption and were excluded from the analysis. Thus, estimated fish consumption rates are based on data for 51 children; 15 from the Tulalip tribe and 36 from the Squaxin Island tribe. Both median and mean fish consumption rates for adults and children within each tribe were calculated in terms of grams per kilogram of body weight per day (g/kg-day). Anadromous fish and shellfish were the groups of fish most frequently consumed by both tribes and sexes. Consumption per body weight varied by sex (males consumed more) and age (those 35 to 64 years old consumed more than those younger and older). The consumption rates for groups of fish differed between the tribes. The distribution of consumption rates was skewed toward large values. In the Tulalip tribes, the estimated adult mean consumption rate for all forms of fish combined was 1.0 g/kg-day, and in the Squaxin Island tribe, the estimated mean rate was also 1.0 g/kg-day (see Table 10-109). Table 10-110 presents consumption rates for adults by species and sex. Table 10-111 and Table 10-112 show consumption rates for adults by species and age for the Squaxin Island and Tulalip tribes, respectively. The mean consumption rate for the Tulalip children was 0.45 g/kg-day, and 2.9 g/kg-day for the Squaxin Island children (see Table 10-113). Table 10-114 presents consumption rates for children by species and sex.

Because this study used the data originally generated by Toy et al. (1996), the advantages and limitations associated with the Toy et al. (1996) study, as described in Section 10.6.6, also apply to this study. However, an advantage of this study is that the consumption rates are based only on individuals who consumed fish within the selected categories.

Chapter 10—Intake of Fish and Shellfish

10.7. OTHER POPULATION STUDIES

10.7.1. U.S. EPA (1999)—Asian and Pacific Islander Seafood Consumption Study in King County, WA

This study was conducted to obtain seafood consumption rates, species, and seafood parts consumed, and cooking methods used by the Asian and Pacific Islander (API) community. Participants were seafood consumers who were first or second generation members of the API ethnic group, 18 years of age or older, and lived in King County, WA. APIs represent one of the most diverse and rapidly growing immigrant populations in the United States. In 1997, APIs (166,000) accounted for 10% of King County's population, an increase from 8% in 1990. Between 1990 and 1997, the total population of King County increased by 9%, while the population of APIs increased by 43% (U.S. EPA, 1999).

This study was conducted in three phases. Phase I focused on identifying target ethnic groups and developing appropriate questionnaires in the language required for each ethnic group. Phase II focused on characterizing seafood consumption patterns for 10 API ethnic groups (Cambodian, Chinese, Filipino, Hmong, Japanese, Korean, Laotian, Mien, Samoan, and Vietnamese) within the study area. Phase III focused on developing culturally appropriate health messages on risks related to seafood consumption and disseminating this information for the API community. The majority of the 202 respondents (89%) were first generation (i.e., born outside the United States). There were slightly more women (53%) than men (47%), and 35% lived under the 1997 Federal Poverty Level (FPL).

In general, it was found that API members consumed seafood at a very high rate. As shown in Table 10-115, the mean overall consumption rate for all seafood combined was 1.9 g/kg body weight-day (g/kg-day), with a median consumption rate of 1.4 g/kg-day. The predominant seafood consumed was shellfish (46% of all seafood). The API community consumed more shellfish (average consumption rate of 0.87 g/kg-day) than all finfish combined (an average consumption rate of 0.82 g/kg-day). Within the category of finfish, pelagic fish were consumed most by the API members, mean consumption rate of 0.38 g/kg-day (median: 0.22 g/kg-day), followed by anadromous fish with a mean consumption rate of 0.20 g/kg-day (median: 0.09 g/kg-day). The mean consumption for freshwater fish was 0.11 g/kg-day (median: 0.04 g/kg-day), and bottom fish was 0.13 g/kg-day (median: 0.05 g/kg-day). Individuals in the lowest income level (under the FPL) consumed more

seafood than those in higher income levels (1–2, 2–3, and >3 times the FPL), but the difference was not statistically significant.

In an effort to capture the participants consuming large quantities of seafood, the survey participants were classified as higher ($N = 44$) or lower ($N = 158$) consumers of shellfish or finfish based on their consumption rates being $\geq 75^{\text{th}}$ (higher) or $\leq 75^{\text{th}}$ (lower) percentile. Table 10-116 shows that people in the >55-years-old-category had the greatest percentage for high consumers of finfish; they had approximately the same percentage as other age groups for shellfish. The Japanese had a greater percentage (52%) for higher finfish consumers, and Vietnamese (50%) were in the higher shellfish consumer category.

Table 10-117 presents seafood consumption rates by ethnicity. In general, members of the Vietnamese and Japanese communities had the highest overall consumption rate, averaging 2.6 g/kg-day (median 2.4 g/kg-day) and 2.2 g/kg-day (median 1.8 g/kg-day), respectively.

Table 10-118 presents consumption rates by sex. The mean consumption rate for all seafood for women was 1.8 g/kg-day (median: 1.4 g/kg-day) and 1.7 g/kg-day (median: 1.3 g/kg-day) for men.

Salmon and tuna were the most frequently consumed finfish. More than 75% of the respondents consumed shrimp, crab, and squid. Table 10-119 presents these data. For all survey participants, the head, bones, eggs, and other organs were consumed 20% of the time. Fillet without skin was consumed 45% of the time, and fillet with skin, 55% of the time. Consumption patterns of shellfish parts varied depending on the type of shellfish.

Preparation methods were also surveyed in the API community. The survey covered two categories of preparation methods: (1) baked, broiled, roasted, or poached and (2) canned, fried, raw, smoked, or dried. The respondents most frequently prepared their finfish and shellfish using the baked, boiled, broiled, roasted, or poached method, averaging 65% and 78%, respectively.

The benefit of this research is that it can be used to improve API-specific risk assessments. API community members consume greater amounts of seafood than the general population, and these consumption patterns may pose a health risk if the consumed seafood is contaminated with toxic chemicals. Because the survey was based on recall, the authors selected 20 respondents for a follow-up re-interview. Its purpose was to assess the reliability of the responses. The results of the re-interview suggest that, based on the difference in means between the original and re-interview responses, the

Chapter 10—Intake of Fish and Shellfish

estimated consumption rates from this study are reliable. One limitation associated with this study is that it is based on a relatively small number of respondents within each ethnic group. Caution should be used to avoid extrapolation of data to other ethnic groups that have potentially significant cultural differences. Further study of the consumption patterns and preparation methods for the Hmong, Laotian, Mien, and Vietnamese communities is also needed because of potential health risks from contaminated seafood.

10.7.2 Shilling et al. (2010)—Contaminated Fish Consumption in California’s Central Valley Delta

Shilling et al. (2010) conducted a survey of 373 anglers and 137 community members between September 2005 and June 2008, in a region of the Sacramento-San Joaquin River Delta where subsistence fishing rates are high. This area was also chosen as an area where mercury concentrations in fish tissues were likely to be high. Anglers were selected for interviews as they were encountered in order to reduce bias, however, approximately 5% of the anglers approached did not speak English and were unable to be interviewed. Community members were chosen for interviews based on knowledge that an extended family member fished in this area. The interviews were conducted primarily in the early morning and late afternoon, and all days of the week were represented. Subjects were told at the beginning of the interview that the study was about fishing activity along the river, but not that it was related to fish contamination. Anglers and community members were grouped according to ethnicity, and fish consumption rates were calculated based on each individual’s 30-day recall of how much and how often types of fish were eaten. Mean, median and 95th percentile fish consumption rates were calculated for study participants according to ethnicity, age, and sex. In addition, fish intake was determined for households containing women of child-bearing age, children, and for respondents whose awareness of warnings about fish contamination in the area ranged from no awareness to high awareness.

Regardless of ethnicity, the fish species that were primarily targeted by anglers in this study were striped bass, salmon, shad, and catfish, similar to those identified in creel survey data for this region from the California Department of Fish and Game. Consumption rates for locally caught and commercially obtained fish are shown in Table 10-120. Mean intake of locally caught fish among all ethnic groups ranged from 6.5 g/day for Native

American anglers to 57.6 g/day for Southeast Asian/Lao anglers. For all anglers, the mean and median consumption rates of locally caught fish were 27.4 and 19.7 g/day, respectively. These values increased to 40.6 g/day (mean) and 26.1 g/day (median) when commercially obtained fish were included. The 95th percentile intake rates for all anglers were 126.6 g/day for local fish consumption and 147.3 g/day for total fish consumption. Fish consumption rates were not significantly different among age groups, but were higher for anglers from households with either children or women of child-bearing age.

No significant trend ($p = 0.78$) was observed across the 3-year study period for the consumption of locally caught fish. Peak consumption rates occurred during the fall, when striped bass and salmon return to the area to spawn and fishing activity is the highest. Fish consumption rates were significantly different for anglers and community members, with the exception of Southeast Asians. No significant difference was observed between the day of the week when surveying was conducted and ethnic group or fish consumption rates, or between anglers with higher or lower awareness of warnings about fish contamination in the area.

The advantages of this study are that the sample size was fairly large and that a number of ethnic groups were included. Limitations of the study include the fact that information on fish consumption was based on 30-day recall data and that the study was limited to one geographic area and may not be representative of the U.S. general population.

10.8. SERVING SIZE STUDIES**10.8.1. Pao et al. (1982)—Foods Commonly Eaten in the United States: Amount per Day and per Eating Occasion**

Pao et al. (1982) used the 1977–1978 NFCS to examine the quantity of fish consumed per eating occasion. For each individual consuming fish in the 3-day survey period, the quantity of fish consumed per eating occasion was derived by dividing the total reported fish intake over the 3-day period by the number of occasions the individual reported eating fish. Table 10-121 displays the distributions, by age and sex, for the quantity of fish consumed per eating occasion (Pao et al., 1982). For the general population, the average quantity of fish consumed per fish meal was 117 grams, with a 95th percentile of 284 grams. Males in the age groups 19–34, 35–64, and 65–74 years had the highest average and 95th percentile quantities among the age-sex groups presented. It should be noted that the serving size

Chapter 10—Intake of Fish and Shellfish

data from this analysis has been superseded by the analysis of the 1994–1996 USDA CSFII data conducted by Smiciklas-Wright et al. (2002).

10.8.2. Smiciklas-Wright et al. (2002)—Foods Commonly Eaten in the United States: Quantities Consumed per Eating Occasion and in a Day, 1994–1996

Using data gathered in the 1994–1996 USDA CSFII, Smiciklas-Wright et al. (2002) calculated distributions for the quantities of canned tuna and other finfish consumed per eating occasion by members of the U.S. population (i.e., serving sizes), over a 2-day period. The estimates of serving size are based on data obtained from 14,262 respondents, ages 2 years and above, who provided 2 days of dietary intake information. Only dietary intake data from users of the specified food were used in the analysis (i.e., consumer-only data).

Table 10-122 and Table 10-123 present serving size data for canned tuna and other finfish, respectively. These data are presented on an as-consumed basis (grams) and represent the quantity of fish consumed per eating occasion. These estimates may be useful for assessing acute exposures to contaminants in specific foods, or other assessments where the amount consumed per eating occasion is necessary. The average meal size for finfish (other than tuna) for adults 20 years and older was 114 g/meal (see Table 10-122). It should be noted that this value represents fish eaten in any form (e.g., as an ingredient in a meal) and not just fish eaten as a meal (e.g., fish fillet).

The advantages of using these data are that they were derived from the USDA CSFII and are representative of the U.S. population. The analysis conducted by Smiciklas-Wright et al. (2002) accounted for individual foods consumed as ingredients of mixed foods. Mixed foods were disaggregated via recipe files so that the individual ingredients could be grouped together with similar foods that were reported separately. Thus, weights of foods consumed as ingredients were combined with weights of foods reported separately to provide a more thorough representation of consumption. However, it should be noted that because the recipes for the mixed foods consumed by respondents were not provided by the respondents, standard recipes were used. As a result, the estimates of the quantity of some food types are based on assumptions about the types and quantities of ingredients consumed as part of mixed foods.

10.9. OTHER FACTORS TO CONSIDER FOR FISH CONSUMPTION

Other factors to consider when using the available survey data include location, climate, season, and ethnicity of the angler or consumer population, as well as the parts of fish consumed and the methods of preparation. Some contaminants (for example, persistent, bioaccumulative, and toxic contaminants such as dioxins and polychlorinated biphenyls) have the affinity to accumulate more in certain tissues, such as the fatty tissue, as well as in certain internal organs. The effects of cooking methods for various food products on the levels of dioxin-like compounds have been addressed by evaluating a number of studies in U.S. EPA (2003). These studies showed various results for contamination losses based on the methodology of the study and the method of food preparation. Refer to U.S. EPA (2003) for a detailed review of these studies.

In addition, some studies suggest that there is a significant decrease of contaminants in cooked fish when compared with raw fish (San Diego County, 1990). Several studies cited in this section have addressed fish preparation methods and parts of fish consumed. Table 10-124 provides summary results from these studies on fish preparation methods; Appendix 10B presents further details on preparation methods, as well as results from some studies on parts of fish consumed.

Users of the data presented in this chapter should ensure that consistent units are used for intake rate and concentration of contaminants in fish. The following sections provide information on converting between wet weight and dry weight, and between wet weight and lipid weight.

10.9.1. Conversion Between Wet and Dry Weight

The intake data presented in this chapter are reported in units of wet weight (i.e., as-consumed or uncooked weight of fish consumed per day or per eating occasion). However, data on the concentration of contaminants in fish may be reported in units of either wet or dry weight (e.g., milligram of contaminant per gram-dry-weight of fish). It is essential that exposure assessors be aware of this difference so that they may ensure consistency between the units used for intake rates and those used for concentration data (i.e., if the contaminant concentration is measured in dry weight of fish, then the dry-weight units should be used for fish intake values).

If necessary, wet-weight (e.g., as-consumed) intake rates may be converted to dry-weight intake rates using the moisture content percentages

Chapter 10—Intake of Fish and Shellfish

presented in Table 10-125 and the following equation:

$$IR_{dw} = IR_{ww} \left[\frac{100 - W}{100} \right] \quad (\text{Eqn. 10-4})$$

where:

IR_{dw} = dry-weight intake rate,
 IR_{ww} = wet-weight intake rate, and
 W = percent water content.

Alternately, dry-weight residue levels in fish may be converted to wet-weight residue levels for use with wet-weight (e.g., as-consumed) intake rates, as follows:

$$C_{ww} = C_{dw} \left[\frac{100 - W}{100} \right] \quad (\text{Eqn. 10-5})$$

where:

C_{ww} = wet-weight concentration,
 C_{dw} = dry-weight concentration, and
 W = percent water content.

The moisture content data presented in Table 10-125 are for selected fish taken from USDA (2007). The moisture content is based on the percent of water present.

10.9.2. Conversion Between Wet-Weight and Lipid-Weight Intake Rates

In some cases, the residue levels of contaminants in fish are reported as the concentration of contaminant per gram of fat. This may be particularly true for lipophilic compounds. When using these residue levels, the assessor should ensure consistency in the exposure-assessment calculations by using consumption rates that are based on the amount of fat consumed for the fish product of interest.

The total fat content (percent) measured and/or calculated in various fish forms (i.e., raw, cooked, smoked, etc.) for selected fish species is presented in Table 10-125, based on data from USDA (2007). The total percent fat content is based on the sum of saturated, monounsaturated, and polyunsaturated fat.

If necessary, wet-weight (e.g., as-consumed) intake rates may be converted to lipid-weight intake

rates using the fat content percentages presented in Table 10-125 and the following equation:

$$IR_{lw} = IR_{ww} \left[\frac{L}{100} \right] \quad (\text{Eqn. 10-6})$$

where:

IR_{lw} = lipid-weight intake rate,
 IR_{ww} = wet-weight intake rate, and
 L = percent lipid (fat) content.

Alternately, wet-weight residue levels in fish may be estimated by multiplying the levels based on fat by the fraction of fat per product as follows:

$$C_{ww} = C_{lw} \left[\frac{L}{100} \right] \quad (\text{Eqn. 10-7})$$

where:

C_{ww} = wet-weight concentration,
 C_{lw} = lipid-weight concentration, and
 L = percent lipid (fat) content.

The resulting residue levels may then be used in conjunction with wet-weight (e.g., as-consumed) consumption rates. The total fat content data presented in Table 10-125 are for selected fish taken from USDA (2007).

Chapter 10—Intake of Fish and Shellfish

Table 10-16. Best Fits of Lognormal Distributions Using the Non-Linear Optimization Method			
	Adults	Teenagers	Children
Shellfish			
μ	1.370	-0.183	0.854
σ	0.858	1.092	0.730
Finfish (freshwater)			
μ	0.334	0.578	-0.559
σ	1.183	0.822	1.141
Finfish (saltwater)			
μ	2.311	1.691	0.881
σ	0.72	0.830	0.970
The following equations may be used with the appropriate μ and σ values to obtain an average Daily Consumption Rate (DCR), in grams, and percentiles of the DCR distribution.			
DCR ₅₀ = exp (μ)			
DCR ₉₀ = exp [μ + z(0.90) × σ]			
DCR ₉₉ = exp [μ + z(0.99) × σ]			
DCR _{avg} = exp [μ + 0.5 × σ ²]

^a Estimates were projected from sample size to the U.S. population using 4-year combined survey weights; consumers only are those individuals who consumed fish at least once during the 2-day reporting period.

N = Sample size.

CI = Confidence interval.

BI = Bootstrap interval; percentile intervals (BI) were estimated using the percentile bootstrap method with 1,000 bootstrap replications.

* The sample size does not meet minimum reporting requirements as described in the *Third Report on Nutrition Monitoring in the United States* (FASEB/LSRO, 1995).

*	Percentiles cannot be estimated due to small sample size.							
Notes:	FL consumption is based on a 7-day recall; CT, MN, and ND consumptions are based on rate of consumption.							
	FL consumption excludes away-from-home consumption by children <18.							
	Statistics are weighted to represent the general population in the states.

Notes:	FL consumption is based on a 7-day recall; CT, MN, and ND consumptions are based on rate of consumption. FL consumption excludes away-from-home consumption by children <18. Statistics are weighted to represent the general population in the states. A respondent can be represented in more than one row.

*	Percentiles cannot be estimated due to small sample size.							
Notes:	FL consumption is based on a 7-day recall; CT, MN, and ND consumptions are based on rate of consumption. FL consumption excludes away-from-home consumption by children <18. Statistics are weighted to represent the general population in the states. Subpopulations statistics are unweighted.

Chapter 10—Intake of Fish and Shellfish

Table 10-72. Estimates of Fish Intake Rates of Licensed Sport Anglers in Maine During the 1989–1990 Ice Fishing or 1990 Open-Water Seasons^a

Percentile Rankings	Intake Rates (g/day)			
	All Waters ^b		Rivers and Streams	
	All Anglers ^c (N = 1,369)	Consuming Anglers ^d (N = 1,053)	River Anglers ^e (N = 741)	Consuming Anglers ^d (N = 464)
50 th (median)	1.1	2.0	0.19	0.99
66 th	2.6	4.0	0.71	1.8
75 th	4.2	5.8	1.3	2.5
90 th	11.0	13.0	3.7	6.1
95 th	21.0	26.0	6.2	12.0
Arithmetic Mean ^f	5.0 [79]	6.4 [77]	1.9 [82]	3.7 [81]

- ^a Estimates are based on rank except for those of arithmetic mean.
- ^b All waters based on fish obtained from all lakes, ponds, streams, and rivers in Maine, from other household sources, and from other non-household sources.
- ^c Licensed anglers who fished during the seasons studied and did or did not consume freshwater fish, and licensed anglers who did not fish but ate freshwater fish caught in Maine during those seasons.
- ^d Licensed anglers who consumed freshwater fish caught in Maine during the seasons studied.
- ^e Those of the "all anglers" who fished on rivers or streams (consumers and non-consumers).
- ^f Values in brackets [] are percentiles at the mean consumption rates.

^a Percentage of consumption = the percent of each category that makes up the total (i.e., 10.6% of total fish eaten was anadromous fish). N = Sample size. SE = Standard error. LCI = 95% lower confidence interval. UCI = 95% upper confidence interval. Note: Confidence intervals were computed based on the Student's t-distribution. Rates were weighted across ethnic groups. Source: U.S. EPA (1999).

^a All consumption rates in g/kg body weight/day. Weighted by population percentage.

N = Sample size.

SE = Standard error.

LCI = Lower confidence interval.

UCI = Upper confidence interval.

Note: *p*-values are based on Kruskal-Wallis test.

APPENDIX 10A:
RESOURCE UTILIZATION DISTRIBUTION

10A.1. RESOURCE UTILIZATION DISTRIBUTION

The percentiles of the resource utilization distribution of Y are to be distinguished from the percentiles of the (standard) distribution of Y . The latter percentiles show what percentage of individuals in the population are consuming below a given level. Thus, the 50th percentile of the distribution of Y is that level such that 50% of individuals consume below it; on the other hand, the 50th percentile of the resource utilization distribution is that level such that 50% of the overall consumption in the population is done by individuals consuming below it.

The percentiles of the resource utilization distribution of Y will always be greater than or equal to the corresponding percentiles of the (standard) distribution of Y , and, in the case of recreational fish consumption, usually considerably exceed the standard percentiles.

To generate the resource utilization distribution, one simply weights each observation in the data set by the Y level for that observation and performs a standard percentile analysis of weighted data. If the data already have weights, then one multiplies the original weights by the Y level for that observation, and then performs the percentile analysis.

Under certain assumptions, the resource utilization percentiles of fish consumption may be related (approximately) to the (standard) percentiles of fish consumption derived from the analysis of creel studies. In this instance, it is assumed that the creel survey data analysis did not employ sampling weights (i.e., weights were implicitly set to one); this is the case for many of the published analyses of creel survey data. In creel studies, the fish consumption rate for the i^{th} individual is usually derived by multiplying the amount of fish consumption per fishing trip (say C_i) by the frequency of fishing (say f_i). If it is assumed that the

probability of sampling an angler is proportional to fishing frequency, then sampling weights of inverse fishing frequency ($1/f_i$) should be employed in the analysis of the survey data. Above it was stated that for data that are already weighted, the resource utilization distribution is generated by multiplying the original weights by the individual's fish consumption level to create new weights. Thus, to generate the resource utilization distribution from the data with weights of $(1/f_i)$, one multiplies $(1/f_i)$ by the fish consumption level of $f_i C_i$ to get new weights of C_i .

Now if C_i (amount of consumption per fishing trip) is constant over the population, then these new weights are constant and can be taken to be one. But weights of one is what (it is assumed) were used in the original creel survey data analysis. Hence, the resource utilization distribution is exactly the same as the original (standard) distribution derived from the creel survey using constant weights.

The accuracy of this approximation of the resource utilization distribution of fish by the (standard) distribution of fish consumption derived from an unweighted analysis of creel survey data depends then on two factors, how approximately constant the C_i 's are in the population and how approximately proportional the relationship between sampling probability and fishing frequency is. Sampling probability will be roughly proportional to frequency if repeated sampling at the same site is limited or if re-interviewing is performed independent of past interviewing status.

Note: For any quantity Y that is consumed by individuals in a population, the percentiles of the "resource utilization distribution" of Y can be formally defined as follows: $Y_p(R)$ is the p th percentile of the resource utilization distribution if p percent of the overall consumption of Y in the population is done by individuals with consumption below $Y_p(R)$ and $100-p$ percent is done by individuals with consumption above $Y_p(R)$.

11. INTAKE OF MEATS, DAIRY PRODUCTS, AND FATS

11.1. INTRODUCTION

This document is an update to Chapter 11 (“Intake of Meats, Dairy Products, and Fats”) of the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011). New information that has become available since 2011 has been added, and the recommended values have been revised as needed to reflect the new information. The chapter includes a comprehensive review of the scientific literature through 2016. The new literature was identified via formal literature searches conducted by U.S. Environmental Protection Agency (EPA) staff as well as targeted Internet searches conducted by the authors of this chapter. Appendix A provides a list of the key terms that were used in the literature searches. Revisions to this chapter have been made in accordance with the approved quality assurance plan for the Exposure Factors Handbook.

The American food supply is generally considered to be one of the safest in the world. Nevertheless, meats, dairy products, and fats can become contaminated with toxic chemicals by several pathways. For example, these foods sources can become contaminated if animals are exposed to contaminated media (i.e., soil, water, or feed crops). To assess exposure through this pathway, information on meat, dairy, and fat ingestion rates are needed.

A variety of terms may be used to define intake of meats, dairy products, and fats (e.g., consumer-only intake, per capita intake, total meat, dairy product, or fat intake, as-consumed intake, uncooked edible portion intake, dry-weight intake). As described in Chapter 9, “Intake of Fruits and Vegetables,” consumer-only intake is defined as the quantity of meats, dairy products, or fats consumed by individuals during the survey period averaged across only the individuals who consumed these food items during the survey period. Per capita intake rates are generated by averaging consumer-only intakes over the entire survey population (including those that reported no intake). In general, per capita intake rates are appropriate for use in exposure assessment for which average dose estimates are of interest because they represent both individuals who ate the foods during the survey period and individuals who may eat the food items at some time, but did not consume them during the survey period. Per capita intake, therefore, represents an average across the entire population of interest, but does so at the expense of underestimating consumption for the subset of the population that consumes the food in question. Total intake refers to the sum of all meats, dairy products, or fats consumed in a day.

Intake rates may be expressed on the basis of the as-consumed weight (e.g., cooked or prepared) or on the uncooked or unprepared weight. As-consumed intake rates are based on the weight of the food in the form that it is consumed and should be used in assessments where the basis for the contaminant concentrations in foods is also indexed to the as-consumed weight. Some of the food ingestion values provided in this chapter are expressed as as-consumed intake rates because this is the way that data were reported by survey respondents. Other values are provided as uncooked weights based on analyses of survey data that account for weight changes that occur during cooking. This adjustment is important because concentration data to be used in the dose equation are often measured in uncooked food samples. Note that cooking can either increase or decrease food weight. Similarly, cooking can increase the mass of a contaminant in food (due to formation reactions, or absorption from cooking oils or water) or decrease the mass of a contaminant in food (due to vaporization, fat loss, or leaching). The combined effects of changes in food weight and changes in contaminant mass can result in either an increase or decrease in contaminant concentration in cooked food. Therefore, if the as-consumed ingestion rate and the uncooked concentration are used in the dose equation, dose may be underestimated or overestimated. It is important for the assessor to be aware of these issues and choose intake rate data that best match the concentration data being used. For more information on cooking losses and conversions necessary to account for such losses, refer to Chapter 13 of this handbook.

Sometimes contaminant concentrations in food are reported on a dry-weight basis. When these data are used in an exposure assessment, it is recommended that dry-weight intake rates also be used. Dry-weight food concentrations and intake rates are based on the weight of the food consumed after the moisture content has been removed. Similarly, when contaminant concentrations in food are reported on a lipid-weight basis, lipid-weight intake rates should be used. For information on converting the intake rates presented in this chapter to dry-weight or lipid-weight intake rates, refer to Sections 11.5 and 11.6 of this chapter.

The purpose of this chapter is to provide intake data for meats, dairy products, and fats. The recommendations for ingestion rates for these food sources for use in risk assessment are provided in the next section, along with a summary of the confidence ratings for these recommendations. The recommended values are based on the key studies identified by EPA for these factors. As described in Chapter 1 of the

Exposure Factors Handbook: 2011 Edition (U.S. EPA, 2011), the key studies represent the most up-to-date and scientifically sound ones for deriving recommendations for exposure factors, whereas other studies are designated "relevant," meaning applicable or pertinent, but not necessarily the most important. For example, studies that provide supporting data or information related to the factor of interest (e.g., percentage of the population consuming meats, dairy products, or fats), or have study designs or approaches that make the data less applicable to the general population (e.g., studies that targeted specific populations or older studies) have been designated as relevant rather than key. Key studies were selected based on the general assessment factors described in Chapter 1 of the Handbook. Following the recommendations, the key study on ingestion of meats and dairy products among the general population is summarized (see Section 11.3.1). Relevant data on general population ingestion of meats and dairy products are also provided (see Section 11.3.2). These studies are presented to provide the reader with added perspective on the current state-of-knowledge pertaining to ingestion of meats and dairy products. Data on pregnant and lactating women are provided in Section 11.3.3, and key and relevant studies on intake of fats are provided in Section 11.4.

11.2. RECOMMENDATIONS

Table 11-1 presents a summary of the recommended values for per capita and consumer-only intake of meats, dairy products, and fats for use in exposure and risk assessment. Table 11-2 provides confidence ratings for these recommendations.

EPA analyses of data from the 2005–2010 National Health and Nutrition Examination Survey (NHANES) were used in selecting recommended intake rates for intake of meats and dairy products by the general population. The EPA analysis of meat and dairy products was conducted using childhood age groups from EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). The EPA analysis of fat intake data from the U.S. Department of Agriculture's (USDA's) Continuing Survey of Food Intake by Individuals (CSFII, U.S. EPA, 2007) were used in selecting recommended intake rates for fats. This study also used the childhood age groups recommended by U.S. EPA (2005).

The NHANES data on which the recommendations for meats and dairy products are based, and the CSFII data on which the recommendations for fats are based are short-term survey data and may not necessarily reflect the

long-term distribution of average daily intake rates. However, because these broad categories of food (i.e., total meats and dairy products), are eaten on a daily basis throughout the year with minimal seasonality, the short-term distribution may be a reasonable approximation of the long-term distribution, although it will display somewhat increased variability. This implies that the upper percentiles shown here will tend to overestimate the corresponding percentiles of the true long-term distribution. In general, the recommended values based on EPA's analyses of NHANES data and CSFII data represent the uncooked weight of the edible portion of meat, dairy, and fats. It should be noted that because the recommendations for fat intake are based on 1994–1996 and 1998 CSFII data, they may not reflect the most recent changes that may have occurred in consumption patterns.

USDA and the U.S. Department of Health and Human Services (USDHHS) jointly developed *Dietary Guidelines for Americans: 2010* that provide information and advice for choosing healthy eating patterns (USDA and USDHHS, 2010). The guidance may differ from the recommended intake rates for meat, dairy, and fats that are provided in this chapter for use in exposure/risk assessment because NHANES and similar surveys reflect actual intake rather than dietary goals.

^a Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption.

^b Total Meat includes: beef, fat; beef, fat-baby food; beef, kidney; beef, liver; beef, liver-baby food; beef, meat; beef, meat byproducts; beef, meat byproducts-baby food; beef, meat, dried; beef, meat-baby food; chicken, fat; chicken, fat-baby food; chicken, liver; chicken, meat; chicken, meat byproducts; chicken, meat byproducts-baby food; chicken, meat-baby food; chicken, skin; chicken, skin-baby food; goat, fat; goat, kidney; goat, liver; goat, meat; goat, meat byproducts; horse, meat; meat, game; pork, fat; pork, fat-baby food; pork, kidney; pork, liver; pork, meat; pork, meat byproducts; pork, meat byproducts-baby food; pork, meat-baby food; pork, skin; poultry, other, fat; poultry, other, liver; poultry, other, meat; poultry, other, meat byproducts; poultry, other, skin; rabbit, meat; sheep, fat; sheep, fat-baby food; sheep, kidney; sheep, liver; sheep, meat; sheep, meat byproducts; sheep, meat-baby food; turkey, fat; turkey, fat-baby food; turkey, liver; turkey, liver-baby food; turkey, meat; turkey, meat byproducts; turkey, meat byproducts-baby food; turkey, meat-baby food; turkey, skin; turkey, skin-baby food.

^c Total Dairy includes: milk, fat; milk, fat-baby food/infant formula; milk, nonfat solids; milk, nonfat solids-baby food/infant formula; milk, sugar (lactose)-baby food/infant formula; milk, water; milk, water-baby food/infant formula.

^d For more information, refer to the Frequently Asked Questions at <http://fcid.foodrisk.org/>.

^e Estimates are less statistically reliable based on guidance published in the *Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: Human Nutrition Information Service, National Center for Health Statistics (HNIS/NCHS) Analytical Working Group Recommendations* (NCHS, 1993).

Table 11-2. Confidence in Recommendations for Intake of Meats, Dairy Products, and Fats ^a		
General Assessment Factors	Rationale	Rating
Soundness		High
<i>Adequacy of Approach</i>	The survey methodology and data analysis were adequate. The surveys sampled nearly 25,000 individuals for meats and dairy products and 20,000 individuals for fats. Analyses of primary data were conducted.	
<i>Minimal (or Defined) Bias</i>	No physical measurements were taken. The method relied on recent recall of meats and dairy products eaten.	
Applicability and Utility		High for meats and dairy products; medium for fats
<i>Exposure Factor of Interest</i>	The key studies were directly relevant to meat, dairy, and fat intake.	
<i>Representativeness</i>	The data were demographically representative of the U.S. population (based on stratified random sample).	
<i>Currency</i>	Data were collected between 2005 and 2010 for meat and dairy products and between 1994 and 1998 for fats.	
<i>Data Collection Period</i>	Data were collected for two nonconsecutive days.	
Clarity and Completeness		High
<i>Accessibility</i>	The NHANES data, the FCID Consumption Calculator, and the CSFII data are publicly available.	
<i>Reproducibility</i>	The methodology used was clearly described; enough information was included to reproduce the results.	
<i>Quality Assurance</i>	NHANES and CSFII follow strict QA/QC procedures. Data generated by the FCID Consumption Calculator has been reviewed by EPA.	
Variability and Uncertainty		Medium to high for averages, low for long-term upper percentiles; low for individual foods
<i>Variability in Population</i>	Full distributions were provided for total meats, total dairy products, and total fats. Means were provided for individual meats and dairy products.	
<i>Uncertainty</i>	Data collection was based on recall of consumption for a 2-day period; the accuracy of using these data to estimate long-term intake (especially at the upper percentiles) is uncertain. However, use of short-term data to estimate chronic ingestion can be assumed for broad categories of foods such as total meats, total dairy products, and total fats. Uncertainty is likely to be greater for individual meats and dairy products.	
Evaluation and Review		Medium
<i>Peer Review</i>	Both the NCHS NHANES and the USDA CSFII survey received high levels of peer review. The EPA analysis of the NHANES data has not been peer reviewed outside the Agency, but the methodology has been used in analysis of previous data.	
<i>Number and Agreement of Studies</i>	There was one key study for intake of meat and dairy products (2005–2010 NHANES) and one key study for fat intake (U.S. EPA, 2007, based on 1994–1996, 1998 CSFII).	
Overall Rating		Medium to high confidence in the averages; Low confidence in the long-term upper percentiles
^a	See Section 1.5.2 in Chapter 1 of the <i>Exposure Factors Handbook: 2011 Edition</i> (U.S. EPA, 2011) for a detailed description of the evaluation criteria used in this table.	
FCID	= Food Commodity Intake Database.	

11.3. INTAKE OF MEAT AND DAIRY PRODUCTS

11.3.1. Key Meat and Dairy Intake Study

11.3.1.1. *EPA Analysis of Consumption Data from 2005–2010 National Health and Nutrition Examination Survey*

The key source of recent information on consumption rates of meat and dairy products is the U.S. Centers for Disease Control and Prevention's National Center for Health Statistics' (NCHS) NHANES. Data from NHANES 2005–2010 have been used by the EPA to generate per capita and consumer-only intake rates for both individual meat and dairy products and total meat and dairy products.

NHANES is designed to assess the health and nutritional status of adults and children in the United States. In 1999, the survey became a continuous program that interviews a nationally representative sample of approximately 7,000 persons each year and examines a nationally representative sample of about 5,000 persons each year, located in counties across the country, 15 of which are visited each year. Data are released on a 2-year basis, thus, for example, the 2005 data are combined with the 2006 data to produce NHANES 2005–2006.

The dietary interview component of NHANES is called *What We Eat in America* (WWEIA) and is conducted by the USDA and the USDHHS. USDHHS' NCHS is responsible for the sample design and data collection and USDA's Food Surveys Research Group is responsible for the dietary data collection methodology, maintenance of the databases used to code and process the data, and data review and processing. Beginning in 2003, two nonconsecutive days of 24-hour intake data were collected. The first day is collected in-person, and the second day is collected by telephone 3 to 10 days later. These data are collected using USDA's dietary data collection instrument, the Automated Multiple Pass Method. This method provides an efficient and accurate means of collecting intakes for large-scale national surveys. It is fully computerized and uses a 5-step interview. Details can be found at USDA's Agriculture Research Service (<http://www.ars.usda.gov/ba/bhnrc/fsrg>).

The 2005–2010 NHANES surveys are stratified, multistage probability samples of the civilian noninstitutionalized U.S. population. The sampling frame was based on the 2000 U.S. population census estimates. Several sets of sampling weights are available for use with the intake data. By using appropriate weights, data for all 6 years of the surveys can be combined. Additional information on NHANES can be obtained at <http://www.cdc.gov/nchs/nhanes.htm>.

The EPA Office of Pesticide Programs used NHANES 2005–2010 data to update the Food Commodity Intake Database (FCID) that was developed in earlier analyses of data from the USDA's CSFII (USDA, 2000; U.S. EPA, 2000) (see Section 11.3.2.3). The updated FCID is available at: <http://fcid.foodrisk.org/>, along with the FCID Consumption Calculator, which was used to develop the estimates provided in this chapter for various age and racial/ethnic groups. The Calculator may also be used to develop estimates for other age groups or population, customized to the users' needs. In the FCID, NHANES data on the foods people reported eating were converted to the quantities of agricultural commodities eaten. "Agricultural commodity" is a term used by EPA to mean plant (or animal) parts used as feed or consumed by humans as food; when such items are raw or unprocessed, they are referred to as "raw agricultural commodities." For example, beef stew may contain the commodities beef, potatoes, carrots, and other vegetables. FCID contains approximately 560 unique commodity names and 8-digit codes. The FCID commodity names and codes were selected and defined by EPA and were based on the EPA Food Commodity Vocabulary (<http://www.epa.gov/pesticides/foodfeed/>). The codes and definitions used to determine the various meat and dairy commodities in the EPA analysis are provided in Appendix B.

Intake rates were generated for a variety of food items/groups based on the agricultural commodities included in the FCID. These intake rates represent intake of all forms of the product (e.g., both home produced and commercially produced) for 2 survey days. For respondents who reported intake on both days, their intake rate represents the average rate for the 2 survey days. For respondents who reported consumption on one day and no consumption on the other day, their intake rate represents the average of zero and nonzero consumption. Two-day average intake rates were calculated for all individuals in the database for each of the food items/groups. These average daily intake rates were divided by each individual's reported body weight to generate intake rates in units of grams per kilogram of body weight per day (g/kg-day). The data were weighted according to the 6-year, 2-day sample weights provided in NHANES 2005–2010 to adjust the data for the sample population to reflect the national population. The 2005–2010 analysis of NHANES/FCID data for meats and dairy products included data for nearly 25,000 respondents.

Summary statistics were generated on a consumer-only and on a per capita basis. Summary statistics, including number of observations,

percentage of the population consuming the meats and dairy products being analyzed, mean intake rate, and standard error of the mean intake rate were calculated for total meats, total dairy products, and selected individual meats and dairy products. Percentiles of the intake rate distribution (i.e., 1st, 5th, 10th, 25th, 50th, 75th, 90th, 95th, 99th, and the maximum value) were also provided for total meats and dairy products. Data were provided for the following childhood age groups: <1 month, 1 to <3 months, 3 to <6 months, 6 to <12 months, 1 to <2 years, 2 to <3 years, 3 to <6 years, 6 to <11 years, 11 to <16 years, and 16 to <21 years to be consistent with those recommended in EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). Data for the birth to <1-year age group were also provided to be consistent with the *Exposure Factors Handbook: 2011 Edition*. For adults, data were provided for ages 21 to <30 years, 30 to <40 years, 40 to <50 years, 50 to <60 years, 60 to <70 years, 70 to <80 years, and 80+ years, and for ages 21 to <50 years and 50+ years. Data were also provided according to the following racial/ethnic groups: Mexican American, non-Hispanic Black, non-Hispanic White, other Hispanic, and other race including multiple races.

Table 11-3 presents per capita intake data for total meats and dairy products in g/kg-day; Table 11-4 provides consumer-only intake data for total meats and total dairy products in g/kg-day. Table 11-5 provides per capita intake data for individual meats and dairy products, and Table 11-6 provides consumer-only intake data for individual meats and dairy products. In general, these data represent intake of the edible portions of uncooked foods.

Because the results are presented in units of g/kg-day, the use of these data in calculating potential dose does not require the body-weight factor to be included in the denominator of the average daily dose equation. It should be noted that converting these intake rates into units of g/day by multiplying by a single average body weight is inappropriate because individual intake rates were indexed to the reported body weights of the survey respondents. If intake data in units of g/day are needed, they can be obtained using the FCID Consumption Calculator which is available at <http://fcid.foodrisk.org/>. Also, note that the distribution of average daily intake rates generated using short-term data (e.g., 2-day) does not necessarily reflect the long-term distribution of average daily intake rates. The distributions generated from short-term and long-term data will differ to the extent that each individual's intake varies from day to day; the distributions will be similar to the extent that

individuals' intakes are constant from day to day. However, for broad categories of foods (e.g., total meats and total dairy) that are eaten on a daily basis throughout the year, the short-term distribution may be a reasonable approximation of the true long-term distribution, although it will show somewhat more variability. In this chapter, distributions are provided only for broad categories of meats and dairy (i.e., total meats and total dairy). Because of the increased variability of the short-term distribution, the short-term upper percentiles shown here may overestimate the corresponding percentiles of the long-term distribution. For individual foods, only the mean, standard error, and percent consuming are provided.

An advantage of using the EPA's analysis of NHANES data is that it provides distributions of intake rates for various age groups of children and adults, normalized by body weight. The data set was designed to be representative of the U.S. population and includes 6 years of intake data combined. Another advantage is the currency of the data; the NHANES data are from 2005–2010. However, short-term dietary data may not accurately reflect long-term eating patterns, and the upper percentiles may overestimate the corresponding percentiles of the true long-term distribution. However, because these are 2-day averages, consumption estimates at the upper end of the intake distribution may be underestimated if these consumption values are used to assess acute (i.e., short-term) exposures.

11.3.2. Relevant Meat and Dairy Intake Studies

11.3.2.1. USDA (1980, 1992, 1996a, b)—*Food and Nutrient Intakes of Individuals in 1 Day in the United States*

USDA calculated mean per capita intake rates for meat and dairy products using Nationwide Food Consumption Survey (NFCS) data from 1977–1978 and 1987–1988 (USDA, 1980, 1992) and CSFII data from 1994 and 1995 (USDA, 1996a, b). The mean per capita intake rates for meat are presented in Tables 11-7 through 11-9 based on intake data for 1 day from the 1977–1978 (see Table 11-7) and 1987–1988 NFCSs (see Table 11-8), and 1994 and 1995 CSFII (see Table 11-9). Tables 11-10 through 11-12 present similar data for dairy products. Note that the age classifications used in the later surveys were slightly different from those used in the 1977–1978 NFCS.

This study provides mean intake estimates for various meat, poultry, and dairy products with some additional categories not included in other studies. The consumption estimates are based on short-term

(i.e., 1-day) dietary data, which may not reflect long-term consumption. Also, intake rates are not normalized to body weight and data are not consistent with EPA's recommended age groups. These data are based on older surveys and may not be entirely representative of current eating patterns, but may provide some historical perspective on intake of these foods.

11.3.2.2. *USDA (1999a)—Food and Nutrient Intakes by Children 1994–1996, 1998, Table Set 17*

USDA (1999a) calculated national probability estimates of food and nutrient intake by children based on 4 years of the CSFII (1994–1996 and 1998) for children ages 9 years and under and on CSFII 1994–1996 only for individuals ages 10 years and over. The CSFII was a series of surveys designed to measure the kinds and amounts of foods eaten by Americans. Intake data, based on 24-hour dietary recall, were collected through in-person interviews on 2 nonconsecutive days. Section 11.3.2.3 provides additional information on these surveys.

USDA (1999a) used sample weights to adjust for nonresponse, to match the sample to the U.S. population in terms of demographic characteristics, and to equalize intakes over the 4 quarters of the year and the 7 days of the week. A total of 503 breast-fed children were excluded from the estimates, but both consumers and nonconsumers were included in the analysis.

USDA (1999a) provided data on the mean per capita quantities (grams) of various food products/groups consumed per individual for 1 day, and the percentage of individuals consuming those foods in 1 day of the survey. Tables 11-13 and 11-14 present data on the mean quantities (grams) of meat and eggs consumed per individual for 1 day, and the percentage of survey individuals consuming meats and eggs on that survey day. Tables 11-15 and 11-16 present similar data for dairy products. Data on mean intakes or mean percentages are based on respondents' Day 1 intakes.

The advantage of the USDA (1999a) study is that it uses the 1994–1996, 1998 CSFII data set, which includes 4 years of intake data, combined, and includes supplemental data on children. This data set is expected to be generally representative of the U.S. population, and includes data on a wide variety of meats and dairy products. The data set is one of a series of USDA data sets that are publicly available. One limitation of this data set is that it is based on 1 day, and short-term dietary data may not accurately reflect long-term eating patterns. Other limitations of this

study are that it only provides mean values of food intake rates, consumption is not normalized by body weight, and presentation of results is not consistent with EPA's recommended age groups. These data are based on older surveys and may not be entirely representative of current eating patterns but may provide some historical perspective on intake of these foods.

11.3.2.3. *EPA Analysis of CSFII 1994–1996, 1998 Based on USDA (2000) and U.S. EPA (2000)*

EPA/Office of Pesticide Programs (OPP), in cooperation with USDA's Agricultural Research Service, used data from the 1994–1996, 1998 CSFII to develop the FCID (U.S. EPA, 2000; USDA, 2000), as described in Section 11.3.1.1. The CSFII 1994–1996 was conducted between January 1994 and January 1997 with a target population of noninstitutionalized individuals in all 50 states and Washington, DC. In each of the 3 survey years, data were collected for a nationally representative sample of individuals of all ages. The CSFII 1998 was conducted between December 1997 and December 1998 and surveyed children 9 years of age and younger. It used the same sample design as the CSFII 1994–1996 and was intended to be merged with CSFII 1994–1996 to increase the sample size for children. The merged surveys are designated as CSFII 1994–1996, 1998 (USDA, 2000). Additional information on the CSFII can be obtained at

<http://www.ars.usda.gov/Services/docs.htm?docid=14531>.

The CSFII 1994–1996, 1998 collected dietary intake data through in-person interviews on 2 nonconsecutive days. The data were based on 24-hour recall. A total of 21,662 individuals provided data for the first day; of those individuals, 20,607 provided data for a second day. The 2-day response rate for the 1994–1996 CSFII was approximately 76%. The 2-day response rate for CSFII 1998 was 82%. The CSFII 1994–1996, 1998 surveys were based on a complex multistage area probability sample design. The sampling frame was organized using 1990 U.S. population census estimates, and the stratification plan took into account geographic location, degree of urbanization, and socioeconomic characteristics. Several sets of sampling weights are available for use with the intake data. By using appropriate weights, data for all 4 years of the surveys can be combined. USDA has recommended that all 4 years be combined to provide an adequate sample size for children.

The meats and dairy items/groups selected for the EPA analysis included total meats and total dairy

products, and individual meats and dairy such as beef, pork, poultry, and eggs. CSFII data on the foods people reported eating were converted to the quantities of agricultural commodities eaten. Intake rates for these food items/groups were calculated and summary statistics were generated on both a per capita and a consumer-only basis using the same general methodology as in the EPA analysis of 2003–2006 NHANES data, as described in Section 11.3.1.1. Because these data were developed for use in EPA's pesticide registration program, the childhood age groups used are slightly different from those recommended in EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005).

Table 11-17 presents per capita intake data for total meat and total dairy products in g/kg-day; Table 11-18 provides consumer-only intake data for total meat and total dairy products in g/kg-day. Table 11-19 provides per capita intake data for certain individual meats and dairy products, and Table 11-20 provides consumer-only intake data for these individual meats and dairy products. In general, these data represent intake of the edible portions of uncooked foods.

Because the results are presented in units of g/kg-day, the use of these data in calculating potential dose does not require the body-weight factor to be included in the denominator of the average daily dose equation. The cautions concerning converting these intake rates into units of g/day by multiplying by a single average body weight and the discussion of the use of short term data in the NHANES description in Section 11.3.1.1 apply to the CSFII estimates as well.

A strength of EPA's analysis is that it provides distributions of intake rates for various age groups, normalized by body weight. The analysis uses the 1994–1996, 1998 CSFII data set, which was designed to be representative of the U.S. population. The data set includes 4 years of intake data combined and is based on a 2-day survey period. As discussed above, short-term dietary data may not accurately reflect long-term eating patterns and may under-represent infrequent consumers of a given food. This is particularly true for the tails (extremes) of the distribution of food intake. Although the analysis as conducted used slightly different age groups than those recommended in EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005), given the similarities in the age groups used, the data should provide suitable intake estimates for the childhood age groups of interest. While the CSFII data are older than the NHANES data, they provide relevant information on consumption in individuals by

season, region of the United States, and urbanization, cohorts that are not available in the publicly released NHANES data.

11.3.2.4. Smiciklas-Wright et al. (2002)—Foods Commonly Eaten in the United States: Quantities Consumed per Eating Occasion and in a Day, 1994–1996

Using data gathered in the 1994–1996 USDA CSFII, Smiciklas-Wright et al. (2002) calculated distributions for the quantities of meat, poultry, and dairy products consumed per eating occasion by members of the U.S. population (i.e., serving sizes). The estimates of serving size are based on data obtained from 14,262 respondents, ages 2 years and above, who provided 2 days of dietary intake information. Only dietary intake data from users of the specified food were used in the analysis (i.e., consumer-only data).

Table 11-21 presents serving size data for meats and dairy products. These data are presented on an as-consumed basis (grams) and represent the quantity of meats and dairy products consumed per eating occasion. These estimates may be useful for assessing acute exposures to contaminants in specific foods, or they may be used in other assessments where the amount consumed per eating occasion is necessary. Only the mean and standard deviation serving size data and percentage of the population consuming the food during the 2-day survey period are presented in this handbook. Percentiles of serving sizes of the foods consumed by these age groups of the U.S. population can be found in Smiciklas-Wright et al. (2002).

The advantages of using these data are that they were derived from the USDA CSFII and are representative of the U.S. population. The analysis conducted by Smiciklas-Wright et al. (2002) accounted for individual foods consumed as ingredients of mixed foods. Mixed foods were disaggregated via recipe files so that the individual ingredients could be grouped together with similar foods that were reported separately. Thus, weights of foods consumed as ingredients were combined with weights of foods reported separately to provide a more thorough representation of consumption. However, note that because the recipes for the mixed foods consumed were not provided by the respondents, standard recipes were used. As a result, the estimates of quantity consumed for some food types are based on assumptions about the types and quantities of ingredients consumed as part of mixed foods. This study used data from the 1994–1996 CSFII; data from the 1998 children's supplement were not included.

11.3.2.5. Vitolins et al. (2002)—Quality of Diets Consumed by Older Rural Adults

Vitolins et al. (2002) conducted a survey to evaluate the dietary intake, by food groups, of older (ages >70 years) rural adults. The sample consisted of 130 community-dwelling residents from two rural counties in North Carolina. Data on dietary intake over the preceding year were obtained in face-to-face interviews conducted in participants' homes, or in a few cases, a senior center. The food frequency questionnaire used in the survey was a modified version of the National Cancer Institute Health Habits and History Questionnaire, which included an expanded food list containing a greater number of ethnic foods than the original food frequency form. Demographic and personal data collected included sex, ethnicity, age, education, denture use, marital status, chronic disease, and weight.

Food items reported in the survey were grouped into food groups similar to the USDA Food Guide Pyramid and the National Cancer Institute's 5 A Day for Better Health program. These groups are: (1) fruits and vegetables; (2) bread, cereal, rice, and pasta; (3) milk, yogurt, and cheese; (4) meat, fish, poultry, beans, and eggs; and (5) fats, oils, sweets, and snacks. Medians, ranges, frequencies, and percentages were used to summarize intake of each food group, broken down by demographic and health characteristics. In addition, multiple regression models were used to determine which demographic and health factors were jointly predictive of intake of each of the five food groups.

Thirty-four percent of the survey participants were African-American, 36% were European American, and 30% were Native American. Sixty-two percent were female, 62% were not married at the time of the interview, and 65% had some high school education or were high school graduates. Almost all of the participants (95%) had one or more chronic diseases. Sixty percent of the respondents were between 70 and 79 years of age; the median age was 78 years old. Table 11-22 presents the median servings of milk, yogurt, and cheese broken down by demographic and health characteristics. None of the demographic characteristics were significantly associated with milk intake, and only ethnicity was found to be borderline ($p = 0.13$). In addition, none of the demographic characteristics were jointly predictive of milk, yogurt, and cheese consumption.

One limitation of the study, as noted by the study authors, is that the study did not collect information on the length of time the participants had been practicing the dietary behaviors reported in the survey. The questionnaire asked participants to report the

frequency of food consumption during the past year. The study authors noted that there are no dietary assessment tools that allow the collection of comprehensive dietary data over years of food consumption. Another limitation of the study is the small sample size used, which makes associations by sex and ethnicity difficult.

11.3.2.6. Fox et al. (2004)—Feeding Infants and Toddlers Study: What Foods Are Infants and Toddlers Eating

Fox et al. (2004) used data from the Feeding Infants and Toddlers study (FITS) to assess food consumption patterns in infants and toddlers. The FITS was sponsored by Gerber Products Company and was conducted to obtain current information on food and nutrient intakes of children, ages 4 to 24 months, in the 50 states and the District of Columbia. The FITS is described in detail in Devaney et al. (2004). FITS was based on a random sample of 3,022 infants and toddlers for which dietary intake data were collected by telephone from their parents or caregivers between March and July 2002. An initial recruitment and household interview was conducted, followed by an interview to obtain information on intake based on 24-hour recall. The interview also addressed growth, development, and feeding patterns. A second dietary recall interview was conducted for a subset of 703 randomly selected respondents. The study over-sampled children in the 4 to 6 and 9 to 11-months age groups; sample weights were adjusted for nonresponse, over-sampling, and under-coverage of some subgroups. The response rate for the FITS was 73% for the recruitment interview. The recruited households had a response rate of 94% for the dietary recall interviews (Devaney et al., 2004).

Fox et al. (2004) analyzed the first set of 24-hour recall data collected from all study participants. For this analysis, children were grouped into six age categories: 4 to 6 months, 7 to 8 months, 9 to 11 months, 12 to 14 months, 15 to 18 months, and 19 to 24 months. Table 11-23 provides the percentage of infants and toddlers consuming milk, meats, or other protein sources at least once in a day. The percentage of children consuming any type of meat or protein source ranged from 14.2% for 4 to 6-month olds to 97.2% for 19 to 24-month olds (see Table 11-23).

The advantages of this study are that the study population represented the U.S. population and the sample size was large. One limitation of the analysis done by Fox et al. (2004) was that only frequency data were provided; no information on actual intake rates was included. In addition, Devaney et al. (2004) noted several limitations associated with the FITS data. For

the FITS, a commercial list of infants and toddlers was used to obtain the sample used in the study. Because many of the households could not be located and did not have children in the target population, a lower response rate than would have occurred in a true national sample was obtained (Devaney et al., 2004). In addition, the sample was likely from a higher socioeconomic status when compared with all U.S. infants in this age group (4 to 24 months old), and the use of a telephone survey may have omitted lower income households without telephones (Devaney et al., 2004).

11.3.2.7. Ponza et al. (2004)—Nutrient Food Intakes and Food Choices of Infants and Toddlers Participating in Women, Infants, and Children (WIC)

Ponza et al. (2004) conducted a study using selected data from FITS to assess feeding patterns, food choices, and nutrient intake of infants and toddlers participating in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). Ponza et al. (2004) evaluated FITS data for the following age groups: 4 to 6 months ($N = 862$), 7 to 11 months ($N = 1,159$), and 12 to 24 months ($N = 996$). Table 11-24 shows the total sample size described by WIC participants and nonparticipants.

The foods consumed were analyzed by tabulating the percentage of infants who consumed specific foods/food groups per day (Ponza et al., 2004). Weighted data were used in all of the analyses used in the study (Ponza et al., 2004). Table 11-24 provides the food choices for infants and toddlers. In general, there was little difference in food choices among WIC participants and nonparticipants, except for consumption of yogurt by infants 7 to 11 months of age and toddlers 12 to 24 months of age (see Table 11-24). Nonparticipants, 7 to 24 months of age, were more likely to eat yogurt than WIC participants (Ponza et al., 2004).

An advantage of this study is that it had a relatively large sample size and was representative of the U.S. general population of infants and children. A limitation of the study is that intake values for foods were not provided. Other limitations are associated with the FITS data and are described previously in Section 11.3.2.6.

11.3.2.8. Mennella et al. (2006)—Feeding Infants and Toddlers Study: The Types of Foods Fed to Hispanic Infants and Toddlers

Mennella et al. (2006) investigated the types of food and beverages consumed by Hispanic infants and toddlers in comparison to the non-Hispanic infants and

toddlers in the United States. The FITS 2002 data for children between 4 and 24 months old were used for the study. The data represent a random sample of 371 Hispanic and 2,367 non-Hispanic infants and toddlers (Mennella et al., 2006). Mennella et al. (2006) grouped the infants as follows: 4 to 5 months ($N = 84$ Hispanic; 538 non-Hispanic), 6 to 11 months ($N = 163$ Hispanic; 1,228 non-Hispanic), and 12 to 24 months ($N = 124$ Hispanic; 871 non-Hispanic) of age.

Table 11-25 provides the percentages of Hispanic and non-Hispanic infants and toddlers consuming milk, meats, or other protein sources on a given day. In most instances, the percentages consuming the different types of meats and protein sources were similar (Mennella et al., 2006).

The advantage of the study is that it provides information on food preferences for Hispanic and non-Hispanic infants and toddlers. A limitation is that the study did not provide food intake data, but provided frequency of use data instead. Other limitations are those noted previously in Section 11.3.2.6 for the FITS data.

11.3.2.9. Fox et al. (2006)—Average Portion of Foods Commonly Eaten by Infants and Toddlers in the United States

Fox et al. (2006) estimated average portion sizes consumed per eating occasion by children 4 to 24 months old who participated in the FITS. The FITS is a cross-sectional study designed to collect and analyze data on feeding practices, food consumption, and usual nutrient intake of U.S. infants and toddlers and is described in Section 11.3.2.6 of this chapter. It included a stratified random sample of 3,022 children between ages 4 and 24 months.

Using the 24-hour recall data, Fox et al. (2006) derived average portion sizes for six major food groups, including meats and other protein sources. Average portion sizes for select individual foods within these major groups were also estimated. For this analysis, children were grouped into six age categories: 4 to 5 months, 6 to 8 months, 9 to 11 months, 12 to 14 months, 15 to 18 months, and 19 to 24 months. Tables 11-26 and 11-27 present the average portion sizes of meats and dairy products for infants and toddlers, respectively.

11.3.2.10. Siega-Riz et al. (2010)—Food Consumption Patterns of Infants and Toddlers: Where Are We Now?; Fox et al. (2010)—Food Consumption Patterns of Young Preschoolers: Are They Starting off on the Right Path?; Deming et al. (2014)—Infant Feeding Practices and Consumption Patterns of Children Participating in WIC

In 2008, a second FITS study was conducted (Fox et al., 2010; Siega-Riz et al., 2010). The study population included 3,273 children ages 0 to 47.9 months. Siega-Riz et al. (2010) described the dietary consumption patterns of 1,596 infants (4 to 5.9 months and 6 to 11.9 months) and toddlers (12 to 23.9 months) in the 2008 FITS. As in the 2002 FITS, parents or primary caregivers of study participants were interviewed by telephone to collect demographic and dietary information (two 24-hour dietary recalls). Food group data were used to calculate the percentage of children who consumed specific foods or food groups at least once per day. Table 11-28 provides the percentage of infants and toddlers consuming various types of meat at least once per day in 2008 (Siega-Riz et al., 2010). In general, the percentage of infants and toddlers consuming meats increased with increasing age (see Table 11-28).

Fox et al. (2010) presented data on the percentages of children, ages 21 to 47.9 months, consuming whole, 2%, 1%, and skim milk. The percentages of children, ages 21–23.9 months old, consuming whole, 2%, 1%, and skim milk were 61%, 28%, 4%, and 2%, respectively. For 24 to 29.9 month old children, the percentages were 34%, 35%, 8%, and 6%, respectively. For 30–35.9 month old children, the percentages were 34%, 36%, 19%, and 10% respectively, and for 36–47.9 month old children, the percentages were 27%, 45%, 14%, and 12%, respectively.

Deming et al. (2014) used the data for children 6–11, 12–23, and 24–47 months old from the 2008 FITS. The percentage of children consuming meats and other protein sources, and milk was estimated based on participation (n = 794) or nonparticipation (n = 2,477) in the WIC program (see Table 11–29).

The limitations of these studies are that the FITS dietary data were reported as the percentage of the respondents consuming per day and not as amounts of meats, milk, or other protein sources consumed per day. However, useful information was provided for the consumption of meats, milk, and other protein sources by children.

11.3.2.11. Briefel et al. (2010)—The Feeding Infants and Toddlers Study 2008; Study Design and Methods

Briefel et al. (2010) used a subsample of the 2008 FITS data to estimate the amount of meats and other protein sources, including milk products, consumed per eating occasion among children ages 12 to 23.9 months. The data were collected as part of a “bridging” study aimed at testing the effects of changes made to the food model booklet and protocol since the 2002 FITS was conducted. A total of 123 children were included in the sample. Table 11-30 provides the mean amount consumed per eating occasion for 2008. Siega-Riz et al. (2010) provided additional information on the 2008 FITS study population between 0 and 2 years of age, and the percentages of children eating meats and dairy products, based on comparisons between the 2002 and 2008 FITS.

The advantage of the Briefel et al. (2010) study is that it provides quantitative information on the amount of meats and other protein sources consumed by eating occasion; other FITS studies provide only percentages of the population eating certain foods. Because this study was based on a subsample of the study population, the sample size is relatively small.

11.3.2.12. Taylor et al. (2012)—Ground Beef Consumption Patterns in the United States, Food Net, 2006 through 2007

Taylor et al. (2012) used data from the Foodborne Diseases Active Surveillance Network (FoodNet) to estimate the frequency of ground beef consumption in the general population. The study was also used to estimate the percentage of the population that ate raw or undercooked (pink) ground beef because eating raw or undercooked ground beef may result in exposure to foodborne pathogens. The Centers for Disease Control, USDA, the Food and Drug Administration and selected state health departments conduct the FoodNet surveys. FoodNet data from 2006 and 2007 were used to evaluate ground beef consumption patterns at sites within 10 states: California, Colorado, Connecticut, Georgia, Maryland, Minnesota, New Mexico, New York, Oregon, and Tennessee. Survey respondents (n = 8,543) were interviewed by telephone, completing a series of questions pertaining to their consumption of ground beef inside and outside the home during the previous 7 days. An estimated 75.3% reported eating some type of ground beef within the previous week; 61.8% and 45.8% reported eating ground beef inside and outside the home, respectively. Most of the ground beef eaten at home was fresh (27.5%), and ground beef eaten outside the home, was most often eaten at restaurants (39%).

This study provides information on the proportion of the population eating different types of ground beef at different locations. However, only data on the percentage of the study population consuming ground beef were provided; Taylor et al. (2012) did not provide intake data.

11.3.3 Pregnant and Lactating Women

EPA estimated food intake rates for pregnant, lactating and all women of child-bearing age (13 to <50 years) using data from the NHANES for the years 2005 to 2010 and the FCID Consumption Calculator available at <http://fcid.foodrisk.org/>, as described in Section 11.3.1.1. NHANES 2005–2010 collected data on dietary recall of foods eaten over the previous 24-hour period on two nonconsecutive days. Two-day data were available for 426 pregnant women, 101 lactating women, and 5,543 women of child-bearing age. EPA’s FCID was used to convert the NHANES “as eaten” food consumption data into consumption of individual meat and dairy commodities, as described in Section 11.3.1.1, and the data were weighted according to sampling weights provided for the years 2005 to 2010. Two-day average intake rates were calculated for each survey respondent for total meats and total dairy, and for a variety of individual meat and dairy products. Summary statistics were calculated for the populations of pregnant, lactating, and females of child-bearing age (i.e., 13 to <50 years) on both a consumer-only and on a per capita basis.

Table 11-31 provides summary statistics for per capita intake of total meats and total dairy products, and Table 11-32 provides the same data on a consumer-only basis. Mean, standard error, 95th percentile per capita, and consumer-only intake rates for individual meats are provided in Table 11-33. Tables 11-31 and 11-32 indicate that the average per capita consumption rates of total dairy for lactating females (5.2 g/kg-day) and pregnant females (4.5 g/kg-day) were higher than that of all females 13 to <50 years (3.6 g/kg-day).

As indicated in Section 11.3.1.1, an advantage of using the EPA’s analysis of NHANES data is it was designed to be representative of the U.S. population. The data set used in this analysis used six years of intake data combined. However, the sample sizes for pregnant and lactating women were relatively small and short-term dietary data may not accurately reflect long-term eating patterns and may under-represent infrequent consumers of a given food. This is particularly true for the tails (extremes) of the food-intake distribution.

Limited data are available on differences in food choices over the duration of pregnancy. Crozier et al.

(2009) collected dietary data in Southampton, U.K. using a food frequency questionnaire for 2,270 women in early pregnancy, 2,649 women in late pregnancy, and 12,572 nonpregnant women. Data on the consumption of 48 foods or food groups were collected. During early pregnancy, intake of processed meats increased. During late pregnancy, intake of puddings, cream, milk, cheese, full-fat spread, cooking fats and salad oils, and red meat increased. Intake of liver and kidney decreased during pregnancy (Crozier et al., 2009). These results indicate that meat and dairy intake rates may change over the course of pregnancy. However, the consumption patterns or food choices observed in this study may not be representative of pregnant women in the United States. Also, while there may be differences in food choices over the course of pregnancy, the data are insufficient to draw specific conclusions. This limitation may need to be considered when assessing exposure among pregnant women.

11.4. INTAKE OF FAT

11.4.1. Key Fat Intake Study

11.4.1.1. *U.S. EPA (2007)—Analysis of Fat Intake Based on the U.S. Department of Agriculture’s 1994–1996, 1998 Continuing Survey of Food Intakes by Individuals*

EPA conducted an analysis to evaluate the dietary intake of fats by individuals in the United States using data from the USDA’s 1994–1996, 1998 CSFII (USDA, 2000). Intakes of CSFII foods were converted to EPA food commodity codes using data provided in EPA’s FCID (U.S. EPA, 2000). The FCID contains a “translation file” that was used to break down the USDA CSFII food codes into 548 EPA commodity codes. The method used to translate USDA food codes into EPA commodity codes is discussed in detail in U.S. EPA (2000).

Each of the 548 EPA commodity codes was assigned a value between zero and one that indicated the mass fraction of fat in that food item. For many sources of fat, a commodity code existed solely for the nutrient fat portion of the food. For example, beef is represented in the FCID database by 10 different commodity codes; several of these codes specifically exclude fat, and one code is described as “nutrient fat only.” In these cases, the fat fraction could be expressed as 0 or 1, as appropriate. Most animal food products and food oils were broken down in this way. The fat contents of other foods in the EPA commodity code list were determined using the USDA Nutrient Database for Standard Reference, Release 13 (USDA, 1999b). For each food item in the EPA code list, the

best available match in the USDA Nutrient Database was used. If multiple values were available for different varieties of the same food item (e.g., green, white, and red grapes), a mean value was calculated. If multiple values were available for different cooking methods (i.e., fried vs. dry cooked), the method least likely to introduce other substances, such as oil or butter, was preferred. In some cases, not all of the items that fell under a given food commodity code could be assigned a fat content. For example, the food commodity code list identified “turkey, meat byproducts” as including gizzard, heart, neck, and tail. Fat contents could be determined only for the gizzard and heart. Because the relative amounts of the different items in the food commodity code were unknown, the mean fat content of these two items was assumed to be the best approximation of the fat content for the food code as a whole.

The analysis was based on respondents who had provided body weights and completed both days of the 2-day survey process. These individuals were grouped according to various age categories. The mean, standard error, and a range of percentiles of fat intake were calculated for 12 food categories (i.e., all fats, animal fats, meat and meat products, beef, pork, poultry, organ meats, milk and dairy products, fish, oils, nuts/seeds/beans/legumes/tubers, and others) and 98 demographic cohorts. Fat intake was calculated as a 2-day average consumption across both survey days in units of grams per day and grams per kilogram of body weight per day for the whole survey population and for consumers only.

A secondary objective of the study was to evaluate fat consumption patterns of individuals who consume high levels of animal fats. The entire data analysis was repeated for a subset of individuals who were identified as high consumers of animal fats. The selection of the high-consumption group was done for each age category individually, rather than on the whole population, because fat intake on a per-body-weight basis is heavily skewed towards young children, and an analysis across the entire American population was desired. For infants, the “less-than-1-year-old” group was used instead of the smaller infant groups (<1 month, 1 to <3 months, etc.). Within each of the age categories, individuals who ranked at or above the 90th percentile of consumption of all animal fats on a per-unit body-weight basis were identified. Because of the sample weighting factors, the high consumer group was not necessarily 10% of each age group. The selected individuals made up a survey population of 2,134 individuals. Fat intake of individuals in this group was calculated in g/day and g/kg-day for the whole population (i.e., per capita) and for consumers only.

The analysis presented in U.S. EPA (2007) was conducted before EPA published the guidance entitled *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). Therefore, the age groups used for children in U.S. EPA (2007) were not entirely consistent with the age groups recommended in the 2005 guidance. A reanalysis of some of the data was conducted to conform with EPA’s recommended age groups for children. The results of this reanalysis are included in Tables 11-34 through 11-39 for all individuals. Only intake rates of all fats are provided in these tables; refer to U.S. EPA (2007) for fat intake rates from individual food sources. Tables 11-34 and 11-35 present intake rates of all fats for the whole population (i.e., per capita) in g/day and g/kg-day, respectively. Tables 11-36 and 11-37 present intake rates of all fats for consumers only in g/day and g/kg-day, respectively. Fat intake rates of all fats for the top decile of animal fat consumers from the consumers-only group are presented in Table 11-38 in g/day and in Table 11-39 in g/kg-day (per capita total fat intake rates for the top decile of animal fat consumers are not provided because they are the same as those for consumers only).

11.4.2. Relevant Fat Intake Studies

11.4.2.1. *Cresanta et al. (1988)/Nicklas et al. (1993)/Frank et al. (1986)—Bogalusa Heart Study*

Cresanta et al. (1988), Nicklas et al. (1993), and Frank et al. (1986) analyzed dietary fat intake data as part of the Bogalusa heart study. The Bogalusa study, an epidemiologic investigation of cardiovascular risk-factor variables and environmental determinants, collected dietary data on subjects residing in Bogalusa, LA, beginning in 1973. Among other research, the study collected fat intake data for children, adolescents, and young adults. Researchers examined various cohorts of subjects, including (1) six cohorts of 10-year olds, (2) two cohorts of 13-year olds, (3) one cohort of subjects from 6 months to 4 years of age, and (4) one cohort of subjects from 10 to 17 years of age (Nicklas, 1995). To collect the data, interviewers used the 24-hour dietary recall method. According to Nicklas (1995), “the diets of children in the Bogalusa study are similar to those reported in national studies of children.” Thus, these data are useful in evaluating the variability of fat intake among the general population. Tables 11-40 and 11-41 present data for 6-month-old to 17-year-old individuals collected during 1973 to 1982 (Frank et al., 1986). Data are presented for total fats, animal fats, vegetable fats, and

fish fats in units of g/day (see Table 11-40) and g/kg-day (see Table 11-41).

11.5. CONVERSION BETWEEN WET- AND DRY-WEIGHT INTAKE RATES

The intake rates presented in this chapter are reported in units of wet weight (i.e., as-consumed or uncooked weight of meats and dairy products consumed per day or per eating occasion). However, data on the concentration of contaminants in meats and dairy products may be reported in units of either wet or dry weight (e.g., mg contaminant per gram dry-weight of meats and dairy products). It is essential that exposure assessors be aware of this difference so that they may ensure consistency between the units used for intake rates and those used for concentration data (i.e., if the contaminant concentration is measured in dry weight of meats and dairy products, then the dry-weight units should be used for their intake values).

If necessary, wet weight (e.g., as-consumed) intake rates may be converted to dry-weight intake rates using the moisture content percentages presented in Table 11-42 or Table 11-43 and the following equation:

$$IR_{dw} = IR_{ww} \left[\frac{100 - W}{100} \right] \quad (\text{Eqn. 11-1})$$

where:

IR_{dw} = dry-weight intake rate,
 IR_{ww} = wet-weight intake rate, and
 W = percent water content.

Alternatively, dry-weight residue levels in meat and dairy products may be converted to wet-weight residue levels for use with wet-weight (e.g., as-consumed) intake rates as follows:

$$C_{ww} = C_{dw} \left[\frac{100 - W}{100} \right] \quad (\text{Eqn. 11-2})$$

where:

C_{ww} = wet-weight concentration,
 C_{dw} = dry-weight concentration, and
 W = percent water content.

The moisture content data presented in Table 11-42 are for selected meats and dairy products taken from USDA (2007). Table 11-43 provides additional data on the water content of meats, dairy products, and fats, based on data from Popkin et al. (2010).

11.6. CONVERSION BETWEEN WET- AND LIPID-WEIGHT INTAKE RATES

In some cases, the residue levels of contaminants in meat and dairy products may be reported as the concentration of contaminant per gram of fat. This may be particularly true for lipophilic compounds. When using these residue levels, the assessor should ensure consistency in the exposure assessment calculations by using consumption rates that are based on the amount of lipids consumed for the meat or dairy product of interest.

If necessary, wet-weight (e.g., as-consumed) intake rates may be converted to lipid-weight intake rates using the fat content percentages presented in Table 11-42 and the following equation:

$$IR_{lw} = IR_{ww} \left[\frac{L}{100} \right] \quad (\text{Eqn. 11-3})$$

where:

IR_{lw} = lipid-weight intake rate,
 IR_{ww} = wet-weight intake rate, and
 L = percentage lipid (fat) content.

Alternately, wet-weight residue levels in meat and dairy products may be estimated by multiplying the levels based on fat by the fraction of fat per product as follows:

$$C_{ww} = C_{lw} \left[\frac{L}{100} \right] \quad (\text{Eqn. 11-4})$$

where:

C_{ww} = wet-weight concentration,
 C_{lw} = lipid-weight concentration, and
 L = percentage lipid (fat) content.

The resulting residue levels may then be used in conjunction with wet-weight (e.g., as-consumed) consumption rates. Table 11-42 presents the total fat

content data for selected meat and dairy products taken from USDA (2007).

Table 11-3. Per Capita 2-Day Average^a Intake of Total Meat and Total Dairy Products Based on 2005–2010 NHANES (g/kg-day, edible portion, uncooked weight)^b (Continued)

^a	Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption. Single day rates can be generated using http://fcid.foodrisk.org/ .
^b	For more information, refer to the Frequently Asked Questions at http://fcid.foodrisk.org/ .
^c	Represents the percentage of individuals consuming these foods at least once over the 2-day survey period. Rounded to whole numbers; thus, values of 100 percent mean that ≥ 99.5 percent of the population consumed the foods during the 2-day survey period.
^d	Total Meat includes: beef, fat; beef, fat-baby food; beef, kidney; beef, liver; beef, liver-baby food; beef, meat; beef, meat byproducts; beef, meat byproducts-baby food; beef, meat, dried; beef, meat-baby food; chicken, fat; chicken, fat-baby food; chicken, liver; chicken, meat; chicken, meat byproducts; chicken, meat byproducts-baby food; chicken, meat-baby food; chicken, skin; chicken, skin-baby food; goat, fat; goat, kidney; goat, liver; goat, meat; goat, meat byproducts; horse, meat; meat, game; pork, fat; pork, fat-baby food; pork, kidney; pork, liver; pork, meat; pork, meat byproducts; pork, meat byproducts-baby food; pork, meat-baby food; pork, skin; poultry, other, fat; poultry, other, liver; poultry, other, meat; poultry, other, meat byproducts; poultry, other, skin; rabbit, meat; sheep, fat; sheep, fat-baby food; sheep, kidney; sheep, liver; sheep, meat; sheep, meat byproducts; sheep, meat-baby food; turkey, fat; turkey, fat-baby food; turkey, liver; turkey, liver-baby food; turkey, meat; turkey, meat byproducts; turkey, meat byproducts-baby food; turkey, meat-baby food; turkey, skin; turkey, skin-baby food.
^e	Estimates are less statistically reliable based on guidance published in the Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: NHIS/NCHS Analytical Working Group Recommendations (NCHS, 1993).
^f	Total Dairy includes: milk, fat; milk, fat-baby food/infant formula; milk, nonfat solids; milk, nonfat solids-baby food/infant formula; milk, sugar (lactose)-baby food/infant formula; milk, water; milk, water-baby food/infant formula.
<i>N</i>	= Sample size.
<i>SE</i>	= Standard error.

- ^a Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption. Single day rates can be generated using <http://fcid.foodrisk.org/>.
- ^b For more information, refer to the Frequently Asked Questions at <http://fcid.foodrisk.org/>.
- ^c PC = Percent consuming. Represents the percentage of individuals consuming these foods at least once over the 2-day survey period.
- ^d Beef includes: beef, fat; beef, fat-baby food; beef, kidney; beef, liver; beef, liver-baby food; beef, meat; beef, meat byproducts; beef, meat byproducts-baby food; beef, meat, dried; beef, meat-baby food.
- ^e Pork includes: pork, fat; pork, fat-baby food; pork, kidney; pork, liver; pork, meat; pork, meat byproducts; pork, meat byproducts-baby food; pork, meat-baby food; pork, skin.
- ^f Poultry includes: chicken, fat; chicken, fat-baby food; chicken, liver; chicken, meat; chicken, meat byproducts; chicken, meat byproducts-baby food; chicken, meat-baby food; chicken, skin; chicken, skin-baby food; poultry, other, fat; poultry, other, liver; poultry, other, meat; poultry, other, meat byproducts; poultry, other, skin; turkey, fat; turkey, fat-baby food; turkey, liver; turkey, liver-baby food; turkey, meat; turkey, meat byproducts; turkey, meat byproducts-baby food; turkey, meat-baby food; turkey, skin; turkey, skin-baby food.
- N = Sample size.
- SE = Standard error.

Table 11-42. Mean Percentage of Moisture and Total Fat Content of Selected Meat and Dairy Products^a

Product	Moisture Content (%)	Total Fat Content (%)	Comment
Meat			
Beef (composite of trimmed retail cuts; all grades)	70.62	6.16	Raw; lean only
	59.25	9.91	Cooked; lean only
	60.44	19.24	Raw; lean and fat, 1/4 in fat trim
	51.43	21.54	Cooked; lean and fat, 1/4 in fat trim
Pork (composite of trimmed retail cuts)	72.34	5.88	Raw; lean only
	60.31	9.66	Cooked; lean only
	65.11	14.95	Raw; lean and fat
	54.55	17.18	Cooked; lean and fat
Cured ham	63.46	12.90	Center slice, unheated; lean and fat
	55.93	8.32	Raw, center slice, country style; lean only
Cured bacon	40.20	45.04	Raw
	12.52	43.27	Cooked, baked
	12.32	41.78	Cooked, broiled
	12.12	40.30	Cooked, pan-fried
	16.49	37.27	Cooked, microwaved
Lamb (composite of trimmed retail cuts)	73.42	5.25	Raw; lean only
	61.96	9.52	Cooked; lean only
	60.70	21.59	Raw; lean and fat, 1/4 in fat trim
	53.72	20.94	Cooked; lean and fat, 1/4 in fat trim
Veal (composite of trimmed retail cuts)	75.91	2.87	Raw; lean only
	60.16	6.58	Cooked; lean only
	72.84	6.77	Raw; lean and fat, 1/4 in fat trim
	57.08	11.39	Cooked; lean and fat, 1/4 in fat trim
Rabbit (domesticated)	72.82	5.55	Raw
	60.61	8.05	Cooked, roasted
	58.82	8.41	Cooked, stewed
Chicken (broilers or fryers)	75.46	3.08	Raw; meat only
	66.81	6.71	Cooked, stewed; meat only
	63.79	7.41	Cooked, roasted; meat only
	57.53	9.12	Cooked, fried; meat only
	65.99	15.06	Raw; meat and skin
	63.93	12.56	Cooked, stewed; meat and skin
	59.45	13.60	Cooked, roasted; meat and skin
	52.41	14.92	Cooked, fried, flour; meat and skin
Duck (domesticated)	73.77	5.95	Raw; meat only
	64.22	11.20	Cooked, roasted; meat only
	48.50	39.34	Raw; meat and skin
	51.84	28.35	Cooked, roasted; meat and skin
Turkey (all classes)	74.16	2.86	Raw; meat only
	64.88	4.97	Cooked, roasted; meat only
	70.40	8.02	Raw; meat and skin
	61.70	9.73	Cooked, roasted; meat and skin
	71.97	8.26	Raw; ground
	59.42	13.15	Cooked; ground

Table 11-42. Mean Percentage of Moisture and Total Fat Content of Selected Meat and Dairy Products^a (Continued)				
Product		Moisture Content (%)	Total Fat Content (%)	Comment
Dairy				
Milk				
	Whole	88.32	3.25	3.25% milkfat
	Human	87.50	4.38	Whole, mature, fluid
	Low-fat (1%)	89.81	0.97	Fluid, with added nonfat milk solids and vitamin A
	Reduced fat (2%)	88.86	1.92	Fluid, with added nonfat milk solids and vitamin A
	Skim or fat free	90.38	0.25	Fluid, with added nonfat milk solids and vitamin A
Cream				
	Half and half	80.57	11.50	Fluid
	Light (coffee cream or table cream)	73.75	19.31	Fluid
	Heavy-whipping	57.71	37.00	Fluid
	Sour	70.95	20.96	Cultured
	Sour, reduced fat	80.14	12.00	Cultured
Butter		15.87	81.11	Salted
Cheese				
	American	39.16	31.25	Pasteurized
	Cheddar	36.75	33.14	
	Swiss	37.12	27.80	
	Cream	53.75	34.87	
	Parmesan	29.16; 20.84	25.83; 28.61	Hard; grated
	Cottage, Low-fat	82.48; 79.31	1.02; 1.93	1% fat; 2% fat
	Colby	38.20	32.11

SUPPLEMENTAL TABLE

CODES AND DEFINITIONS USED TO DETERMINE THE VARIOUS COMMODITIES USED IN THE EPA ANALYSIS OF WHAT WE EAT IN AMERICA FOOD COMMODITY INTAKE DATABASE (WWEIA-FCID) DATA

The U.S. Environmental Protection Agency (EPA) analyses of the National Health and Nutrition Examination Survey (NHANES) 2005–2010 food consumption data provided in the EPA’s Exposure Factors Handbook (EFH) was performed using the What We Eat in America Food Commodity Intake Database (WWEIA-FCID) (<http://fcid.foodrisk.org/>), which converted the WWEIA food items into FCID raw agricultural commodities using recipes developed by EPA. This supplement lists the FCID commodities used to generate statistics for corresponding foods and food categories as defined in the Exposure Factors Handbook. For example, “beef” as defined here in the EFH consists of the following ten FCID commodities: beef, meat (3100044000); beef, meat-baby food (3100044001); beef, meat, dried (3100045000); beef, meat byproducts (3100046000); beef, meat byproducts-baby food (3100046001); beef, fat (3100047000); beef, fat-baby food (3100047001); beef, kidney (3100048000); beef, liver (3100049000); and beef, liver-baby food (3100049001).

Table B-1. Food Commodity Codes and Definitions Used in Analysis of the 2005–2010 (and 2003–2008) NHANES WWEIA		
EFH Food Category	EPA Food Commodity Codes	
Dairy	3600222000 Milk, fat 3600222001 Milk, fat-baby food/infant formula 3600223000 Milk, nonfat solids 3600223001 Milk, nonfat solids-baby food/infant formula	3600224000 Milk, water 3600224001 Milk, water-baby food/infant formula 3600225001 Milk, sugar (lactose)-baby food/infant formula
Beef	3100044000 Beef, meat 3100044001 Beef, meat-baby food 3100045000 Beef, meat, dried 3100046000 Beef, meat byproducts 3100046001 Beef, meat byproducts-baby food	3100047000 Beef, fat 3100047001 Beef, fat-baby food 3100048000 Beef, kidney 3100049000 Beef, liver 3100049001 Beef, liver-baby food
Pork	3400290000 Pork, meat 3400290001 Pork, meat-baby food 3400291000 Pork, skin 3400292000 Pork, meat byproducts 3400292001 Pork, meat byproducts-baby food	3400293000 Pork, fat 3400293001 Pork, fat-baby food 3400294000 Pork, kidney 3400295000 Pork, liver
Poultry	4000093000 Chicken, meat 4000093001 Chicken, meat-baby food 4000094000 Chicken, liver 4000095000 Chicken, meat byproducts 4000095001 Chicken, meat byproducts-baby food 4000096000 Chicken, fat 4000096001 Chicken, fat-baby food 4000097000 Chicken, skin 4000097001 Chicken, skin-baby food 5000382000 Turkey, meat 5000382001 Turkey, meat-baby food 5000383000 Turkey, liver	5000383001 Turkey, liver-baby food 5000384000 Turkey, meat byproducts 5000384001 Turkey, meat byproducts-baby food 5000385000 Turkey, fat 5000385001 Turkey, fat-baby food 5000386000 Turkey, skin 5000386001 Turkey, skin-baby food 6000301000 Poultry, other, meat 6000302000 Poultry, other, liver 6000303000 Poultry, other, meat byproducts 6000304000 Poultry, other, fat 6000305000 Poultry, other, skin

12. INTAKE OF GRAIN PRODUCTS

12.1. INTRODUCTION

This document is an update to Chapter 12 (Intake of Grain Products) of the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011). The recommended values for the general population in this chapter have been updated using NHANES data for 2005–2010; the 2011 version of this chapter used NHANES data for 2003–2006. The 2018 recommendations include some more disaggregated age groupings than the 2011 Handbook (for those under age 1 and for adults), and for some childhood age groups provide more statistically reliable estimates because the new analysis uses 6 years of NHANES data versus four in the 2011 estimates.

For the estimates of the mean per capita intake of total grains there was some decrease in the ages 21 to 50 years of age, but not in those over 50 years of age. For younger and more disaggregated ages, there is no simple pattern in the updates to the estimates, but Appendix A provides a comparison of the recommended values in this update to those of the 2011 Handbook.

This update also provides, for the first time, intake data for pregnant and lactating women based on NHANES 2005–2010 data. Recent relevant studies based on data other than NHANES are also summarized to provide additional perspective on grain intake.

This chapter includes a comprehensive review of the scientific literature through 2016. The new literature was identified via formal literature searches conducted by U.S. Environmental Protection Agency (EPA) staff as well as targeted internet searches conducted by the authors of this chapter. Appendix B provides a list of the key terms that were used in the literature searches. Revisions to this chapter have been made in accordance with the approved quality assurance plan for the *Exposure Factors Handbook*.

The American food supply is generally considered to be one of the safest in the world. Nevertheless, grain products can become contaminated with toxic chemicals by several different pathways. Ambient air pollutants may be deposited on or absorbed by the plants, or dissolved in rainfall or irrigation waters that contact the plants. Pollutants may also be absorbed through plant roots from contaminated soil and ground water. The addition of pesticides, soil additives, and fertilizers may also result in contamination of grain products. To assess exposure through this pathway, information on ingestion rates of grain products is needed.

A variety of terms may be used to define intake of grain products (e.g., consumer-only intake, per capita

intake, total grain intake, as-consumed intake, uncooked edible intake, dry-weight intake). As described in Chapter 9 “Intake of Fruits and Vegetables,” consumer-only intake is defined as the quantity of grain products consumed by individuals during the survey period. These data are generated by averaging intake across only the individuals in the survey who consumed these food items. Per capita intake rates are generated by averaging consumer-only intakes over the entire population (including those that reported no intake). In general, per capita intake rates are appropriate for use in exposure assessments for which average dose estimates for individuals are of interest because they represent both individuals who ate the foods during the survey period and those who may eat the food items at some time but did not consume them during the survey period. Per capita intake, therefore, represents an average across the entire population of interest, but does so at the expense of underestimating consumption for the subset of the population that consumed the food in question. Total grain intake refers to the sum of all grain products consumed in a day.

Intake rates may be expressed on the basis of the as-consumed weight (e.g., cooked or prepared) or on the uncooked or unprepared weight. As-consumed intake rates are based on the weight of the food in the form that it is consumed and should be used in assessments where the basis for the contaminant concentrations in foods is also indexed to the as-consumed weight. Some of the food ingestion values provided in this chapter are expressed as as-consumed intake rates because this is the way in which data were reported by survey respondents. Other values are provided as uncooked weights based on analyses of survey data that account for weight changes that occur during cooking. This adjustment is important because concentration data to be used in the dose equation are often measured in uncooked food samples. Note that cooking can either increase or decrease food weight. Similarly, cooking can increase the mass of a contaminant in food (due to formation reactions, or absorption from cooking oils or water) or decrease the mass of a contaminant in food (due to vaporization, fat loss, or leaching). The combined effects of changes in food weight and contaminant mass can result in either an increase or decrease in contaminant concentration in cooked food. Therefore, if the as-consumed ingestion rate and the uncooked concentration are used in the dose equation, dose may be under-estimated or over-estimated. It is important for the assessor to be aware of these issues and choose intake rate data that best match the concentration data being used. For more information on cooking losses

and conversions necessary to account for such losses, refer to Chapter 13 of this handbook.

Sometimes contaminant concentrations in food are reported on a dry-weight basis. When these data are used in an exposure assessment, it is recommended that dry-weight intake rates also be used. Dry-weight food concentrations and intake rates are based on the weight of the food consumed after the moisture content has been removed. For information on converting the intake rates presented in this chapter to dry-weight intake rates, refer to Section 12.4.

The purpose of this chapter is to provide intake data for grain products for the general population. The recommendations for ingestion rates for these food sources are provided in the next section, along with a summary of the confidence ratings for these recommendations. The recommended values are based on the key study identified by EPA for this factor. As described in Chapter 1 of the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011), the key studies represent the most up-to-date and scientifically sound ones for deriving recommendations for exposure factors, whereas other studies are designated "relevant," meaning applicable or pertinent, but not necessarily the most important. For example, studies that provide supporting data or information related to the factor of interest (e.g., percentage of the population consuming grains and products), or have study designs or approaches that make the data less applicable to the general population (e.g., studies that targeted specific populations or older studies) have been designated as relevant rather than key. Key studies were selected based on the general assessment factors described in Chapter 1 of the Handbook. Following the recommendations, the key study on ingestion of grain products is summarized. Relevant data on ingestion of grain products are also provided. These data are presented to provide the reader with added perspective on the current state-of-knowledge pertaining to ingestion of grain products.

12.2. RECOMMENDATIONS

Table 12-1 presents a summary of the recommended values for per capita and consumer-only intake of grain products for use in exposure and risk assessment. Table 12-2 provides confidence ratings for the grain intake recommendations for the general population.

The EPA analysis of data from the 2005–2010 National Health and Nutrition Examination Survey (NHANES) was used in selecting recommended intake rates. The U.S. EPA analysis was conducted using the childhood age groups in EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing*

Childhood Exposures to Environmental Contaminants (U.S. EPA, 2005).

The NHANES data on which the recommendations are based are short-term survey data and may not necessarily reflect the long-term distribution of average daily intake rates. However, because broad categories of food (i.e., total grains), are eaten on a daily basis throughout the year with minimal seasonality, the short-term distribution may be a reasonable approximation of the long-term distribution, although it will display somewhat increased variability. This implies that the upper percentiles shown here will tend to overestimate the corresponding percentiles of the true long-term distribution. In general, the recommended values based on EPA's analysis of NHANES data represent the uncooked weight of the edible portion of grain products.

U.S. Department of Agriculture (USDA) and the U.S. Department of Health and Human Services (USDHHS) jointly developed *Dietary Guidelines for Americans: 2010* that provide information and advice for choosing healthy eating patterns (USDA and USDHHS, 2010). The guidance may differ from the recommended intake rates for grain and grain products that are provided in this chapter for use in exposure/risk assessment because NHANES and similar surveys reflect actual intake rather than dietary goals.

Table 12-1. Recommended Values for 2-Day Average ^a Intake of Grains ^b (edible portion, uncooked weight) ^c								
Age Group	Per Capita		Consumers Only		Multiple Percentiles	Source		
	Mean	95 th Percentile	Mean	95 th Percentile				
	g/kg-day	g/kg-day	g/kg-day	g/kg-day				
Total Grains								
Birth to <1 month	0.6	2.9 ^d	2.7	6.1 ^d	See Tables 12-3 and 12-4	EPA analysis of NHANES 2005–2010

Whole Population	2.5	6.5	2.5	6.5				
Individual Grain Products—See Tables 12-5 and 12-6								
^a	Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption.							
^b	Total Grains includes: amaranth, grain; barley, bran; barley, flour; barley, flour baby food; barley, pearled barley; barley, pearled barley baby food; buckwheat; buckwheat, flour; corn, field, bran; corn, field, flour; corn, field, flour baby food; corn, field, meal; corn, field, meal baby food; corn, field, starch; corn, field, starch baby food; corn, pop; corn, sweet; corn, sweet baby food; millet, grain; oat, bran; oat, flour; oat, flour baby food; oat, groats/rolled oats; oat, groats/rolled oats baby food; psyllium, seed; quinoa, grain; rice, bran; rice, bran baby food; rice, brown; rice, brown baby food; rice, flour; rice, flour baby food; rice, white; rice, white baby food; rye, flour; rye, grain; sorghum, grain; triticale, flour; triticale, flour baby food; wheat, bran; wheat, flour; wheat, flour baby food; wheat, germ; wheat, grain; wheat, grain baby food; wild rice.							
^c	For more information on the recipes used to convert the foods people reported eating to the quantities of agricultural commodities eaten, refer to the Frequently Asked Questions at http://fcid.foodrisk.org/ .							
^d	Estimates are less statistically reliable based on guidance published in the <i>Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and Continuing Survey of Food Intake by Individuals (CSFII) Reports: Human Nutrition Information Service (HNIS)/National Center for Health Statistics (NCHS) Analytical Working Group Recommendations</i> (NCHS, 1993).							

Table 12-2. Confidence in Recommendations for Intake of Grain Products ^a		
General Assessment Factors	Rationale	Rating
Soundness		High
<i>Adequacy of Approach</i>	The survey methodology and data analysis were adequate. The survey sampled nearly 25,000 individuals. An analysis of primary data was conducted.	
<i>Minimal (or defined) Bias</i>	No physical measurements were taken. The method relied on recent recall of grain products eaten.	
Applicability and Use		High
<i>Exposure Factor of Interest</i>	The key study was directly relevant to grain intake.	
<i>Representativeness</i>	The data were demographically representative of the U.S. population (based on stratified random sample).	
<i>Currency</i>	Data were collected between 2005 and 2010.	
<i>Data Collection Period</i>	Data were collected for 2 nonconsecutive days.	
Clarity and Completeness		High
<i>Accessibility</i>	The NHANES data and the FCID Consumption Calculator are publicly available.	
<i>Reproducibility</i>	The methodology used was clearly described; enough information was included to reproduce the results.	
<i>Quality Assurance</i>	NHANES follows strict quality assurance/quality control procedures. The EPA analysis has only been reviewed internally, but the methodology has been used in an analysis of previous data.	
Variability and Uncertainty		Medium to high for averages, low for long-term upper percentiles; low for individual foods
<i>Variability in Population</i>	Full distributions were provided for total grains. Means were provided for individual grain products.	
<i>Minimal Uncertainty</i>	Data collection was based on recall for a two-day period; the accuracy of using these data to estimate long-term intake (especially at the upper percentiles) is uncertain. However, use of short-term data to estimate chronic ingestion can be assumed for broad categories of foods such as total grains. Uncertainty is greater for individual grain products.	
Evaluation and Review		Medium
<i>Peer Review</i>	The NCHS NHANES survey received a high level of peer review. The EPA analysis of these data has not been peer reviewed outside the Agency, but the methodology has been used in an analysis of previous data.	
<i>Number and Agreement of Studies</i>	There was one key study.	
Overall Rating		Medium to High confidence in the averages; Low confidence in the long-term upper percentiles
^a	See Section 1.5.2 in Chapter 1 of the <i>Exposure Factors Handbook: 2011 Edition</i> (U.S. EPA, 2011) for a detailed description of the evaluation criteria used in this table.	
FCID	= Food Commodity Intake Database.	

12.3. INTAKE STUDIES

12.3.1. Key Grain Intake Study

12.3.1.1. *EPA Analysis of Consumption Data from 2005–2010 National Health and Nutrition Examination Survey*

The key source of recent information on consumption rates of grain products is the U.S. Centers for Disease Control and Prevention's National Center for Health Statistics' (NCHS) NHANES. Data from NHANES 2005–2010 have been used by the EPA to generate per capita and consumer-only intake rates for both individual grain products and total grain products.

NHANES is designed to assess the health and nutritional status of adults and children in the United States. In 1999, the survey became a continuous program that interviews a nationally representative sample of approximately 5,000 persons each year in counties across the country, 15 of which are visited annually. Data are released on a 2-year basis; thus, for example, the 2005 data are combined with the 2006 data to produce NHANES 2005–2006.

The dietary interview component of NHANES is called *What We Eat in America* (WWEIA) and is conducted by the USDA and the USDHHS. USDHHS' NCHS is responsible for the sample design and data collection, and USDA's Food Surveys Research Group is responsible for the dietary data collection methodology, maintenance of the databases used to code and process the data, and data review and processing. Beginning in 2003, 2 nonconsecutive days of 24-hour intake data were collected. The first day was collected in person, and the second day was collected by telephone, 3 to 10 days later. These data were collected using USDA's dietary data collection instrument, the Automated Multiple Pass Method, which provides an efficient and accurate means of collecting intakes for large-scale national surveys. It is fully computerized and uses a five-step interview. Details can be found at USDA's Agriculture Research Service (<http://www.ars.usda.gov/ba/bhnrc/fsrg>).

The 2005–2010 NHANES surveys are stratified, multistage probability samples of the civilian noninstitutionalized U.S. population. The sampling frame was based on the 2000 U.S. population census estimates. Several sets of sampling weights are available for use with the intake data. By using appropriate weights, data for all 6 years of the surveys can be combined. Additional information on NHANES can be obtained at <http://www.cdc.gov/nchs/nhanes.htm>.

The EPA used NHANES 2005–2010 data to update the Food Commodity Intake Database (FCID)

that was developed in earlier analyses of data from the USDA's Continuing Survey of Food Intake by Individuals (CSFII) (USDA, 2000; U.S. EPA, 2000) (see Section 12.3.2.4). The updated FCID is available at: <http://fcid.foodrisk.org/>, along with the FCID Consumption Calculator which was used to develop the estimates provided in this chapter for various age and race/ethnic groups. The Calculator may also be used to develop estimates for other age groups or populations, customized to the users' needs. In the FCID, NHANES data on the foods people reported eating were converted to the quantities of agricultural commodities eaten. "Agricultural commodity" is a term used by EPA to mean plant (or animal) parts used as feed or consumed by humans as food; when such items are raw or unprocessed, they are referred to as "raw agricultural commodities." For example, an apple pie may contain the commodities apples, flour, fat, sugar, and spices. FCID contains approximately 560 unique commodity names and 8-digit codes. The FCID commodity names and codes were selected and defined by EPA and were based on the EPA Food Commodity

Vocabulary (<http://www.epa.gov/pesticides/foodfeed/>). The codes and definitions used to determine the various commodities in the EPA analysis for grains are provided in Appendix C.

Intake rates were generated for a variety of food items/groups based on the agricultural commodities included in the FCID. These intake rates represent intake of all forms of the product (e.g., both home produced and commercially produced) for 2 survey days. For respondents who reported intake on both days, their intake rate represents the average rate for the 2 survey days. For respondents who reported consumption on one day and no consumption on the other day, their intake rate represents the average of zero and nonzero consumption. Two-day average intake rates were calculated for all individuals in the database for each of the food items/groups. These average daily intake rates were divided by each individual's reported body weight to generate intake rates in units of grams per kilogram of body weight per day (g/kg-day). The data were weighted according to the 6-year, 2-day sample weights provided in NHANES 2005–2010 to adjust the data for the sample population to reflect the national population. The 2005–2010 analysis of NHANES/FCID data for grains included data for nearly 25,000 respondents.

Summary statistics were generated on a consumer-only and on a per capita basis. Summary statistics, including number of observations, percentage of the population consuming the grains being analyzed, mean intake rate, and standard error of the mean intake rate, were calculated for total grains

and selected individual grains. Percentiles of the intake rate distribution (i.e., 1st, 5th, 10th, 25th, 50th, 75th, 90th, 95th, 99th, and the maximum value) were also provided for total grains. Data were provided for the following childhood age groups: birth to <1 month, 1 to <3 months, 3 to <6 months, 6 to <12 months, 1 to <2 years, 2 to <3 years, 3 to <6 years, 6 to <11 years, 11 to <16 years, and 16 to <21 years to be consistent with those recommended in EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). Data for the birth to <1-year age group were also provided to be consistent with the Exposure Factors Handbook: 2011 Edition. For adults, data were provided for ages 21 to <30 years, 30 to <40 years, 40 to <50 years, 50 to <60 years, 60 to <70 years, 70 to <80 years, and 80+ years, and for ages 21 to <50 years and 50+ years. Data were also provided according to the following racial/ethnic groups: Mexican American, non-Hispanic black, non-Hispanic white, other Hispanic, and other race including multiple races.

Table 12-3 presents per capita intake data for total grains in g/kg-day; Table 12-4 provides consumer-only intake data for total grains in g/kg-day. Table 12-5 provides per capita intake data for individual grains (rice and cereal) in g/kg-day, and Table 12-6 provides consumer-only intake data for individual grains in g/kg-day. In general, these data represent intake of the edible portions of (uncooked) foods.

Because the results are presented in units of g/kg-day, the use of these data in calculating potential dose does not require the body-weight factor to be included in the denominator of the average daily dose equation. It should be noted that converting these intake rates into units of g/day by multiplying by a single average body weight is inappropriate because individual intake rates were indexed to the reported body weights of the survey respondents. If intake data in units of g/day are needed, they can be obtained using the FCID Consumption Calculator which is available at <http://fcid.foodrisk.org/>. Also, note that the distribution of average daily intake rates generated using short-term data (e.g., 2-day) does not necessarily reflect the long-term distribution of average daily intake rates. The distributions generated from short-term and long-term data will differ to the extent that each individual's intake varies from day to day; the distributions will be similar to the extent that individuals' intakes are constant from day to day. Day-to-day variation in intake among individuals will be high for grains that are not typically eaten every day. For these grains, the intake distribution generated from short-term data will not be a good reflection of

the long-term distribution. On the other hand, for broad categories of foods (e.g., total grains) that are eaten on a daily basis throughout the year, the short-term distribution may be a reasonable approximation of the true long-term distribution, although it will show somewhat more variability. In this chapter, distributions are provided for broad categories of grains (e.g., total grains). Because of the increased variability of the short-term distribution, the short-term upper percentiles shown here may overestimate the corresponding percentiles of the long-term distribution. For individual foods, only the mean, standard error, and percentage of people consuming are provided.

An advantage of using the EPA's analysis of NHANES data is that it provides distributions of intake rates for various age groups of children and adults, normalized by body weight. The data set was designed to be representative of the U.S. population and includes 6 years of intake data combined. Another advantage is the currency of the data; the NHANES data are from 2005–2010. However, short-term dietary data may not accurately reflect long-term eating patterns, and the upper percentiles may overestimate the corresponding percentiles of the true long-term distribution. However, because these are 2-day averages, consumption estimates at the upper end of the intake distribution may be underestimated if these consumption values are used to assess acute (i.e., short-term) exposures.

12.3.2. Relevant Grain Intake Studies

12.3.2.1. *USDA (1980, 1992, 1996a, b)—Food and Nutrient Intakes of Individuals in 1 Day in the United States*

USDA calculated mean per capita intake rates for total and individual grain products using Nationwide Food Consumption Survey (NFCS) data from 1977–1978 and 1987–1988 (USDA, 1980, 1992) and CSFII data from 1994 and 1995 (USDA, 1996a, b). The mean per capita intake rates for grain products are presented in Tables 12-7 and 12-8 for the two NFCS survey years, respectively. Table 12-9 presents similar data from the 1994 and 1995 CSFII for grain products.

The advantages of using these data are that they provide mean intake estimates for various grain products that are not included in other studies. The consumption estimates are based on short-term (i.e., 1-day) dietary data, which may not reflect long-term consumption. Also, intake rates are not normalized to body weight, and data are not consistent with EPA's recommended age groups. These data are based on older surveys and may not be entirely representative of current eating patterns, but may

provide some historical perspective on intake of these foods.

12.3.2.2. *USDA (1999a)—Food Consumption, Prices, and Expenditures, 1970–1997*

The USDA's Economic Research Service calculates the amount of food available for human consumption in the United States annually and generates supply and utilization balance sheets which are based on the flow of food items from production to end uses. Total available supply is estimated as the sum of production (i.e., some products are measured at the farm level or during processing), starting inventories, and imports (USDA, 1999a). The availability of food for human use, commonly termed as "food disappearance," is determined by subtracting exported foods, products used in industries, farm inputs (seed and feed), and end-of-the-year inventories from the total available supply (USDA, 1999a). USDA (1999a) calculates the per capita food consumption by dividing the total food disappearance by the total U.S. population.

USDA (1999a) estimated per capita consumption data for grain products from 1970–1997. In this section, the 1997 values, which are the most recent final data, are presented. Table 12-10 presents per capita consumption in 1997 for grains.

An advantage of this study is that it provides per capita consumption rates for grains that are representative of long-term intake because disappearance data are generated annually. Daily per capita intake rates are generated by dividing annual consumption by 365 days/year. One of the limitations of this study is that disappearance data do not account for losses from the food supply from waste, spoilage, or foods fed to pets. Thus, intake rates based on these data may overestimate daily consumption because they are based on the total quantity of marketable commodity used. Therefore, these data may be useful for estimating bounding exposure estimates. Note that per capita estimates based on food disappearance are not a direct measure of actual consumption or quantity ingested, instead the data are used as indicators of changes in usage over time (USDA, 1999a). These data are based on older surveys and may not be entirely representative of current consumption patterns.

12.3.2.3. *USDA (1999b)—Food and Nutrient Intakes by Children 1994–1996, 1998, Table Set 17*

USDA (1999b) calculated national probability estimates of food and nutrient intake by children based on 4 years of the CSFII (1994–1996 and 1998) for children ages 9 years and under, and on CSFII

1994–1996 only for individuals aged 10 years and over. The CSFII was a series of surveys designed to measure the kinds and amounts of foods eaten by Americans. Intake data, based on 24-hour dietary recall, were collected through in-person interviews on 2 nonconsecutive days. Section 12.3.2.4 provides additional information on these surveys.

USDA used sample weights to adjust for nonresponse, to match the sample to the U.S. population in terms of demographic characteristics, and to equalize intakes over the four quarters of the year and the 7 days of the week. A total of 503 breast-fed children were excluded from the estimates, but both consumers and nonconsumers were included in the analysis.

USDA (1999b) provided data on the mean per capita quantities (grams) of various food products/groups consumed per individual for 1 day, and the percentage of individuals consuming those foods in 1 day of the survey. Tables 12-11 and 12-12 present data on the mean quantities (grams) of grain products consumed per individual for 1 day, and the percentage of survey individuals consuming grain products that survey day. Data on mean intakes or mean percentages are based on respondents' Day-1 intakes.

The advantage of the USDA (1999b) study is that it uses the 1994–1996, 1998 CSFII data set, which includes 4 years of intake data, combined, along with supplemental data on children. This data set is expected to be generally representative of the U.S. population and includes data on a wide variety of grain products. The data set is one of a series of USDA data sets that are publicly available. One limitation of this data set is that it is based on 1 day, and short-term dietary data may not accurately reflect long-term eating patterns. Other limitations of this study are that it only provides mean values of food intake rates, consumption is not normalized by body weight, and presentation of results is not consistent with EPA's recommended age groups. These data are based on older surveys and may not be entirely representative of current eating patterns, but may provide some historical perspective on intake of these foods.

12.3.2.4. *EPA Analysis of Continuing Survey of Food Intake by Individuals (CSFII) 1994–1996, 1998*

EPA/Office of Pesticide Programs, in cooperation with USDA's Agricultural Research Service, used data from the 1994–1996, 1998 CSFII to develop the FCID (U.S. EPA, 2000; USDA, 2000), as described in Section 12.3.1.1. The CSFII 1994–1996 was conducted between January 1994 and January 1997

with a target population of noninstitutionalized individuals in all 50 states and Washington, DC. In each of the 3 survey years, data were collected for a nationally representative sample of individuals of all ages. The CSFII 1998 was conducted between December 1997 and December 1998 and surveyed children 9 years of age and younger. It used the same sample design as the CSFII 1994–1996 and was intended to be merged with CSFII 1994–1996 to increase the sample size for children. The merged surveys are designated as CSFII 1994–1996, 1998 (USDA, 2000). Additional information on the CSFII can be obtained at <http://www.ars.usda.gov/Services/docs.htm?docid=14531>.

The CSFII 1994–1996, 1998 collected dietary intake data through in-person interviews on 2 nonconsecutive days. The data were based on 24-hour recall. A total of 21,662 individuals provided data for the first day; of those individuals, 20,607 provided data for a second day. The 2-day response rate for the 1994–1996 CSFII was approximately 76%. The 2-day response rate for CSFII 1998 was 82%. The CSFII 1994–1996, 1998 surveys were based on a complex multistage area probability sample design. The sampling frame was organized using 1990 U.S. population census estimates, and the stratification plan took into account geographic location, degree of urbanization, and socioeconomic characteristics. Several sets of sampling weights are available for use with the intake data. By using appropriate weights, data for all 4 years of the surveys can be combined. USDA has recommended that all 4 years be combined to provide an adequate sample size for children.

The grain items/groups selected for the EPA analysis included total grains and individual grain products, such as cereal and rice. EPA (2003) presents the food codes and definitions used to determine the various grain products used in the analysis. CSFII data on the foods people reported eating were converted to the quantities of agricultural commodities eaten. Intake rates for these food items/groups and summary statistics were generated on both a per capita and a consumer-only basis using the same general methodology as in the EPA analysis of 2003–2006 NHANES data, as described in Section 12.3.1.1. Because these data were developed for use in EPA's pesticide registration program, the childhood age groups used are slightly different from those recommended in EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005).

Table 12-13 presents per capita intake data for total grains in g/kg-day; Table 12-14 provides consumer-only intake data for total grains in g/kg-day.

Table 12-15 provides per capita intake data for individual grain products, and Table 12-16 provides consumer-only intake data for individual grain products. In general, these data represent intake of the edible portions of unprepared (i.e., uncooked) foods. Tables 12-17 through 12-24 present per capita intake data for individual grain products. The data come from CSFII 1994–1996 only. The results are presented in units of g/kg-day. These data represent as-consumed intake rates.

Because the results are presented in units of g/kg-day, the use of these data in calculating potential dose does not require the body-weight factor to be included in the denominator of the average daily dose equation. The cautions concerning converting these intake rates into units of g/day by multiplying by a single average body weight and the discussion of the use of short term data in the NHANES description in Section 12.3.1.1, apply to the CSFII estimates as well.

A strength of EPA's analysis is that it provides distributions of intake rates for various age groups of individuals, normalized by body weight. The analysis uses the 1994–1996, 1998 CSFII data set, which was designed to be representative of the U.S. population. Also, the data set includes 4 years of intake data combined and is based on a 2-day survey period. However, as discussed above, short-term dietary data may not accurately reflect long-term eating patterns and may under-represent infrequent consumers of a given food. This is particularly true for the tails (extremes) of the distribution of food intake. Also, the analysis was conducted using slightly different childhood age groups than those recommended in EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). However, given the similarities in the childhood age groups used, the data should provide suitable intake estimates for the age groups of interest. While the CSFII data are older than the NHANES data, they provide relevant information on consumption by season, region of the United States, and level of urbanization, breakdowns that are not available in the publically released NHANES data.

12.3.2.5. Smiciklas-Wright et al. (2002)—Foods Commonly Eaten in the United States: Quantities Consumed per Eating Occasion and in a Day, 1994–1996

Using data gathered in the 1994–1996 USDA CSFII, Smiciklas-Wright et al. (2002) calculated distributions for the quantities of grain products consumed per eating occasion by members of the U.S. population (i.e., serving sizes). The estimates of

serving size are based on data obtained from 14,262 respondents, ages 2 and above, who provided 2 days of dietary intake information. Only dietary intake data from users of the specified food were used in the analysis (i.e., consumer-only data). Table 12-25 presents, as consumed, the quantity of grain products consumed per eating occasion and the percentage of individuals using these foods in a 2-day period for a selected variety of grain products. Table 12-26 presents the same data by sex and age.

These data are presented on an as-consumed basis (grams) and represent the quantity of grain products consumed per eating occasion. These estimates may be useful for assessing acute exposures to contaminants in specific foods, or they may be used in other assessments where the amount consumed per eating occasion is necessary. Only the mean and standard deviation serving size data and percentage of the population consuming the food during the 2-day survey period are presented in this handbook. Percentiles of serving sizes of the foods consumed by these age groups of the U.S. population can be found in Smiciklas-Wright et al. (2002).

The advantages of using these data are that they were derived from the USDA CSFII and are representative of the U.S. population. The analysis conducted by Smiciklas-Wright et al. (2002) accounted for individual foods consumed as ingredients of mixed foods. Mixed foods were disaggregated via recipe files so that the individual ingredients could be grouped together with similar foods that were reported separately. Thus, weights of foods consumed as ingredients were combined with weights of foods reported separately to provide a more thorough representation of consumption. However, note that because the recipes for the mixed foods consumed were not provided by the respondents, standard recipes were used. As a result, the estimates of quantity consumed for some food types are based on assumptions about the types and quantities of ingredients consumed as part of mixed foods. This study used data from the 1994 to 1996 CSFII; data from the 1998 children's supplement were not included.

12.3.2.6. *Vitolins et al. (2002)—Quality of Diets Consumed by Older Rural Adults*

Vitolins et al. (2002) conducted a survey to evaluate the dietary intake, by food groups, of older (ages >70 years) rural adults. The sample consisted of 130 community-dwelling residents from two rural counties in North Carolina. Data on dietary intake over the preceding year were obtained in face-to-face interviews conducted in participants' homes, or in a

few cases, a senior center. The food frequency questionnaire used in the survey was a modified version of the National Cancer Institute Health Habits and History Questionnaire, which included an expanded food list containing a greater number of ethnic foods than the original food frequency form. Demographic and personal data collected included sex, ethnicity, age, education, denture use, marital status, chronic disease, and weight.

Food items reported in the survey were grouped into food groups similar to the USDA Food Guide Pyramid and the National Cancer Institute's 5 A Day for Better Health program. These groups are (1) fruits and vegetables; (2) bread, cereal, rice, and pasta; (3) milk, yogurt, and cheese; (4) meat, fish, poultry, beans, and eggs; and (5) fats, oils, sweets, and snacks. Medians, ranges, frequencies, and percentages were used to summarize intake of each food group, broken down by demographic and health characteristics. In addition, multiple regression models were used to determine which demographic and health factors were jointly predictive of intake of each of the five food groups.

Thirty-four percent of the survey participants were African-American, 36% were European American, and 30% were Native American. Sixty-two percent were female, 62% were not married at the time of the interview, and 65% had some high school education or were high school graduates. Almost all of the participants (95%) had one or more chronic diseases. Sixty percent of the respondents were between 70 and 79 years of age; the median age was 78 years old. Table 12-27 presents the median servings of bread, cereal, rice, and pasta broken down by demographic and health characteristic. Only sex was statistically predictive of bread, cereal, rice, and pasta intake ($p < 0.01$), with males consuming approximately an extra serving per day compared to women. Also, the multiple regression model indicated that sex was predictive of breads, cereal, rice, and pasta intake after controlling for other demographic variables.

One limitation of the study, as noted by the study authors, is that the study did not collect information on the length of time the participants had been practicing the dietary behaviors reported in the survey. The questionnaire asked participants to report the frequency of food consumption during the past year. The study authors noted that, currently, there are no dietary assessment tools that allow the collection of comprehensive dietary data over years of food consumption. Another limitation of the study is that the small sample size used makes associations by sex and ethnicity difficult.

12.3.2.7. *Fox et al. (2004)—Feeding Infants and Toddlers Study: What Foods Are Infants and Toddlers Eating*

Fox et al. (2004) used data from the Feeding Infants and Toddlers study (FITS) to assess food consumption patterns in infants and toddlers. The FITS was sponsored by Gerber Products Company and was conducted to obtain current information on food and nutrient intakes of children, ages 4 to 24 months, in the 50 states and the District of Columbia. The FITS is described in detail in Devaney et al. (2004). FITS was based on a random sample of 3,022 infants and toddlers for which dietary intake data were collected by telephone from their parents or caregivers between March and July 2002. An initial recruitment and household interview was conducted, followed by an interview to obtain information on intake based on 24-hour recall. The interview also addressed growth, development, and feeding patterns. A second dietary recall interview was conducted for a subset of 703 randomly selected respondents. The study over-sampled children in the age groups of 4 to 6 and 9 to 11 months; sample weights were adjusted for nonresponse, oversampling, and undercoverage of some subgroups. The response rate for the FITS was 73% for the recruitment interview. The recruited households had a response rate of 94% for the dietary recall interviews (Devaney et al., 2004).

Fox et al. (2004) analyzed the first set of 24-hour recall data collected from all study participants. For this analysis, children were grouped into six age categories: 4 to 6 months, 7 to 8 months, 9 to 11 months, 12 to 14 months, 15 to 18 months, and 19 to 24 months. Table 12-28 provides the percentage of infants and toddlers consuming different types of grains or grain products at least once per day. The percentages of children eating any type of grain or grain product ranged from 65.8% for 4- to 6-month-olds to 99.2% for 19- to 24-month-olds.

The advantages of this study is that it represents the U.S. population, and the sample size was large. One limitation of the analysis done by Fox et al. (2004) is that only frequency data were provided; no information on actual intake rates was included. In addition, Devaney et al. (2004) noted several limitations associated with the FITS data. For the FITS, a commercial list of infants and toddlers was used to obtain the sample used in the study. Because many of the households could not be located and did not have children in the target population, a lower response rate than would have occurred in a true national sample was obtained (Devaney et al., 2004). In addition, the sample was likely from a higher socioeconomic status when compared with all U.S.

infants in this age group (4 to 24 months old), and the use of a telephone survey may have omitted lower-income households without telephones (Devaney et al., 2004).

12.3.2.8. *Ponza et al. (2004)—Nutrient Food Intakes and Food Choices of Infants and Toddlers Participating in Women, Infants, and Children (WIC)*

Ponza et al. (2004) conducted a study using selected data from the FITS to assess feeding patterns, food choices, and nutrient intake of infants and toddlers participating in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). Ponza et al. (2004) evaluated FITS data for the following age groups: 4 to 6 months ($N = 862$), 7 to 11 months ($N = 1,159$), and 12 to 24 months ($N = 996$). Table 12-29 shows the total sample size described by WIC participants and nonparticipants.

The foods consumed were analyzed by tabulating the percentage of infants who consumed specific foods/food groups per day (Ponza et al., 2004). Weighted data were used in all of the analyses of the study (Ponza et al., 2004). Table 12-29 provides information on the food choices for the infants and toddlers studied. In general, there was little difference in grain product choices among WIC participants and nonparticipants, except for the 7- to 11-months age category (see Table 12-29). Nonparticipants, ages 7 to 11 months, were more likely to eat noninfant cereals than WIC participants.

An advantage of this study is that it had a relatively large sample size and was representative of the U.S. general population of infants and children. A limitation of the study is that intake values for foods were not provided. Other limitations are those associated with the FITS data, as described previously in Section 12.3.2.7.

12.3.2.9. *Fox et al. (2006)—Average Portion of Foods Commonly Eaten by Infants and Toddlers in the United States*

Fox et al. (2006) estimated average portion sizes consumed per eating occasion by children 4 to 24 months old who participated in the FITS. The FITS is a cross-sectional study designed to collect and analyze data on feeding practices, food consumption, and usual nutrient intake of U.S. infants and toddlers and is described in Section 12.3.2.7 of this chapter. It included a stratified random sample of 3,022 children between ages 4 and 24 months.

Using the 24-hour recall data, Fox et al. (2006) derived average portion sizes for six major food groups, including breads and grains. Average portion

sizes for select individual foods within these major groups were also estimated. For this analysis, infants were grouped into three age categories: 4 to 5 months, 6 to 8 months, and 9 to 11 months. Toddlers were also grouped into three age categories: 12 to 14 months, 15 to 18 months, and 19 to 24 months. Tables 12-30 and 12-31 present the average portion sizes for grain products for infants and toddlers, respectively.

The advantages and limitations described in Section 12.3.2.8 also apply here. These data represent portion size and not daily intake.

12.3.2.10. Mennella et al. (2006)—Feeding Infants and Toddlers Study: The Types of Foods Fed to Hispanic Infants and Toddlers

Mennella et al. (2006) investigated the types of food and beverages consumed by Hispanic infants and toddlers in comparison to the non-Hispanic infants and toddlers in the United States. The FITS 2002 data for children between 4 and 24 months of age were used for the study. The data represent a random sample of 371 Hispanic and 2,367 non-Hispanic infants and toddlers (Mennella et al., 2006). Mennella et al. (2006) grouped the infants as follows: 4 to 5 months ($N = 84$ Hispanic; 538 non-Hispanic), 6 to 11 months ($N = 163$ Hispanic; 1,228 non-Hispanic), and 12 to 24 months ($N = 124$ Hispanic; 871 non-Hispanic) of age.

Table 12-32 provides the percentage of Hispanic and non-Hispanic infants and toddlers consuming grain products. The overall percentages of Hispanic and non-Hispanic infants and toddlers consuming any type of grain product were similar, but there were differences in the individual types of grains products consumed. For example, 6-to 11-month-old Hispanic children were more likely to eat rice and pasta than non-Hispanic children in this age groups.

The advantage of the study is that it provides information on food preferences for Hispanic and non-Hispanic infants and toddlers. A limitation is that the study did not provide food intake data but provided frequency of use data instead. Other limitations are those noted previously in Section 12.3.2.7 for the FITS data.

12.3.2.11. Siega-Riz et al. (2010)—Food Consumption Patterns of Infants and Toddlers: Where are We Now?; Fox et al. (2010)—Food Consumption Patterns of Young Preschoolers: Are They Starting Off on the Right Path?; Deming et al. (2014)—Infant Feeding Practices and Consumption Patterns of Children Participating in WIC

In 2008, a second FITS study was conducted (Fox et al., 2010; Siega-Riz et al., 2010). The study population included 3,273 children ages 0 to 47.9 months. Siega-Riz et al. (2010) described the dietary consumption patterns of 1,596 infants (ages 4 to 5.9 months and 6 to 11.9 months) and toddlers (ages 12 to 23.9 months) in the 2008 FITS. As in the 2002 FITS, parents or primary caregivers of study participants were interviewed by telephone to collect demographic and dietary information (two 24-hour dietary recalls). Food group data were used to calculate the percentage of children who consumed specific foods or food groups at least once per day. Table 12-33 provides the percentage of infants and toddlers consuming grain and grain products at least once per day in 2008 (Siega-Riz et al., 2010). The percentage of infants and toddlers consuming any type of grain and grain products ranged from 52.0% for the 4- to 5.9-month age group to 99.2% for the 12- to 14.9-month age group (see Table 12-33).

Fox et al. (2010) presented similar data for 2- and 3-year-old children. The mean percentage of 2- and 3-year old children eating any type of grain or grain product in a day was 97.7% (see Table 12-33).

Deming et al. (2014) used the data for children 6–11, 12–23, and 24–47 months old from the 2008 FITS. The percentage of children consuming grains and grain products was estimated based on participation ($N = 794$) or nonparticipation ($N = 2,477$) in the WIC program (see Table 12–34). Overall consumption of total grains was similar among WIC participants and non-WIC participants, but some differences were observed for individual grain products, as shown in Table 12-34.

The limitations of these studies are that the FITS dietary data were reported as the percentage of the respondents consuming per day and not as amounts of grain and grain products consumed per day. However, useful information was provided for the consumption of grain and grain products by infants and toddlers.

12.3.2.12. Briefel et al. (2010)—The Feeding Infants and Toddlers Study 2008: Study Design and Methods

Briefel et al. (2010) used a subsample of the 2008 FITS data to estimate the amount of grain and grain products consumed per eating occasion among children ages 12 to 23.9 months. The data were collected as part of a “bridging” study aimed at testing the effects of changes made to the food model booklet and protocol since the 2002 FITS was conducted. A total of 123 children were included in the sample. Table 12-35 provides the mean amount consumed per eating occasion for 2008. On average, children ages 12 to 23.9 months consumed 41 g of grain and grain products per eating occasion. For individual grain products, portion size per eating occasion was greatest for non-infant cereals (52 g) followed by bread, rolls, biscuits, bagels and tortillas (23 g); and crackers, pretzels, and rice cakes (13 g).

The Briefel et al. (2010) study provides quantitative information on the amount of grain and grain products consumed by eating occasion; other FITS studies provide only percentages of the population eating certain foods. Because this study was based on a subsample of the study population, the sample size is relatively small.

12.3.2.13. Reicks et al. (2014)—Total Dietary Fiber Intakes in the U.S. Population Are Related to Whole Grain Consumption: Results from the National Health and Nutrition Examination Survey 2009 to 2010.

Reicks et al. (2014) used 1-day data from the 2009–2010 NHANES to evaluate relationships between whole grain intake and dietary fiber intake among children and adolescents (2–18 years of age), and adults (19 years and older). Survey respondents were categorized according to three groups based on their whole grain intake: none (0 ounce equivalents/day, low (>0 to <3 ounce equivalents/day), and high (≥3 ounce equivalents/day). Among children and adolescents, 38.8% had no whole grain intake, 58.3% were in the low intake group, and 2.9% were in the high intake group. Among adults, 41.9% had no whole grain intake, 50.4% were in the low intake group, and 7.7% were in the high intake group. The primary whole grain food sources among children were ready-to-eat cereals (25%) and yeast breads/rolls (24%), followed by oatmeal (12%), and popcorn (12%). Among adults, the primary whole grain food sources were yeast bread/rolls (27%), oatmeal (21%), and ready-to-eat cereals (20%). For all children and adolescents, the mean whole grain intake rate was 0.57

ounce equivalents/day, and for all adults, the mean whole grain intake rate was 0.82 ounce equivalents/day. Reicks et al. (2014) also observed that individuals in the high whole grain intake group had significantly greater total dietary fiber intake than those in the low or no whole grain intake groups.

This study provides intake data in ounce equivalents only. Data for children and adolescents represent ages 2 to 18 years, but data for finer age ranges are not provided. However, the study provides perspective on whole grain intake that is not provided in other studies summarized in this chapter.

12.3.3. Pregnant and Lactating Women

EPA estimated food intake rates for pregnant, lactating, and all women of child-bearing age (13 to <50 years) using data from NHANES for the years 2005 to 2010 and the FCID Consumption Calculator available at <http://fcid.foodrisk.org>, as described in Section 12.3.1.1. NHANES 2005–2010 collected data on dietary recall of foods eaten over the previous 24-hour period on 2 nonconsecutive days. Two-day data were available for 426 pregnant women, 101 lactating women, and 5,543 women of child-bearing age. EPA’s FCID was used to convert the NHANES “as eaten” food consumption data into consumption of individual grain commodities, as described in Section 12.3.1.1, and the data were weighted according to sampling weights provided for the years 2005 to 2010. Two-day average intake rates were calculated for each survey respondent for total grains, and for individual grain products. Summary statistics were calculated for the populations of pregnant women, lactating women, and women of child-bearing age on both a consumer-only and on a per capita basis. Table 12-36 provides summary statistics for per capita and consumer-only intake of total grains. Pregnant females were found to have higher mean consumption of total grains (160 g/day) than lactating (133 g/day), and all females of child-bearing age (131 g/day) on a g/day basis. However, the mean intake rate of total grains for pregnant females (2.2 g/kg-day) was similar to that of lactating (2.1 g/kg-day), and all females of child-bearing age (1.9 g/kg-day) when indexed to body weight (i.e., on a g/kg-day basis) (see Table 12-36). Mean, standard error, 95th percentile per capita, and consumer-only intake rates for individual grains are provided in Table 12-37.

As indicated in Section 12.3.1.1, an advantage of using the EPA’s analysis of NHANES data is that it was designed to be representative of the U.S. population. The data set used in this analysis used 6 years of intake data combined. However, the sample

sizes for pregnant and lactating women were relatively small and short-term dietary data may not accurately reflect long-term eating patterns and may under-represent infrequent consumers of a given food. This is particularly true for the tails (extremes) of the distribution of food intake.

Limited data are available on differences in food choices over the duration of pregnancy. Crozier et al. (2009) collected dietary data using a food frequency questionnaire for 2,270 women in early pregnancy (11.4-12.3 weeks gestation); 2,649 women in late pregnancy (34.3-34.9 weeks gestation); and 12,572 nonpregnant women in Southampton, U.K. Data on the consumption of 48 foods or food groups were collected. Crozier et al. (2009) observed that intake of white bread, breakfast cereals, cakes, and biscuits (cookies) increased during early pregnancy. Intake of 10 foods or food groups decreased, including rice and pasta (Crozier et al., 2009). Although these results indicate that grain intake rates may change over the course of pregnancy, the consumption patterns or food choices observed in this study may not be representative of pregnant women in the United States.

12.4. CONVERSION BETWEEN WET- AND DRY-WEIGHT INTAKE RATES

The intake data presented in this chapter are reported in units of wet weight (i.e., as-consumed or uncooked weight of grain products consumed per day or per eating occasion). However, data on the concentration of contaminants in grain products may be reported in units of either wet or dry weight (e.g., mg contaminant per gram dry weight of grain products). It is essential that exposure assessors be aware of this difference, so that they may ensure consistency between the units used for intake rates and those used for concentration data (i.e., if the contaminant concentration is measured in dry weight of grain products, then the dry-weight units should be used for their intake values).

If necessary, wet-weight (e.g., as consumed) intake rates may be converted to dry-weight intake rates using the moisture content percentages presented in Tables 12-38 or 12-39 and the following equation:

$$IR_{dw} = IR_{ww} \left[\frac{100 - W}{100} \right] \quad (\text{Eqn. 12-1})$$

where:

$$\begin{aligned} IR_{dw} &= \text{dry-weight intake rate,} \\ IR_{ww} &= \text{wet-weight intake rate, and} \\ W &= \text{percentage water content.} \end{aligned}$$

Alternatively, dry-weight residue levels in grain products may be converted to wet-weight residue levels for use with wet-weight (e.g., as consumed) intake rates as follows:

$$C_{ww} = C_{dw} \left[\frac{100 - W}{100} \right] \quad (\text{Eqn. 12-2})$$

where:

$$\begin{aligned} C_{ww} &= \text{wet concentration rate,} \\ C_{dw} &= \text{dry-weight concentration, and} \\ W &= \text{percentage water content.} \end{aligned}$$

The moisture data presented in Table 12-38 are for selected grain products taken from USDA (2007). Table 12-39 provides additional data on the water content of grain and grain products based on data from Popkin et al. (2010).

**Table12-3. Per Capita 2-Day Average^a Intake of Total Grains^b Based on 2005–2010 NHANES (g/kg-day, edible portion, uncooked weight)^c
(Continued)**

^a	Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption. Single day rates can be generated using http://fcid.foodrisk.org/ .
^b	Total Grains includes: amaranth, grain; barley, bran; barley, flour; barley, flour baby food; barley, pearled barley; barley, pearled barley baby food; buckwheat, flour; corn, field, bran; corn, field, flour; corn, field, flour baby food; corn, field, meal; corn, field, meal baby food; corn, field, starch; corn, field, starch baby food; corn, pop; corn, sweet; corn, sweet baby food; millet, grain; oat, bran; oat, flour; oat, flour baby food; oat, groats/rolled oats; oat, groats/rolled oats baby food; psyllium, seed; quinoa, grain; rice, bran; rice, bran baby food; rice, brown; rice, brown baby food; rice, flour; rice, flour baby food; rice, white; rice, white baby food; rye, flour; rye, grain; sorghum, grain; triticale, flour; triticale, flour baby food; wheat, bran; wheat, flour; wheat, flour baby food; wheat, germ; wheat, grain; wheat, grain baby food; wild rice.
^c	For more information, refer to the Frequently Asked Questions at http://fcid.foodrisk.org/ .
^d	Represents the percentage of individuals consuming grains at least once over the 2-day survey period. Rounded to whole numbers; thus, values of 100 percent mean that ≥99.5 percent of the population consumed the foods during the 2-day survey period.
^e	Estimates are less statistically reliable based on guidance published in the Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports:/HNIS/NCHS Analytical Working Group Recommendations (NCHS, 1993).
<i>N</i>	= Sample size.
SE	= Standard error.

Rye flour	0.7
Rice ^c	24
Total corn products ^d	29
Oat products ^e	8
Barley products ^f	0.9
Total flour and cereal products ^g	249
^a Original data were presented in lbs/year; data were converted to g/day by multiplying by a factor of 454 g/lb and dividing by 365 days/year. Consumption of most items at the processing level. Excludes quantities used in alcoholic beverages and fuel.	
^b Includes white, whole wheat, and durum flour.	
^c Milled basis.	
^d Includes corn flour and meal, hominy and grits, and corn starch.	
^e Includes rolled oats, ready-to-eat oat cereals, oat flour, and oat bran.	
^f Includes barley flour, pearl barley, and malt and malt extract used in food processing.	
^g Excludes wheat not ground into flour.	
Source: USDA (1999a).

^a	Based on data from 1994–1996, 1998 CSFII.										
^b	Includes yeast breads, rolls, cereals, pastas, quick breads, pancakes, French toast, cakes, cookies, pastries, pies, crackers, popcorn, pretzels, corn chips, and mixtures having a grain product as a main ingredient. Excludes grain products that were ingredients in food mixtures coded as a single item and tabulated under another food group; for example, noodles in tuna noodle casserole are tabulated under Meat, Poultry, and Fish.										
^c	Includes mixtures having a grain product as a main ingredient, such as burritos, tacos, pizza, egg rolls, quiche, spaghetti with sauce, rice and pasta mixtures; frozen meals in which the main course is a grain mixture; noodle and rice soups; and baby-food macaroni and spaghetti mixtures.										
^d	Estimate is not statistically reliable due to small sample size reporting intake.										
Note:	Consumption amounts shown are representative of the first day of each participant’s survey response.

^a Indicates a SE value that is greater than 0 but less than 0.5.

^b Indicates a statistic that is potentially unreliable because of small sample size or large coefficient of variation.

N = Sample size.

PC = Percent consuming at least once in 2 days.

SE = Standard error of the mean.

^a Point estimate is considered imprecise because of small sample size and uncommon or very common event.

^b Includes both ready-to-eat and cooked cereals.

^c Defined as cereals with more than 21.2 g sugar per 100 g.

^d Also includes biscuits, bagels, and tortillas.

^e Does not include bread and rolls in sandwiches. Sandwiches are included in mixed dishes.

^f Does not include rice or pasta in mixed dishes.

^g Includes dishes that are primarily grain; other mixed dishes that include grain in combination with protein and/or vegetables are reported elsewhere.

N = Sample size.

NR = Not reported.

^a	Per capita and consumer-only intake values are the same for pregnant and lactating women because 100% of these populations consumed total grains on at least one of the two survey days. For women of child-bearing age, the per capita and consumer-only values are virtually the same because 5,538 of the 5,543 women (99.9%) consumed grains on at least one of the two survey days. Small differences between the consumer-only and per capita rates were observed for these women only at the 1 st percentile where the consumer-only intake rates were estimated to be 21 g/day and 0.3 g/kg-day compared to per capita intake rates of 17 g/day and 0.2 g/kg-day, respectively, as shown in this table, and at the 25 th percentile where the consumer only rate is 1.2 g/kg-day compared to the per capita rate of 1.1 g/kg-day.														
^b	Based on the average of two days of food consumption reported for each NHANES respondent. If the respondent reported zero consumption on one of the two days and non-zero consumption on the other day, his/her average consumption would be the average of zero and non-zero consumption. Single day rates can be generated using http://fcid.foodrisk.org/ .														
^c	Total grains include: amaranth, grain; barley, bran; barley, flour; barley, flour baby food; barley, pearled barley; barley, pearled barley baby food; buckwheat; buckwheat, flour; corn, field, bran; corn, field, flour; corn, field, flour baby food; corn, field, meal; corn, field, meal baby food; corn, field, starch; corn, field, starch baby food; corn, pop; corn, sweet; corn, sweet baby food; millet, grain; oat, bran; oat, flour; oat, flour baby food; oat, groats/rolled oats; oat, groats/rolled oats baby food; psyllium, seed; quinoa, grain; rice, bran; rice, bran baby food; rice, brown; rice, brown baby food; rice, flour; rice, flour baby food; rice, white; rice, white baby food; rye, flour; rye, grain; sorghum, grain; triticale, flour; triticale, flour baby food; wheat, bran; wheat, flour; wheat, flour baby food; wheat, germ; wheat, grain; wheat, grain baby food; wild rice.														
^d	Represents the percentage of individuals consuming grains at least once over the 2-day survey period.														
^e	Estimates are less statistically reliable based on guidance published in the Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: HNIS/NCHS Analytical Working Group Recommendations (NCHS, 1993).														
N	= Sample size.														
SE	= Standard error.

SUPPLEMENTAL TABLES

CODES AND DEFINITIONS USED TO DETERMINE THE VARIOUS COMMODITIES USED IN THE EPA ANALYSIS OF WHAT WE EAT IN AMERICA (WWEIA)-FCID DATA

The EPA analyses of the National Health and Nutrition Examination Survey (NHANES) 2005–2010 food consumption data provided in the EPA’s Exposure Factors Handbook (EFH) was performed using the What We Eat in America Food Commodity Intake Database (WWEIA-FCID) (<http://fcid.foodrisk.org/>), which converted the WWEIA food items into FCID raw agricultural commodities using recipes developed by EPA. This supplement lists the FCID commodities used to generate statistics for corresponding foods and food categories as defined in the EFH.

Table C-1. Food Commodity Codes and Definitions Used in Analysis of the 2005–2010 (and 2003–2008) NHANES WWEIA				
EFH Food Category	EPA Food Commodity Codes			
Grains	1500025000	Barley, pearled barley	1500323000	Rice, white
	1500025001	Barley, pearled barley baby food	1500323001	Rice, white baby food

Chapter 13—Intake of Home-Produced Foods

13. INTAKE OF HOME-PRODUCED FOODS**13.1. INTRODUCTION**

Ingestion of home-produced foods can be a pathway for exposure to environmental contaminants. Home-produced foods can become contaminated in various ways. Ambient pollutants in the air may be deposited on plants, adsorbed onto or absorbed by the plants, or dissolved in rainfall or irrigation waters that contact the plants. Pollutants also may be adsorbed onto plant roots from contaminated soil and water. Finally, the addition of pesticides, soil additives, and fertilizers to crops or gardens may result in contamination of food products. Meat and dairy products can become contaminated if animals consume contaminated soil, water, or feed crops. Farmers, as well as rural and urban residents who consume home-produced foods, may be potentially exposed if these foods become contaminated. Exposure via the consumption of home-produced foods may be a significant route of exposure for these populations [U.S. Environmental Protection Agency (EPA) (1996, 1989)]. For example, consumption of home-produced fruits, vegetables, game, and fish has been shown to have an effect on blood lead levels in areas where soil lead contamination exists (U.S. EPA, 1994). At Superfund sites where soil contamination is found, ingestion of home-produced foods has been considered a potential route of exposure (U.S. EPA, 1993, 1991). Assessing exposures to individuals who consume home-produced foods requires knowledge of intake rates of such foods.

Data from the 1987–1988 Nationwide Food Consumption Survey (NFCS) were used to generate intake rates for home-produced foods. The methods used to analyze the 1987–1988 NFCS data are presented in Section 13.3.

13.2. RECOMMENDATIONS

The data presented in this section may be used to assess exposure to contaminants in foods grown, raised, or caught at a specific site. Table 13-1 presents the recommended values for mean and upper percentile (i.e., 95th percentile) intake rates among consumers of the various home-produced food groups. The consumer-only data presented represent average daily intake rates of food items/groups over the 7-day survey period and do not account for variations in eating habits during the rest of the year. Thus, the recommended upper-percentile values, as well as the percentiles of the distributions presented in Section 13.3.1 may not necessarily reflect the long-term distribution of average daily intake of home-produced foods. Table 13-1 also provides

mean and 95th percentile per capita intake rates for populations that garden, farm, or raise animals. Table 13-2 presents the confidence ratings for home-produced food intake.

Because the consumer-only home-produced food intake rates presented in this chapter (See Section 13.3.1) are based on foods as brought into the household and not in the form in which they are consumed, preparation loss factors should be applied as appropriate. These factors are necessary to convert intake rates to those that are representative of foods “as consumed.” The per capita data presented in this chapter (See Section 13.3.2) account for preparation and post-cooking losses. Additional conversions may be necessary for both consumer-only and per capita data to ensure that the form of the food used to estimate intake (e.g., wet or dry weight) is consistent with the form used to measure contaminant concentration (see Section 13.3).

The NFCS data used to generate intake rates of home-produced foods are more than 20 years old and may not be reflective of current eating patterns among consumers of home-produced foods. Although the U.S. Department of Agriculture (USDA) and others have conducted other food consumption studies since the release of the 1987–1988 NFCS, these studies do not include information on home-produced foods.

Because the consumer-only analysis was conducted prior to the issuance of EPA’s *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005), the age groups used are not entirely consistent with recent guidelines. Also, recommended home-produced food intake rates are not provided for children less than 1 year of age because the methodology used is based on the apportionment of home-produced foods used by a household among the members of that household who consume those foods. It was assumed that the diets of children under 1 year of age differ markedly from that of other household members; thus, they were not assumed to consume any portion of the home-produced food brought into the home.

Chapter 13—Intake of Home-Produced Foods

Table 13-2. Confidence in Recommendations for Intake of Home-Produced Foods

General Assessment Factors	Rationale	Rating
Soundness		Medium (Means) Low (Distributions)
<i>Adequacy of Approach</i>	The NFCS survey methodology and the approach to data analysis were adequate, but individual intakes were inferred from household consumption data. The sample size was large (approximately 10,000 individuals).	
<i>Minimal (or Defined) Bias</i>	Non-response bias cannot be ruled out due to low response rate. Also, some biases may have occurred from using household data to estimate individual intake.	
Applicability and Utility		Low (Means and short-term distributions) Low (Long-term distributions)
<i>Exposure Factor of Interest</i>	The U.S. EPA analysis of the NFCS data specifically addressed home-produced intake.	
<i>Representativeness</i>	Data from a nationwide survey, representative of the general U.S. population was used.	
<i>Currency</i>	The data were collected in 1987–1988.	
<i>Data Collection Period</i>	Household data were collected over 1 week.	
Clarity and Completeness		High
<i>Accessibility</i>	The methods used to analyze the data are described in detail in this handbook; the primary data are accessible through USDA.	
<i>Reproducibility</i>	Sufficient details on the methods used to analyze the data are presented to allow the results to be reproduced.	
<i>Quality Assurance</i>	Quality assurance of NFCS data was good; quality control of the secondary data was sufficient.	
Variability and Uncertainty		Low to Medium
<i>Variability in Population</i>	Full distributions of home-produced intake rates were provided in the NFCS analysis. Phillips and Moya (2012) presented mean and 95 th percentile values.	
<i>Uncertainty</i>	Sources of uncertainty include: individuals' estimates of food weights, allocation of household food to family members, and potential changes in eating patterns since these data were collected.	
Evaluation and Review		Medium
<i>Peer Review</i>	The study was reviewed by USDA and EPA.	
<i>Number and Agreement of Studies</i>	There was one key study that described the primary analysis of NFCS data and 1 key study that described a secondary analysis of the NFCS home-produced data.	
Overall Rating		Low to Medium (Means and short-term distributions) Low (Long-term distributions)

Chapter 13—Intake of Home-Produced Foods

13.3. KEY STUDY FOR INTAKE OF HOME-PRODUCED FOODS**13.3.1. U.S. EPA Analysis of NFCS 1987–1988; Moya and Phillips (2001) Analysis of Consumption of Home-Produced Foods**

U.S. EPA's National Center for Environmental Assessment (NCEA) analyzed USDA's 1987–1988 NFCS data to generate intake rates for home-produced foods. In addition, Moya and Phillips (2001) present a summary of these analyses. For the purposes of this study, home-produced foods were defined as home-produced fruits and vegetables, meat and dairy products derived from consumer-raised livestock or game meat, and home-caught fish.

Until 1988, USDA conducted the NFCS every 10 years to analyze the food consumption behavior and dietary status of Americans (USDA, 1992). While more recent food consumption surveys have been conducted to estimate food intake among the general population (e.g., USDA's Continuing Survey of Food Intake by Individuals [CSFII] and the National Health and Nutrition Examination Survey [NHANES]), these surveys have not collected data that can be used to estimate consumption of home-produced foods. Thus, the 1987–1988 NFCS data set is currently the best available source of information for this factor.

The 1987–1988 NFCS was conducted between April 1987 and August 1988. The survey used a statistical sampling technique designed to ensure that all seasons, geographic regions of the 48 conterminous states in the United States, and socioeconomic and demographic groups were represented (USDA, 1994). There were two components of the NFCS. The household component collected information over a 7-day period on the socioeconomic and demographic characteristics of households, as well as the types, amount, value, and sources of foods consumed by the household (USDA, 1994). Meanwhile, the individual intake component collected information on food intakes of individuals within each household over a 3-day period (USDA, 1993). The sample size for the 1987–1988 survey was approximately 4,300 households (more than 10,000 individuals; approximately 3,000 children). This was a decrease from the previous survey conducted in 1977–1978, which sampled approximately 15,000 households (more than 36,000 individuals) (USDA, 1994). The sample size was lower in the 1987–1988 survey as a result of budgetary constraints and low response rate [38% for the household survey and 31% for the individual survey; USDA (1993)].

The USDA data were adjusted by applying

sample weights calculated by USDA to the data set prior to analysis. The USDA sample weights were designed to “adjust for survey non-response and other vagaries of the sample selection process” (USDA, 1988). Also, the USDA weights are calculated “so that the weighted sample total equals the known population total, in thousands, for several characteristics thought to be correlated with eating behavior” (USDA, 1988).

The food groups selected for analysis of home-produced food intake included major food groups (i.e., total fruits, total vegetables, total meats, total dairy, total fish and shellfish) and individual food items for which greater than 30 households reported eating the home-produced form of the item; fruits and vegetables categorized as exposed, protected, and roots; and various USDA fruit and vegetable subcategories (e.g., dark green vegetables, citrus fruits). These food groups were identified in the NFCS data base according to NFCS-defined food codes. Appendix 13A presents the codes and definitions used to determine the major food groups. Foods with these codes, for which the source was identified as home-produced, were included in the analysis. The codes and definitions for individual items in these food groups, as well as other subcategories (e.g., exposed, protected, dark green, citrus) considered to be home-produced are in Appendix 13B.

Although the individual intake component of the NFCS gives the best measure of the amount of each food group eaten by each individual in the household, it could not be used directly to measure consumption of home-produced food because the individual component does not identify the source of the food item (i.e., as home-produced or not). Therefore, an analytical method that incorporated data from both the household and individual survey components was developed to estimate individual home-produced food intake.

The household data were used to determine (1) the amount of each home-produced food items used during a week by household members, and (2) the number of meals eaten in the household by each household member during a week. Note that the household survey reports the total amount of each food item used in the household (whether by guests or household members); the amount used by household members was derived by multiplying the total amount used in the household by the proportion of all meals served in the household (during the survey week) that were consumed by household members. The individual survey data were used to generate average sex- and age-specific serving sizes for each food item. The age categories used in the

Chapter 13—Intake of Home-Produced Foods

analysis were as follows: 1 to 2 years, 3 to 5 years, 6 to 11 years, 12 to 19 years, 20 to 39 years, 40 to 69 years, and 70 years and older (intake rates were not calculated for children under 1 year of age; the rationale for this is discussed after equation 13-1). The serving sizes were used during subsequent analyses to generate home-produced food intake rates for individual household members. Assuming that the proportion of the household quantity of each home-produced food item/group was a function of the number of meals and the mean sex- and age-specific serving size for each family member, individual intakes of home-produced food were calculated for all members of the survey population using the following general equation:

$$w_i = w_f \left[\frac{m_i q_i}{\sum_{i=1}^n m_i q_i} \right] \quad (\text{Eqn. 13-1})$$

where:

- w_i = Home-produced amount of food item/group attributed to member i during the week (g/week),
- w_f = Total quantity of home-produced food item/group used by the family members (g/week),
- m_i = Number of meals of household food consumed by member i during the week (meals/week), and
- q_i = Serving size for an individual within the age and sex category of the member (g/meal).

Daily intake of a home-produced food group was determined by dividing the weekly value (w_i) by 7. Intake rates were indexed to the self-reported body weight of the survey respondent and reported in units of g/kg-day. Intake rates were not calculated for children less than 1 year of age because their diet differs markedly from that of other household members, and, thus, the assumption that all members share all foods would be invalid for this age group.

For the major food groups (i.e., fruits, vegetables, meats, dairy, and fish) and individual foods consumed by at least 30 households, distributions of home-produced intake among consumers were generated for the entire data set and for the following

subcategories: age groups, urbanization categories, seasons, racial classifications, regions, and responses to a questionnaire.

Consumers were defined as members of survey households who reported consumption of the food item/group of interest during the 1-week survey period.

In addition, for the major food groups, distributions were generated for each region by season, urbanization, and responses to the questionnaire. Table 13-3 presents the codes, definitions, and a description of the data included in each of the subcategories. Intake rates were not calculated for food items/groups for which less than 30 households reported home-produced usage because the number of observations may be inadequate for generating distributions that would be representative of that segment of consumers. Fruits and vegetables were also classified as exposed, protected, or roots, as shown in Appendix 13B. *Exposed foods* are those that are grown above ground and are likely to be contaminated by pollutants deposited on surfaces of the foods that are eaten. *Protected products* are those that have outer protective coatings that are typically removed before consumption.

Distributions of intake were tabulated for these food classes for the same subcategories listed previously. Distributions were also tabulated for the following USDA food classifications: dark green vegetables, deep yellow vegetables, other vegetables, citrus fruits, and other fruits. Finally, the percentages of total intake of the food items/groups consumed within survey households that can be attributed to home production were tabulated. The percentage of intake that was home-produced was calculated as the ratio of total intake of the home-produced food item/group by the survey population to the total intake of all forms of the food by the survey population.

Percentiles of average daily intake derived from short-time intervals (e.g., 7 days) will not, in general, be reflective of long-term patterns. This is especially true in regards to consumption of many home-produced products (e.g., fruits, vegetables), where a strong seasonal component often is associated with their use. For the major food categories, to try to derive the long-term distribution of average daily intake rates from the short-term data available here, an approach was developed that attempted to account for seasonal variability in consumption. This approach used regional “seasonally adjusted distributions” to approximate regional long-term distributions and then combined these regional adjusted distributions (in proportion to

Chapter 13—Intake of Home-Produced Foods

the weights for each region) to obtain a U.S. adjusted distribution that approximated the U.S. long-term distribution. See Moya and Phillips (2001) for details.

The percentiles of the seasonally adjusted distribution for a given region were generated by averaging the corresponding percentiles of each of the four seasonal distributions of the region. More formally, the seasonally adjusted distribution for each region is such that its inverse cumulative distribution function is the average of the inverse cumulative distribution functions of each of the seasonal distributions of that region. The use of regional seasonally adjusted distributions to approximate regional long-term distributions is based on the assumption that each individual consumes the same regional percentile levels for each season and consumes at a constant weekly rate throughout a given season. For instance, if the 60th percentile weekly intake level in the South is 14.0 grams in the summer and 7.0 grams in each of the three other seasons, then the individual in the South with an average weekly intake of 14.0 grams during the summer is assumed to have an intake of 14.0 grams for each week of the summer and an intake of 7.0 grams for each week of the other seasons.

Note that the seasonally adjusted distributions were generated using the overall distributions (i.e., both consumers and non-consumers). However, because all the other distributions presented in this section are based on consumers only, the percentiles for the adjusted distributions have been revised to reflect the percentiles among consumers only. Given the assumption about how each individual consumes, the percentage consuming for the seasonally adjusted distributions gives an estimate of the percentage of the population consuming the specified food category at any time during the year.

The intake data presented in this chapter for consumers of home-produced foods and the total number of individuals surveyed may be used to calculate the mean and the percentiles of the distribution of home-produced food consumption in the overall population (consumers and non-consumers) as follows:

Assuming that IR_p is the home-produced intake rate of the food group at the p^{th} percentile and N_c is the weighted number of individuals consuming the home-produced food item, and N_T is the weighted total number of individuals surveyed, then $N_T - N_c$ is the weighted number of individuals who reported zero consumption of the food item. In addition, there are $(p / 100 \times N_c)$ individuals below the p^{th} percentile. Therefore, the percentile that corresponds to a particular intake rate (IR_p) for the overall distribution of home-produced food consumption (including

consumers and non-consumers) can be obtained by:

$$p_{\text{overall}}^{\text{th}} = 100 \times \frac{\left(\frac{p}{100} \times N_c + (N_T - N_c) \right)}{N_T} \quad (\text{Eqn. 13-2})$$

For example, the percentile of the overall population that is equivalent to the 50th percentile consumer-only intake rate for home-produced fruits would be calculated as follows:

From Table 13-5, the 50th percentile home-produced fruit intake rate (IR_{50}) is 1.07 g/kg-day. The weighted number of individuals consuming fruits (N_c) is 14,744,000. From Table 13-4, the weighted total number of individuals surveyed (N_T) is 188,019,000. The number of individuals consuming fruits below the 50th percentile is

$$p / 100 \times N_c = (0.5) \times (14,744,000) \\ = 7,372,000$$

The number of individuals that did not consume fruit during the survey period is

$$N_T - N_c = 188,019,000 - 14,744,000 \\ = 173,275,000$$

The total number of individuals with home-produced intake rates at or below 1.07 g/kg-day is

$$(p / 100 \times N_c) + (N_T - N_c) = 7,372,000 \\ + 173,275,000 \\ = 180,647,000$$

The percentile of the overall population that is represented by this intake rate is

$$p_{\text{overall}}^{\text{th}} = 100 \times (180,647,000 / 188,019,000) \\ 96^{\text{th}} \text{ percentile}$$

Therefore, an intake rate of 1.07 g/kg-day of home-produced fruit corresponds to the 96th percentile of the overall population.

Chapter 13—Intake of Home-Produced Foods

Following this same procedure, 5.97 g/kg-day, which is the 90th percentile of the consumers-only population, corresponds to the 99th percentile of the overall population. Likewise, 0.063 g/kg-day, which is the 1st percentile of the consumers-only population, corresponds to the 92nd percentile of the overall population. Note that the consumers-only distribution corresponds to the tail of the distribution for the overall population. Consumption rates below the 92nd percentile are very close to zero. The mean intake rate for the overall population can be calculated by multiplying the mean intake rate among consumers by the proportion of individuals consuming the home-produced food item N_c / N_T .

Table 13-4 displays the weighted numbers N_T and the unweighted total survey sample sizes for each subcategory and overall. Note that the total unweighted number of observations in Table 13-4 (9,852) is somewhat lower than the number of observations reported by USDA; this study only used observations for family members for which age and body weight were specified.

The intake rate distributions (among consumers) for total home-produced fruits, vegetables, meats, fish, and dairy products are shown, respectively, in Table 13-5 through Table 13-29. These tables also show the proportion of respondents consuming the item during the (1-week) survey period. Home-produced vegetables were the most commonly consumed of the major food groups (18.3%), followed by fruit (7.8%), meat (4.9%), fish (2.1%), and dairy products (0.7%). The intake rates for the major food groups varied according to region, age, urbanization code, race, and responses to survey questions. In general, intake rates of home-produced foods were higher among populations in non-metropolitan and suburban areas and lowest in central city areas. Results of the regional analyses indicate that intake of home-produced fruits, vegetables, meat, and dairy products was generally highest for individuals in the Midwest and South regions and lowest for those in the Northeast region. Intake rates of home-caught fish were generally highest among consumers in the South. Home-produced intake was generally higher among individuals who indicated that they operate a farm, grow their own vegetables, raise animals, and catch their own fish. The results of the seasonal analyses for all regions combined indicate that, in general, home-produced fruits and vegetables were eaten at a higher rate in summer and home-caught fish was consumed at a higher rate in spring; however, seasonal intake varied based on individual regions. Table 13-30 presents seasonally adjusted intake rate distributions for the major food groups.

Table 13-31 through Table 13-57 show distributions of intake for individual home-produced food items for households that reported consuming the home-produced form of the food during the survey period. Intake rate distributions among consumers for home-produced foods categorized as exposed fruits and vegetables, protected fruits and vegetables, and root vegetables are presented in Table 13-58 through Table 13-62; the intake distributions for various USDA classifications (e.g., dark green vegetables) are presented in Table 13-63 through Table 13-67. The results are presented in units of g/kg-day. Table 13-68 presents the fraction of household intake attributed to home-produced forms of the food items/groups evaluated. Thus, use of these data in calculating potential dose does not require the body-weight factor to be included in the denominator of the average daily dose in equation 1-2 in Chapter 1. Note that converting these intake rates into units of g/day by multiplying by a single average body weight is inappropriate, because individual intake rates were indexed to the reported body weights of the survey respondents.

As mentioned previously, the intake rates derived in this section are based on the amount of household food consumption. As measured by the NFCS, the amount of food consumed by the household is a measure of consumption in an economic sense (i.e., a measure of the weight of food brought into the household that has been consumed [used up] in some manner). In addition to food being consumed by persons, food may be used up by spoiling, by being discarded (e.g., inedible parts), through cooking processes, and other methods.

USDA estimated preparation losses for various foods (USDA, 1975). For meats, a net cooking loss, which includes dripping and volatile losses, and a net post-cooking loss, which involves losses from cutting, bones, excess fat, scraps and juices, were derived for a variety of cuts and cooking methods. For each meat type, U.S. EPA has averaged these losses across all cuts and cooking methods to obtain a mean net cooking loss and a mean net post-cooking loss. Table 13-69 provides mean percentage values for all meats and fish. For individual fruits and vegetables, USDA (1975) also gave cooking and post-cooking losses. These data, averaged across all types of fruits and vegetables to give mean net cooking and post-cooking losses, also are provided in Table 13-69.

The formula presented in equation 13-3 can be used to convert the home-produced intake rates tabulated here to rates reflecting actual consumption:

Chapter 13—Intake of Home-Produced Foods

$$I_A = I \times (1 - L_1) \times (1 - L_2) \quad (\text{Eqn. 13-3})$$

where:

- I_A = the adjusted intake rate,
- I = the tabulated intake rate,
- L_1 = the cooking or preparation loss, and
- L_2 = the post-cooking loss.

Corrections based on post-cooking losses only apply to fruits that are eaten in cooked forms. For raw forms of the fruits, paring or preparation loss data should be used to correct for losses from the removal of skin, peel, core, caps, pits, stems, and defects, or from the draining of liquids from canned or frozen forms. To obtain preparation losses for food categories, the preparation losses of the individual foods making up the category can be averaged.

In calculating ingestion exposure, assessors should use consistent forms (e.g., as consumed or dry weight) in combining intake rates with contaminant concentrations (see Chapter 9).

The USDA NFCS data set is the largest publicly available source of information on home-produced food consumption habits in the United States. The advantages of using this data set are that it is expected to be representative of the U.S. population and that it provides information on a wide variety of food groups. However, the data collected by the USDA NFCS are based on short-term dietary recall, and the intake distributions generated from this data set may not accurately reflect long-term intake patterns, particularly with the tails (extremes) of the distributions. Also, the two survey components (i.e., household and individual) do not define food items/groups in a consistent manner; as a result, some errors may be introduced into these analyses because the two survey components are linked. The results presented in this chapter also may be biased by assumptions that are inherent in the analytical method utilized. The analytical method may not capture all high-end consumers within households because average serving sizes are used in calculating the proportion of home-produced food consumed by each household member. Thus, for instance, in a two-person household in which one member had high intake and another had low intake, the method used would assume that both members had an equal and moderate level of intake. In addition, the analyses assume that all family members consume a portion of the home-produced food used within the household. However, not all family members may consume each home-produced food item, and serving sizes allocated

in this instance may not be entirely representative of the portion of household foods consumed by each family member. As was mentioned earlier, no analyses were performed for children under 1 year of age.

The preparation loss factors discussed previously are intended to convert intake rates based on “household consumption” to rates reflective of what individuals actually consume. However, these factors do not include losses to spoilage, feeding to pets, food thrown away, and other methods. It also should be noted that because this analysis is based on the 1987–1988 NFCS, it may not reflect recent changes in food consumption patterns. The low response rate associated with the 1987–1988 NFCS also contributes to the uncertainty of the home-produced intake rates generated using these data.

13.3.2. Phillips and Moya (2012)—Estimation of Age-Specific Per Capita Home-Produced Food Intake Among Populations That Garden, Farm, or Raise Animals

Phillips and Moya (2012) used the consumer intake data for home-produced fruits, vegetables, meats, and dairy products from the analysis described in Section 13.3.1 to estimate per capita intake rates for the populations that garden, farm, or raise animals. The consumer-only intake values in Section 13.3.1 are based on short-term dietary survey data and may be appropriate for estimating short-term intake, but may over-estimate exposure over longer time periods. Also, the intake rates in Section 13.3.1 represent intake of foods brought into the household and have not been adjusted to account for preparation losses and post-cooking losses. Phillips and Moya (2012) converted the distribution of consumer-only intake rates for populations that garden, farm, and raise animals to the distribution of per capita rates using equation 13-2 and adjusted these data to account for preparation losses and post-cooking losses using equation 13-3. Data for households that garden, farm, or raise animals were used because they were assumed to represent both households who ate home-produced foods during the survey period as well as those who did not eat home-produced foods during the survey period, but may eat these foods at some other time during the year. Also, the data in Section 13.3.1 for the populations that garden, farm, or raise animals are not provided by age group, but represent data for all ages of the survey population combined. Phillips and Moya (2012) calculated age-specific intake rates using ratios of age-specific dietary intake to total population intake rates, based on survey data for intake of total fruits, vegetables,

Chapter 13—Intake of Home-Produced Foods

meats, and dairy from all sources (i.e., both home-produced and commercial sources) from the 1994-1996, 1998 CSFII, as described in Chapters 9 and 11. The age groups used are those recommended in U.S. EPA (2005). Age-specific intake mean and 95th percentile intake rates were estimated as: age-specific ratio \times mean (or 95th percentile) per capita intake for the total population, where the age-specific ratio = age-specific mean per capita total intake (g/kg-day)/ total population mean per capita total intake (g/kg-day). Table 13-70 provides the both the adjusted and unadjusted estimated mean and 95th per-capita intake rates for the total populations that garden, farm, and raise animals. Table 13-70 also provides age-specific per capita intake rates based on data that have been adjusted to account for preparation and post-cooking losses.

The advantages of this analysis are that it provides data for populations that may be of particular interest because they may represent the high-end of the per capita home-produced food intake distribution (Phillips and Moya, 2012), and that age-specific intake rates are provided for the age groups recommended by U.S. EPA (2005). However, it should be noted that these estimates are based on data that are more than 20 years old and may not reflect recent changes in consumption patterns. Also, the data for children less than 1 year of age are considered to be less certain than for other age groups because the diets of children in this age range would be expected to be highly variable (Phillips and Moya, 2012). Other limitations associated with this analysis are the same as those described in Section 13.3.1 for the analysis of the NFCS data.

13.4. RELEVANT STUDY FOR INTAKE OF HOME-PRODUCED FOODS

13.4.1. National Gardening Association (2009)

According to a survey by the National Gardening Association (2009), an estimated 36 million (or 31%) of U.S. households participated in food gardening in 2008. Food gardening includes growing vegetables, berries, fruit, and herbs. Of the estimated 36 million food-gardening households, 23% participated in vegetable gardening, 12% participated in herb gardening, 10% participated in growing fruit trees, and 6% grew berries. Table 13-71 contains demographic data on food gardening in 2008 by sex, age, education, household income, and household size. Table 13-72 contains information on the types of vegetables grown by home gardeners in 2008. Tomatoes, cucumbers, peppers, beans, carrots, summer squash, onions, lettuce, peas, and corn are among the vegetables grown by the largest

percentage of gardeners.

Table 13-3. Subcategory Codes, Definitions, and Descriptions

Code	Definition	Description
Region ^a		
1	Northeast	Includes Connecticut, Maine, Massachusetts, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, and Vermont.
2	Midwest	Includes Illinois, Indiana, Iowa, Kansas, Michigan, Minnesota, Missouri, Nebraska, North Dakota, Ohio, South Dakota, and Wisconsin.
3	South	Includes Alabama, Arkansas, Delaware, District of Columbia, Florida, Georgia, Kentucky, Louisiana, Maryland, Mississippi, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, Virginia, and West Virginia.
4	West	Includes Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, Utah, Washington, and Wyoming.
Urbanization		
1	Central City	Cities with populations of 50,000 or more that is the main city within the metropolitan statistical area (MSA).
2	Suburban	An area that is generally within the boundaries of an MSA but is not within the legal limit of the central city.
3	Non-metropolitan	An area that is not within an MSA.
Race		
1	--	White (Caucasian)
2	--	Black
3	--	Asian and Pacific Islander
4	--	Native American, Aleuts, and Eskimos
5, 8, 9	Other/NA	Don't know, no answer, some other race
Responses to Survey Questions		
Grow	Question 75	Did anyone in the household grow any vegetables or fruit for use in the household?
Raise Animals	Question 76	Did anyone in the household produce any animal products such as milk, eggs, meat, or poultry for home use in your household?
Fish/Hunt	Question 77	Did anyone in the household catch any fish or shoot game for home use?
Farm	Question 79	Did anyone in the household operate a farm or ranch?
Season		
Spring	-	April, May, June
Summer	-	July, August, September
Fall	-	October, November, December
Winter	-	January, February, March
^a Alaska and Hawaii were not included. Source: USDA (1988).

Chapter 13—Intake of Home-Produced Foods

Table 13-69. Percent Weight Losses From Food Preparation		
Food Group	Mean Net Preparation/Cooking Loss (%)	Mean Net Post Cooking (%)
Meats ^a	29.7 ^b	29.7 ^c
Fish and shellfish ^d	31.5 ^b	10.5 ^c
Fruits	25.4 ^e	30.5 ^f
Vegetables ^g	12.4 ^h	22 ⁱ
^a	Averaged over various cuts and preparation methods for various meats including beef, pork, chicken, turkey, lamb, and veal.	
^b	Includes dripping and volatile losses during cooking.	
^c	Includes losses from cutting, shrinkage, excess fat, bones, scraps, and juices.	
^d	Averaged over a variety of fish and shellfish to include bass, bluefish, butterfish, cod, flounder, haddock, halibut, lake trout, mackerel, perch, porgy, red snapper, rockfish, salmon, sea trout, shad, smelt, sole, spot, squid, swordfish steak, trout, whitefish, clams, crab, crayfish, lobster, oysters, and shrimp and shrimp dishes.	
^e	Based on preparation losses. Averaged over apples, pears, peaches, strawberries, and oranges. Includes losses from removal of skin or peel, core or pit, stems or caps, seeds, and defects. Also includes losses from removal of drained liquids from canned or frozen forms.	
^f	Averaged over apples and peaches. Include losses from draining cooked forms.	
^g	Averaged over various vegetables to include asparagus, beets, broccoli, cabbage, carrots, corn, cucumbers, lettuce, lima beans, okra, onions, green peas, peppers, pumpkins, snap beans, tomatoes, and potatoes.	
^h	Includes losses due to paring, trimming, flowering the stalk, thawing, draining, scraping, shelling, slicing, husking, chopping, and dicing and gains from the addition of water, fat, or other ingredients.	
ⁱ	Averaged over various preparation methods. Includes losses from draining or removal of skin. Based on potatoes only.

^a	Calculated as: per capita home-produced intake for total population of households that garden, farm, or raise animals (See Section 13.3.1), times age-specific ratio of mean per capita total intake to mean per capita total intake for total population, based on analysis of 1994–96 and 1998 CSFII data (See Chapters 9 and 11).															
^b	Not adjusted for food preparation or post-cooking losses.															
^c	Adjusted to account for food preparation and post-cooking losses; no adjustments made to dairy.															
^d	Estimates are uncertain for this age group because of the wide range of intake patterns for children under 1 year of age.

	493- Fresh Tomatoes	722- Dark Green Non-Leafy Veg.
	4941- Fresh Asparagus	74- Tomatoes and Tomato Mixtures
	4943- Fresh Beans, Snap or Wax	7510050 Alfalfa Sprouts
	4944- Fresh Cabbage	7510075 Artichoke, Jerusalem, raw
	4945- Fresh Lettuce	7510080 Asparagus, raw
	4946- Fresh Okra	75101- Beans, sprouts and green, raw
	49481- Fresh Artichokes	7510275 Brussel Sprouts, raw
	49483- Fresh Brussel Sprouts	7510280 Buckwheat Sprouts, raw
	4951- Fresh Celery	7510300 Cabbage, raw
	4952- Fresh Cucumbers	7510400 Cabbage, Chinese, raw
	4955- Fresh Cauliflower	7510500 Cabbage, Red, raw
	4958103 Fresh Kohlrabi	7510700 Cauliflower, raw
	4958111 Fresh Jerusalem Artichokes	7510900 Celery, raw
	4958112 Fresh Mushrooms	7510950 Chives, raw
	4958113 Mushrooms, home canned	7511100 Cucumber, raw
	4958114 Mushrooms, home frozen	7511120 Eggplant, raw
	4958118 Fresh Eggplant	7511200 Kohlrabi, raw
	4958119 Eggplant, cooked	75113- Lettuce, raw
	4958120 Eggplant, home frozen	7511500 Mushrooms, raw
	4958200 Fresh Summer Squash	7511900 Parsley
	4958201 Summer Squash, cooked	7512100 Pepper, hot chili
	4958202 Summer Squash, home canned	75122- Peppers, raw
	4958203 Summer Squash, home frozen	7512750 Seaweed, raw
	4958402 Fresh Bean Sprouts	7512775 Snowpeas, raw
	4958403 Fresh Alfalfa Sprouts	75128- Summer Squash, raw
	4958504 Bamboo Shoots	7513210 Celery Juice
	4958506 Seaweed	7514100 Cabbage or Cole Slaw
	4958508 Tree Fern, fresh	7514130 Chinese Cabbage Salad
	4958601 Sauerkraut	7514150 Celery with cheese
	5111- Dark Green Vegetables (all are exposed)	75142- Cucumber salads
	5113- Tomatoes	75143- Lettuce salads
	5114101 Asparagus, comm. canned	7514410 Lettuce, wilted with bacon dressing
	51144- Beans, green, snap, yellow, comm. canned	7514600 Greek salad
	5114704 Snow Peas, comm. canned	7514700 Spinach salad
	5114801 Sauerkraut, comm. canned	7520600 Algae, dried
	5114901 Artichokes, comm. canned	75201- Artichoke, cooked
	5114902 Bamboo Shoots, comm. canned	75202- Asparagus, cooked
	5114903 Bean Sprouts, comm. canned	75203- Bamboo Shoots, cooked
	5114904 Cabbage, comm. canned	752049- Beans, string, cooked
	5114905 Cabbage, comm. canned, no sauce	75205- Beans, green, cooked/canned
	5114906 Cauliflower, comm. canned, no sauce	75206- Beans, yellow, cooked/canned
	5114907 Eggplant, comm. canned, no sauce	75207- Bean Sprouts, cooked
	5114913 Mushrooms, comm. canned	752085- Breadfruit
	5114914 Okra, comm. canned	752090- Brussel Sprouts, cooked
	5114918 Seaweeds, comm. canned	75210- Cabbage, Chinese, cooked
	5114920 Summer Squash, comm. canned	75211- Cabbage, green, cooked

Chapter 13—Intake of Home-Produced Foods

Table 13B-1. Food Codes and Definitions for Individual Food Items Used in Analysis of the 1987–1988 USDA NFCS Household Data to Estimate Fraction of Food Intake That Is Home-Produced (continued)

Food Product	Household Code/Definition	Individual Code
Exposed Veg. (cont.)	5114923 Chinese or Celery Cabbage, comm. canned	75212- Cabbage, red, cooked
	51152- Tomatoes, canned, low sod.	752130- Cabbage, savoy, cooked
	5115301 Asparagus, canned, low sod.	75214- Cauliflower
	5115302 Beans, Green, canned, low sod.	75215- Celery, Chives, Christophine (chayote)
	5115303 Beans, Yellow, canned, low sod.	752167- Cucumber, cooked
	5115309 Mushrooms, canned, low sod.	752170- Eggplant, cooked
	51154- Greens, canned, low sod.	752171- Fern shoots
	5115501 Sauerkraut, low sodium	752172- Fern shoots
	5211- Dark Gr. Veg., comm. frozen (all exp.)	752173- Flowers of sesbania, squash or lily
	52131- Asparagus, comm. froz.	7521801 Kohlrabi, cooked
	52133- Beans, snap, green, yellow, comm. froz.	75219- Mushrooms, cooked
	5213407 Peapods, comm. froz.	75220- Okra/lettuce, cooked
	5213408 Peapods, with sauce, comm. froz.	7522116 Palm Hearts, cooked
	5213409 Peapods, with other veg., comm. froz.	7522121 Parsley, cooked
	5213701 Brussel Sprouts, comm. froz.	75226- Peppers, pimento, cooked
	5213702 Brussel Sprouts, comm. froz. with cheese	75230- Sauerkraut, cooked/canned
	5213703 Brussel Sprouts, comm. froz. with other veg.	75231- Snowpeas, cooked
	5213705 Cauliflower, comm. froz.	75232- Seaweed
	5213706 Cauliflower, comm. froz. with sauce	75233- Summer Squash
	5213707 Cauliflower, comm. froz. with other veg.	7540050 Artichokes, stuffed
	5213708 Caul., comm. froz. with other veg. & sauce	7540101 Asparagus, creamed or with cheese
	5213709 Summer Squash, comm. froz.	75403- Beans, green with sauce
	5213710 Summer Squash, comm. froz. with other veg.	75404- Beans, yellow with sauce
	5213716 Eggplant, comm. froz.	7540601 Brussel Sprouts, creamed
	5213718 Mushrooms with sauce, comm. froz.	7540701 Cabbage, creamed
	5213719 Mushrooms, comm. froz.	75409- Cauliflower, creamed
	5213720 Okra, comm. froz.	75410- Celery/Chiles, creamed
	5213721 Okra, comm. froz., with sauce	75412- Eggplant, fried, with sauce, etc.
	5311- Canned Tomato Juice and Tomato Mixtures	75413- Kohlrabi, creamed
	5312102 Canned Sauerkraut Juice	75414- Mushrooms, Okra, fried, stuffed, creamed
	5321- Frozen Tomato Juice	754180- Squash, baked, fried, creamed, etc.
	5371- Fresh Tomato Juice	7541822 Christophine, creamed
	5381102 Aseptically Packed Tomato Juice	7550011 Beans, pickled
	5413101 Dry Algae	7550051 Celery, pickled
	5413102 Dry Celery	7550201 Cauliflower, pickled
	5413103 Dry Chives	755025- Cabbage, pickled
	5413109 Dry Mushrooms	7550301 Cucumber pickles, dill
	5413111 Dry Parsley	7550302 Cucumber pickles, relish
	5413112 Dry Green Peppers	7550303 Cucumber pickles, sour
	5413113 Dry Red Peppers	7550304 Cucumber pickles, sweet
	5413114 Dry Seaweed	7550305 Cucumber pickles, fresh
	5413115 Dry Tomatoes	7550307 Cucumber, Kim Chee
	(does not include soups, sauces, gravies, mixtures, and ready-to-eat dinners; includes baby foods except mixtures)	7550308 Eggplant, pickled
		7550311 Cucumber pickles, dill, reduced salt
		7550314 Cucumber pickles, sweet, reduced salt
		7550500 Mushrooms, pickled
		7550700 Okra, pickled
		75510- Olives
		7551101 Peppers, hot
		7551102 Peppers, pickled
		7551301 Seaweed, pickled
		7553500 Zucchini, pickled
		76102- Dark Green Veg., baby
		76401- Beans, baby (excl. most soups & mixtures)

Chapter 14—Total Food Intake

14. TOTAL FOOD INTAKE**14.1. INTRODUCTION**

The U.S. food supply is generally considered to be one of the safest in the world. Nevertheless, contamination of foods may occur as a result of environmental pollution of the air, water, or soil, or the intentional use of chemicals such as pesticides or other agrochemicals. Ingestion of contaminated foods is a potential pathway of exposure to such contaminants. To assess chemical exposure through this pathway, information on food ingestion rates is needed. Chapters 9 through 13 of this handbook report per capita and consumer-only data on food consumption rates for various food items and food categories. These intake rates were estimated by the U.S. Environmental Protection Agency (EPA) using databases developed by the U.S. Department of Agriculture (USDA). U.S. EPA (2007) expanded the analysis of food intake in order to examine individuals' food consumption habits in greater detail. Using data from the USDA's Continuing Survey of Food Intake by Individuals (CSFII) conducted in 1994–1996 and 1998, U.S. EPA (2007) derived distributions to characterize (1) the total food intake among various groups in the U.S. population, subdivided by age, race, geographic region, and urbanization; (2) the contribution of various food categories (e.g., meats, grains, vegetables, etc.) to total food intake among these populations; and (3) the contribution of various food categories to total food intake among individuals exhibiting low- or high-end consumption patterns of a specific food category (e.g., individuals below the 10th percentile or above the 90th percentile for fish consumption). These data may be useful for assessing exposure among populations exhibiting lower or higher than usual intake of certain types of foods (e.g., people who eat little or no meat, or people who eat large quantities of fish). Recently, U.S. EPA's Office of Pesticide Programs (OPP) used data from the 2003 to

2006 National Health and Nutrition Examination Survey (NHANES) to estimate intake of various foods, including total foods.

The recommendations for total food intake rates are provided in the next section, along with a summary of the confidence ratings for these recommendations. Following the recommendations, the studies on total food intake are summarized.

14.2. RECOMMENDATIONS

Table 14-1 presents a summary of recommended values for total food intake. Table 14-2 presents the confidence ratings for these recommendations. The recommended total food intake rates are based on data from the U.S. EPA/OPP's recent analysis of NHANES data from 2003 to 2006. For information about the proportion of total intake represented by the major food groups, it is recommended that the data based on a re-analysis of the data from U.S. EPA (2007) be used. Section 14.4 describes this re-analysis, and Table 14-3 through Table 14-11 provide the data. However, it should be noted that, because the U.S. EPA (2007) data are based on 1994–1996 and 1998 CSFII data, they may not reflect recent changes that may have occurred in consumption patterns.

Both of the studies of total dietary intake presented in this chapter are based on data collected over a 2-day period and may not necessarily reflect the long-term distribution of average daily intake rates. However, because the broad categories of foods used in this analysis (e.g., total foods, total fruits, total vegetables, etc.) are typically eaten on a daily basis throughout the year with minimal seasonality, the short-term distribution may be a reasonable approximation of the long-term distribution, although it will display somewhat increased variability. This implies that the upper percentiles shown here will tend to overestimate the corresponding percentiles of the true long-term distribution.

Table 14-1. Recommended Values for Per Capita Total Food Intake, Edible Portion, Uncooked Weight				
Age Group (years)	Mean	95 th Percentile	Multiple Percentiles	Source
g/kg-day				
Children				
Birth to <1	91	208 ^c	See Table 14-12	U.S. EPA/OPP analysis of NHANES 2003–2006
1 to <3	113	185 ^c		
3 to <6	79	137		
6 to <11 ^a	47	92		
11 to <16 ^b	28	56		
16 to <21 ^b	28	56		
Adults				
21 to <50	29	63		
≥50	29	59		
^a	Based on data for ages 6 to <13 years.			
^b	Based on data for ages 13 to <20 years.			
14.2.1. *	^c	Estimates are less statistically reliable based on guidance published in the <i>Joint Policy on Variance Estimation and Statistical Reporting Standards on NHANES III and CSFII Reports: NHIS/NCHS Analytical Working Group Recommendations</i> (NCHS, 1993).		

Note: Total food intake was defined as intake of the sum of all foods, beverages, and water ingested.

Chapter 14—Total Food Intake

Table 14-2. Confidence in Recommendations for Total Food Intake		
General Assessment Factors	Rationale	Rating
Soundness		High
<i>Adequacy of Approach</i>	The survey methodologies were adequate and the analytical approaches were competently executed. The study sizes were very large; sample sizes varied with age. The response rates were good. The studies analyzed primary data on recall of ingestion.	
<i>Minimal (or Defined) Bias</i>	No direct measurements were taken. The studies relied on survey data.	
Applicability and Utility		Medium
<i>Exposure Factor of Interest</i>	The analyses were specifically designed to address food intake.	
<i>Representativeness</i>	The populations studied were representative of the U.S. population.	
<i>Currency</i>	The data used were the most current data publicly available at the time the analysis was conducted for the handbook. However, the data used in the re-analysis of the U.S. EPA study are now 11–15 years old. The national trends in bodyweight,(increasing obesity prevalence) may in part be due to changes in food intake patterns.	
<i>Data Collection Period</i>	Ingestion rates were estimated based on short-term data collected in the CSFII 1994–1996, 1998 and NHANES 2003–2006.	
Clarity and Completeness		Medium
<i>Accessibility</i>	The NHANES and CSFII data are publicly available. The U.S. EPA (2007) report is available online.	
<i>Reproducibility</i>	The methodology was clearly presented; enough information was included to reproduce results.	
<i>Quality Assurance</i>	NHANES and CSFII follow strict QA/QC procedures. U.S. EPA's analysis of NHANES data has only been reviewed internally, but the methodology has been used in an analysis of previous data.	
Variability and Uncertainty		Medium
<i>Variability in Population</i>	Short term distributions of total intake were provided. The survey was not designed to capture long-term day-to-day variability.	
<i>Uncertainty</i>	The survey data were based on recall over a 2-day period. The U.S. EPA/OPP analysis of NHANES data included all foods, beverages, and water ingested. Beverages, sugar, candy, and sweets, and nuts and nut products were not included in the re-analysis of the U.S. EPA (2007) data. There is also some uncertainty associated with the translation of mixed foods (i.e., recipes) to food commodity ingredients in both studies.	
Evaluation and Review		Medium
<i>Peer Review</i>	The USDA CSFII survey received a high level of peer review. The U.S. EPA (2007) analysis was also peer reviewed; however, the re-analysis of these data using the new age categories for children was not peer reviewed outside the Agency. The methodology used in the NHANES 2003–2006 analysis is the same as used in previous peer-reviewed analysis conducted by U.S. EPA/OPP.	
<i>Number and Agreement of Studies</i>	Two studies were available for this factor.	
Overall Rating		Medium

14.3. STUDIES OF TOTAL FOOD INTAKE**14.4. U.S. EPA Re-Analysis of 1994–1996, 1998 Continuing Survey of Food Intake by Individuals (CSFII), Based on U.S. EPA (2007)—Analysis of Total Food Intake and Composition of Individual's Diet Based on U.S. Department of Agriculture's (USDA's) 1994–1996, 1998 CSFII**

U.S. EPA's National Center for Environmental Assessment (NCEA) conducted an analysis to evaluate the total food intake of individuals in the United States using data from the USDA's 1994–1996, 1998 CSFII ([USDA, 2000](#)) and U.S. EPA's *Food Commodity Intake Database* (FCID) ([U.S. EPA, 2000](#)). The 1994–1996 CSFII and its 1998 Supplemental Children's Survey were designed to obtain data from a statistically representative sample of non-institutionalized persons living in the United States. Survey participants were selected using a multistage process. The respondents were interviewed twice to collect information on food consumption during 2 non-consecutive days. For both survey days, data were collected by an in-home interviewer. The Day 2 interview was conducted 3 to 10 days later and on a different day of the week. Of the more than 20,000 individuals surveyed, approximately 10,000 were under 21 years of age, and approximately 9,000 were under the age of 11. The 1994–1996 survey and 1998 supplement are referred to collectively as CSFII 1994–1996, 1998. Each individual in the survey was assigned a sample weight based on his or her demographic data; these weights were taken into account when calculating mean and percentile values of food consumption for the various demographic categories that were analyzed in the study. The sample weighting process used in the CSFII 1994–1996, 1998 is discussed in detail in [USDA \(2000\)](#).

For the analysis of total food intake, food commodity codes provided in U.S. EPA's FCID ([U.S. EPA, 2000](#)) were used to translate as-eaten foods (e.g., beef stew) identified by USDA food codes in the CSFII data set into food commodities (e.g., beef, potatoes, carrots, etc.). The method used to translate USDA food codes into U.S. EPA commodity codes is discussed in detail in [USDA \(2000\)](#). The U.S. EPA commodity codes were assigned to broad food categories (e.g., total meats, total vegetables, etc.) for use in the analysis. Total food intake was defined as intake of the sum of all foods in the following major food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats.

Beverages, sugar, candy, and sweets, and nuts (and nut products) were not included because they could not be categorized into the major food groups. Also, human milk intake was not included. Percent consuming, mean, standard error, and a range of percentile values were calculated on the basis of grams of food per kilogram of body weight per day (g/kg-day) and on the basis of grams per day (g/day). In addition to total food intake, intake of the various major food groups for the various age groups in units of g/day and g/kg-day were also estimated for comparison to total intake.

To evaluate variability in the contributions of the major food groups to total food intake, individuals were ranked from lowest to highest, based on total food intake. Three subsets of individuals were defined, as follows: a group at the low end of the distribution of total intake (below the 10th percentile of total intake), a mid-range or central group (the 45th to 55th percentile of total intake), and a group at the high end of the distribution of total intake (above the 90th percentile of total intake). Mean total food intake (in g/day and g/kg-day), mean intake of each of the major food groups (in g/day and g/kg-day), and the percent of total food intake that each of these food groups represents were calculated for each of the three populations (i.e., individuals with low-end, central, and high-end total food intake). A similar analysis was conducted to estimate the contribution of the major food groups to total food intake for individuals at the low-end, central, and high-end of the distribution of total meat intake, total dairy intake, total meat and dairy intake, total fish intake, and total fruit and vegetable intake. For example, to evaluate the variability in the diets of individuals at the low-end, mid-range, and high-end of the distribution of total meat intake, survey individuals were ranked according to their reported total meat intake. Three subsets of individuals were formed as described above. Mean total food intake, intake of the major food groups, and the percent of total food intake represented by each of the major food groups were tabulated. U.S. EPA (2007) presented the results of the analysis for the following age groups: <1 year, 1 to 2 years, 3 to 5 years, 6 to 11 years, 12 to 19 years, 20 to 39 years, 40 to 69 years, and 70 years and older. The data were tabulated in units of g/kg-day and g/day.

The analysis presented in U.S. EPA (2007) was conducted before U.S. EPA published the guidance entitled *Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* ([U.S. EPA, 2005](#)). As a result, the age groups used for children in U.S. EPA (2007) were not

Chapter 14—Total Food Intake

entirely consistent with the age groups recommended in the 2005 guidance. In order to conform to the standard age categories for children recommended in *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005), each of the tables from U.S. EPA (2007) was modified by re-analyzing the source data and applying the new childhood age categories (i.e., <1 month, 1 to <3 months, 3 to <6 months, 6 to <12 months, 1 to <2 years, 2 to <3 years, 3 to <6 years, 6 to <11 years, 11 to <16 years, and 16 to <21 years). Table 14-3 presents distributions of total food intake in units of g/day and g/kg-day. Table 14-4 and Table 14-5 compare total food intake to intake of the various major food groups for the various age groups in units of g/day and g/kg-day, respectively. It should be noted that some U.S. EPA commodity codes are listed under more than one food category. For this reason, in the tables, the intake rates for the individual food categories do not necessarily add up to the figure given for total food intake (U.S. EPA, 2007). Also, data are not reported for food groups for which there were less than 20 consumers in a particular age group. Table 14-6 through Table 14-11 present the contributions of the major food groups to total food intake for individuals (in the various age groups) at the low-end, central, and high-end of the distribution of total food intake (see Table 14-6), total meat intake (see Table 14-7), total meat and dairy intake (see Table 14-8), total fish intake (see Table 14-9), total fruit and vegetable intake (see Table 14-10), and total dairy intake (see Table 14-11) in units of g/day and g/kg-day. For each of the three classes of consumers, consumption of nine different food categories is presented (i.e., total foods, dairy, meats, fish, eggs, grains, vegetables, fruits, and fats). For example, in Table 14-9 one will find the mean consumption of meats, eggs, vegetables, etc. for individuals with an unusually high (or low or average) consumption of fish.

As discussed in previous chapters, the 1994–1996, 1998 CSFII data have both advantages and limitations with regard to estimating food intake rates. The large sample size (more than 20,000 persons) is sufficient to allow categorization within narrowly defined age categories. In addition, the survey was designed to obtain a statistically valid sample of the entire U.S. population that included children and low income groups. However, the survey design is of limited utility for assessing small and potentially at-risk populations based on ethnicity, medical status, geography, or other factors (such as activity level). Another limitation is that data are based on a 2-day survey period and, as such, may not

accurately reflect long-term eating patterns. This is particularly true for the extremes of the distribution of food intake.

14.4.1. U.S. EPA Analysis of National Health and Nutrition Examination Survey (NHANES) 2003–2006 Data

U.S. EPA/OPP used data from the 2003 to 2006 NHANES to estimate intake of various individual foods, major food groups, and total foods. This chapter presents the data for total foods (Chapter 9 provides data on the intake of fruits and vegetables; Chapter 11 provides data on intake of meat, dairy products, and fats, and Chapter 12 provides data on intake of grain and grain products). The total intake rates presented here represent intake of all forms of foods eaten (e.g., both home produced and commercially produced). Individuals who provided data for 2 days of the survey were included in the intake estimates. Individuals who did not provide information on body weight or for whom identifying information was unavailable were excluded from the analysis. The U.S. EPA/OPP analysis of 2003–2006 NHANES data included all foods, beverages, and water ingested. Two-day average intake rates were calculated for all individuals in the database for each of the food items/groups. These average daily intake rates were divided by each individual's reported body weight to generate intake rates in units of grams per kilogram of body weight per day (g/kg-day). The data were weighted according to the 4-year, 2-day sample weights provided in the 2003–2006 NHANES to adjust the data for the sample population to reflect the national population.

Intake data from the NHANES were based on uncooked forms of the edible portion of the food items/groups. Summary statistics, including: number of individuals represented in the estimates, mean intake rate, and standard error of the mean intake rate were calculated for total foods. Percentiles of the intake rate distribution (i.e., 1st, 5th, 10th, 25th, 50th, 75th, 90th, 95th, 99th, and the maximum value) were also provided. The data represent per capita data. However, the intake rates are the same as those for consumers only because all survey respondents ate some type of food during the survey period. Data were provided for the following age groups: <1 year, 1 to <3 years, 3 to <6 years, 6 to <13 years, 13 to <20 years, 20 to <50 years, ≥50 years, females only—13 to 49 years, and all ages combined. Data were also generated for various racial/ethnic groups (i.e., Mexican American, non-Hispanic Black, non-Hispanic White, other Hispanic, and other race). Table 14-12 presents intake data for total foods in

g/kg-day from the 2003–2006 NHANES analysis for these age groups and racial/ethnic groups.

The strength of U.S. EPA's analysis is that it provides distributions of total food intake for various age groups of children and adults, normalized by body weight. The analysis uses the 2003–2006 NHANES data set, which was designed to be representative of the U.S. population. The data set includes 4 years of intake data combined, and is based on a 2-day survey period. Because these data were developed for use in U.S. EPA's pesticide registration program, the childhood age groups used are slightly different than those recommended in U.S. EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). However, given the similarities in the age groups used, the data should provide suitable intake estimates for the age groups of interest. The data for infants <12 months could not be separated out into the recommended age groups due to sample size limitations. This analysis generated data for total foods only. Analyses to estimate the proportion of total food intake represented by the various food groups were not conducted for this data set.

^a Total food intake was defined as intake of the sum of all foods in the following major food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats. Beverages, sugar, candy, and sweets, and nuts (and nut products) were not included because they could not be categorized into the major food groups.

^b Number of consumers. The number of consumers of total food may be less than the number of individuals in the study sample for the youngest age groups because human milk was not included in the total food intake estimates presented here.

^c Sample size.

PC = Percent consuming.

SE = Standard error.

- = Value not available.

Source: U.S. EPA analysis of 1994–1996, 1998 CSFII.

^a	Number of consumers. The number of consumers of total food may be less than the number of individuals in the study sample for the youngest age groups because human milk was not included in the total food intake estimates presented here.														
^b	Sample size.														
^c	Total food intake was defined as intake of the sum of all foods in the following major food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats. Beverages, sugar, candy, and sweets, and nuts and nut products were not included because they could not be categorized into the major food groups.														
PC	= Percent consuming.														
SE	= Standard error.														
-	= Value not available or data not reported where the number of consumers was less than 20.														
Source:	U.S. EPA analysis of 1994–1996, 1998 CSFII.

^a	Number of consumers. The number of consumers of total food may be less than the number of individuals in the study sample for the youngest age groups because human milk was not included in the total food intake estimates presented here.														
^b	Sample size.														
^c	Total food intake was defined as intake of the sum of all foods in the following major food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats. Beverages, sugar, candy, and sweets, and nuts and nut products were not included because they could not be categorized into the major food groups.														
PC	= Percent consuming.														
SE	= Standard error.														
-	= Data not reported where the number of consumers was less than 20.														
Source:	U.S. EPA analysis of 1994–1996, 1998 CSFII.

^a Total food intake was defined as intake of the sum of all foods in the following major food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats. Beverages, sugar, candy, and sweets, and nuts and nut products were not included because they could not be categorized into the major food groups.

^b Includes added fats such as butter, margarine, dressings and sauces, vegetable oil, etc.; does not include fats eaten as components of other foods such as meats.

^a	Total food intake was defined as intake of the sum of all foods in the following major food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats. Beverages, sugar, candy, and sweets, and nuts and nut products were not included because they could not be categorized into the major food groups.												
^b	Includes added fats such as butter, margarine, dressings and sauces, vegetable oil, etc.; does not include fats eaten as components of other foods such as meats.												
^c	All individuals in this sample group consumed 0 g/day of meat. Therefore, results are reported in the low-end decile.												
^d	Only one individual in this sample group consumed more than 0 g/day of meat. This result is reported in the high-end decile. All other samples are reported in the low-end decile.												
^e	All individuals in this sample group below the 89 th percentile consumed 0 g/day of meat. Therefore, only high-end and low-end consumer groups are reported.

^a Total food intake was defined as intake of the sum of all foods in the following major food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats. Beverages, sugar, candy, and sweets, and nuts and nut products were not included because they could not be categorized into the major food groups.													
^b Includes added fats such as butter, margarine, dressings and sauces, vegetable oil, etc.; does not include fats eaten as components of other foods such as meats.													
Source: U.S. EPA analysis of 1994–1996, 1998 CSFII.

- ^a All individuals in this sample group consumed 0 g/day of fish. Therefore, only low-end consumers are reported.
- ^b Total food intake was defined as intake of the sum of all foods in the following major food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats. Beverages, sugar, candy, and sweets, and nuts and nut products were not included because they could not be categorized into the major food groups.
- ^c Includes added fats such as butter, margarine, dressings and sauces, vegetable oil, etc.; does not include fats eaten as components of other foods such as meats.
- ^d Only one individual in this sample group consumed more than 0 g/day of fish. Therefore, this sample is reported in the high-end consumer group and all other samples are placed in the low-end consumer group.
- ^e All individuals in this sample group below the 80th percentile consumed 0 g/day of fish. Therefore, only high-end and low-end consumer groups are reported.

^a Total food intake was defined as intake of the sum of all foods in the following major food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats. Beverages, sugar, candy, and sweets, and nuts and nut products were not included because they could not be categorized into the major food groups.													
^b Includes added fats such as butter, margarine, dressings and sauces, vegetable oil, etc.; does not include fats eaten as components of other foods such as meats.													
Source: U.S. EPA analysis of 1994–1996, 1998 CSFII.

15. HUMAN MILK INTAKE**15.1. INTRODUCTION**

Human lactation is known to impart a wide range of benefits to nursing infants, including protection against infection, increases in cognitive development, and avoidance of allergies due to intolerance to cow's milk ([Gartner et al., 2005](#)). Ingestion of human milk also has been associated with a reduction in risk of post-neonatal death in the United States. ([Chen and Rogan, 2004](#)). The American Academy of Pediatrics (AAP) recommends exclusive breast-feeding for approximately the first 6 months and supports the continuation of breast-feeding for the first year and beyond if desired by the mother and child ([Gartner et al., 2005](#)). However, contaminants may find their way into human milk of lactating mothers because mothers are themselves exposed, thus making human milk a potential source of exposure to toxic substances for nursing infants. Lipid-soluble chemical compounds accumulate in body fat and may be transferred to breast-fed infants in the lipid portion of human milk. Water soluble chemicals also may partition into the aqueous phase and be excreted via human milk. Because nursing infants obtain most—if not all—of their dietary intake from human milk, they are especially vulnerable to exposures to these compounds. Estimating the magnitude of the potential dose to infants from human milk requires information on the milk intake rate (quantity of human milk consumed per day) and the duration (months) over which breast-feeding occurs. Information on the fat content of human milk also is needed for estimating dose from human milk residue concentrations that have been indexed to lipid content.

Several studies have generated data on human milk intake. Typically, human milk intake has been measured over a 24-hour period by weighing the infant before and after each feeding without changing its clothing (test weighing). The sum of the difference between the measured weights over the 24-hour period is assumed to be equivalent to the amount of human milk consumed daily. Intakes measured using this procedure are often corrected for evaporative water losses (insensible water losses) between infant weighings ([NAS, 1991](#)). Neville et al. (1988) evaluated the validity of the test weight approach among bottle-fed infants by comparing the weights of milk taken from bottles with the differences between the infants' weights before and after feeding. When test weight data were corrected for insensible weight loss, they were not significantly different from bottle weights. Conversions between weight and volume of human milk consumed are made using the density of

human milk (approximately 1.03 g/mL) ([NAS, 1991](#)). Techniques for measuring human milk intake using stable isotopes such as deuterium have been developed. The advantages of these techniques over test weighing procedures are that they are less burdensome for the mother and do not interfere with normal behavior ([Albernaz et al., 2003](#)). However, few data based on this technique were found in the literature.

Among infants born in 2004, 73.8% were breast-fed postpartum, 41.5% at 6 months, and 20.9% at 12 months. Studies of nursing mothers in industrialized countries have shown that average intakes among infants ranged from approximately 500 to 800 mL/day, with the highest intake reported for infants 3 to <6 months old (see Table 15-1).

The recommendations for human milk intake rates and lipid intake rates are provided in the next section along with a summary of the confidence ratings for these recommendations. The recommended values are based on key studies identified by U.S. Environmental Protection Agency (EPA) for this factor. Following the recommendations, key studies on human milk intake are summarized. Relevant data on lipid content and fat intake, breast-feeding duration, and the estimated percentage of the U.S. population that breast-feeds also are presented.

A number of other studies exist in the literature, but they focus on other aspects of lactation such as growth patterns of nursing infants, supplementary food and energy intake, and nutrition of lactating mothers ([González-Cossío et al., 1998](#); [Drewett et al., 1993](#); [Dewey et al., 1992](#)). These studies are not included in this chapter because they do not focus on the exposure factor of interest. Other studies in the literature focus on formula intake. Because some baby formula is prepared by adding water, these data are presented in Chapter 3-Ingestion of Water and Other Select Liquids.

15.2. RECOMMENDATIONS

The studies described in Section 15.3 were used in selecting recommended values for human milk intake and lipid intake. Although different survey designs, testing periods, and populations were used by the studies to estimate intake, the mean and standard deviation estimates reported in these studies are relatively consistent. There are, however, limitations with the data. With the exception of Butte et al. (1984) and Arcus-Arth et al. (2005), data were not presented on a body weight basis. This is particularly important because intake rates may be higher on a body weight basis for younger infants

than older infants. Also, the data used to derive the recommendations are more than 15 years old and the sample size of the studies was small. Other populations of concern—such as mothers highly committed to breast-feeding, sometimes for periods longer than 1 year—may not be captured by the studies presented in this chapter. Note that data for infants 12 months old are not included in the recommendation table because the U.S. EPA's standard age group for children, as described in Chapter 1 of this handbook, is 6 to <12 months and it may not be appropriate to use this value to represent the next age group of 1 to <2 years old.

15.2.1. Human Milk Intake

Table 15-1 presents a summary of recommended values for human milk and lipid intake rates, and Table 15-2 presents the confidence ratings for these recommendations. The human milk intake rates for nursing infants that have been reported in the studies described in this section are summarized in Table 15-3 in units of mL/day and in Table 15-4 in units of mL/kg-day (i.e., indexed to body weight). It should be noted that the decrease in human milk with age is likely a result of complementary foods being introduced as the child grows and not necessarily a decrease in total energy intake. To conform to the new standardized age groupings used in this handbook (see Chapter 1), data from Pao et al. (1980), Dewey and Lönnnerdal (1983), Butte et al. (1984), Neville et al. (1988), Dewey et al. (1991a), Dewey et al. (1991b), Butte et al. (2000), and Arcus-Arth et al. (2005) were compiled for each month of the first year of life. Recommendations were converted to mL/day by using a density of human milk of 1.03 g/mL, and rounded to two significant figures. Only two studies [i.e., Butte et al. (1984), and Arcus-Arth et al. (2005)] provided data on a body weight basis. For some months, multiple studies were available; for others only one study was available. Weighted means were calculated for each age in months. When upper percentiles were not available from a study, they were estimated by adding two standard deviations to the mean value. When multiple studies were available, recommendations for upper percentiles were calculated as the midpoint of the range of upper percentile values of the studies available for each age in months. These month-by-month intakes were composited to yield intake rates for the standardized age groups by calculating a weighted average. Recommendations are provided for the population of exclusively breast-fed infants because this population may have higher exposures than partially breast-fed infants.

Exclusively breast-fed in this chapter refers to infants whose sole source of milk comes from human milk, with no other milk substitutes. *Partially breast-fed* refers to infants whose source of milk comes from both human milk and other milk substitutes (i.e., formula). Note that some studies define partially breast-fed as infants whose dietary intake comes from not only human milk and formula, but also from other solid foods (e.g., strained fruits, vegetables, meats).

15.2.2. Lipid Content and Lipid Intake

Table 15-5 presents recommended lipid intake rates in units of mL/day. The table parallels the human milk intake tables (see Table 15-3). With the exception of the data from Butte et al. (1984), the rates were calculated assuming a lipid content of 4% (Kent et al., 2006; Arcus-Arth et al., 2005; Mitoulas et al., 2003; Mitoulas et al., 2002; NAS, 1991; Butte et al., 1984). In the case of the Butte et al. (1984) study, lipid intake rates were provided and were used in place of the estimated lipid intakes. Table 15-6 presents lipid intake rates on a body weight basis (mL/kg-day). These were calculated from the values presented in Table 15-4 multiplied by 4% lipid content.

Table 15-1. Recommended Values for Human Milk and Lipid Intake Rates for Exclusively Breast-Fed Infants

Age Group	Mean		Upper Percentile ^a		Source
	mL/day	mL/kg-day	mL/day	mL/kg-day	
Human Milk Intake					
Birth to <1 month	510	150	950	220	b, c
1 to <3 months	690	140	980	190	b, c, d, e, f
3 to <6 months	770	110	1,000	150	b, c, d, e, f, g, h
6 to <12 months	620	83	1,000	130	b, c, d, f, g, h
Lipid Intake ⁱ					
Birth to <1 month	20	6.0	38	8.7	b, c
1 to <3 months	27	5.5	40	8.0	b, c, d, e, f
3 to <6 months	30	4.2	42	6.1	b, c, d, e, f, g, h
6 to <12 months	25	3.3	42	5.2	b, c, d, f, g, h
^a	Upper percentile is reported as mean plus 2 standard deviations.				
^b	Neville et al. (1988).				
^c	Arcus-Arth et al. (2005).				
^d	Pao et al. (1980).				
^e	Butte et al. (1984).				
^f	Dewey and Lönnnerdal (1983).				
^g	Butte et al. (2000).				
^h	Dewey et al. (1991b).				
ⁱ	The recommended value for the lipid content of human milk is 4.0%. See Section 15.4				

Table 15-2. Confidence in Recommendations for Human Milk Intake

General Assessment Factors	Rationale	Rating
Soundness		Medium
<i>Adequacy of Approach</i>	Methodology uses changes in body weight as a surrogate for total ingestion. More sophisticated techniques measuring stable isotopes have been developed, but data with this technique were not available. Sample sizes from individual studies were relatively small (7–108). Mothers selected for the studies were volunteers. The studies analyzed primary data.	
<i>Minimal (or defined) Bias</i>	Mothers were instructed in the use of infant scales to minimize measurement errors. Three out of the eight studies indicated correcting data for insensible water loss. Some biases may be introduced by including partially breast-fed infants.	
Applicability and Utility		Medium
<i>Exposure Factor of Interest</i>	The studies focused on estimating human milk intake.	
<i>Representativeness</i>	Most studies focused on the U.S. population, but were not national samples. Populations studied were mainly from high socioeconomic status. One study included populations from Sweden and Finland. However, this may not affect the amount of intake, but, rather, the prevalence and initiation of lactation.	
<i>Currency</i>	Studies were conducted between 1980 and 2000. However, this may not affect the amount of intake but rather the prevalence and initiation of lactation.	
<i>Data Collection Period</i>	Infants were not studied long enough to fully characterize day-to-day variability.	
Clarity and Completeness		Medium
<i>Accessibility</i>	All key studies are available from the peer-reviewed literature.	
<i>Reproducibility</i>	The methodology was clearly presented, but some studies did not discuss adjustments due to insensible weight loss.	
<i>Quality Assurance</i>	Some steps were taken to ensure data quality. For example, mothers were trained to use the scales. However, this element could not be fully evaluated from the information presented in the published studies.	
Variability and Uncertainty		Low
<i>Variability in Population</i>	Variability was not very well-characterized. Mothers committed to breast-feeding more than 1 year were not captured.	
<i>Uncertainty</i>	Not correcting for insensible water loss may underestimate intake.	
Evaluation and Review		High
<i>Peer Review</i>	The studies appeared in peer-reviewed journals.	
<i>Number and Agreement of Studies</i>	There are eight key studies. The results of studies from different researchers are in agreement.	
Overall Rating		Medium

Chapter 15—Human Milk Intake

15.3. KEY STUDIES ON HUMAN MILK INTAKE**15.3.1. Pao et al. (1980)—Milk Intakes and Feeding Patterns of Breast-Fed Infants**

Pao et al. (1980) conducted a study of 22 healthy nursing infants to estimate human milk intake rates. Infants were categorized as completely breast-fed or partially breast-fed. Breast-feeding mothers were recruited through La Leche League groups. Except for one Black infant, all other infants were from White middle-class families in southwestern Ohio. The goal of the study was to enroll infants as close to 1 month of age as possible and to obtain records near 1, 3, 6, and 9 months of age (Pao et al., 1980). However, not all mother-infant pairs participated at each time interval. Data were collected for these 22 infants using the test weighing method. Records were collected for three consecutive 24-hour periods at each test interval. The weight of human milk was converted to volume by assuming a density of 1.03 g/mL. Daily intake rates were calculated for each infant based on the mean of the three 24-hour periods. Table 15-7 presents mean daily human milk intake rates for the infants surveyed at each time interval. These data are presented as they are reported in Pao et al. (1980). For completely breast-fed infants, the mean intake rates were 600 mL/day at 1 month of age, 833 mL/day at 3 months of age, and 682 mL/day at 6 months of age. Partially breast-fed infants had mean intake rates of 485 mL/day, 467 mL/day, 395 mL/day, and <554 mL/day at 1, 3, 6, and 9 months of age, respectively. Pao et al. (1980) also noted that intake rates for boys in both groups were slightly higher than for girls.

The advantage of this study is that data for both exclusively and partially breast-fed infants were collected for multiple time periods. Also, data for individual infants were collected over 3 consecutive days, which would account for some individual variability. However, the number of infants in the study was relatively small. In addition, this study did not account for insensible weight loss, which may underestimate the amount of human milk ingested.

15.3.2. Dewey and Lönnerdal (1983)—Milk and Nutrient Intake of Breast-Fed Infants From 1 to 6 Months: Relation to Growth and Fatness

Dewey and Lönnerdal (1983) monitored the dietary intake of 20 nursing infants between age 1 and 6 months. The number of study participants dropped to 13 by the end of the 6th month. Most of the infants in the study were exclusively breast-fed.

One infant's intake was supplemented by formula during the first and second month of life. During the 3rd, 4th, and 5th months, three, four, and five infants, respectively, were given some formula to supplement their intake. Two infants were given only formula (no human milk) during the 6th month. According to Dewey and Lönnerdal (1983), the mothers were all well-educated and recruited through Lamaze childbirth classes in the Davis area of California. Human milk intake volume was estimated based on two 24-hour test weighings per month. Table 15-8 presents human milk intake rates for the various age groups. Human milk intake averaged 673, 782, and 896 mL/day at 1, 3, and 6 months of age, respectively.

The advantage of this study is that it evaluated nursing infants for a period of 6 months based on two 24-hour observations per infant per month. However, corrections for insensible weight loss apparently were not made. Also, the number of infants in the study was relatively small, and the study participants were not representative of the general population. During the study period, some infants were given some formula (i.e., up to five infants during the 5th month). Without the raw data, these subjects could not be excluded from the study results. Thus, these subjects may affect the results when deriving recommendations for exclusively breast-fed infants.

15.3.3. Butte et al. (1984)—Human Milk Intake and Growth in Exclusively Breast-Fed Infants

Human milk intake was studied in exclusively breast-fed infants during the first 4 months of life (Butte et al., 1984). Nursing mothers were recruited through the Baylor Milk Bank Program in Texas. Forty-five mother-infant pairs participated in the study. However, data for some time periods (i.e., 1, 2, 3, or 4 months) were missing for some mothers as a result of illness or other factors. The mothers were from the middle-to-upper socioeconomic stratum and had a mean age of 28.0 ± 3.1 years. A total of 41 mothers were White, 2 were Hispanic, 1 was Asian, and 1 was West Indian. Infant growth progressed satisfactorily during the course of the study.

The amount of milk ingested over a 24-hour period was determined by weighing the infant before and after feeding. The study did not indicate whether the data were corrected for insensible water or weight loss. The study evaluated the accuracy of the test weighing procedure using a bottle-fed infant. Test weighing occurred over a 24-hour period for most study participants, but intake among several infants was studied over longer periods (48 to 96 hours) to

assess individual variation in intake. Eight of the infants received some food supplementation during the study period. Six of them received less than 60 kcal/day of formula, oatmeal, glucose water, or rice water for 1 or 2 days. One infant received an additional 90 kcal/day of infant formula and rice water for 6 days during the 4th month because of inadequate milk production. When converting values reported as g/day to mL/day, using a conversion factor of 1.03 g/mL, mean human milk intake ranged from 702 mL/day at 3 months to 729 mL/day at 1 month, with an overall mean of 712 mL/day for the entire study period (see Table 15-9). Intakes also were calculated on the basis of body weight (see Table 15-9).

The advantage of this study is that data for a larger number of exclusively breast-fed infants were collected than in previous studies. However, data were collected for infants up to 4 months and day-to-day variability was not characterized for all infants. Eighteen percent (i.e., 8 out of 45) of the infants received some formula supplementation during the study period. Without the raw data, these subjects could not be excluded from the study results. Therefore, values derived from this study for exclusively breast-fed infants may be somewhat underestimated.

15.3.4. Neville et al. (1988)—Studies in Human Lactation: Milk Volumes in Lactating Women During the Onset of Lactation and Full Lactation

Neville et al. (1988) studied human milk intake among 13 infants during the 1st year of life. The mothers were all multiparous, non-smoking, White women of middle- to upper-socioeconomic status living in Denver, CO. All women in the study practiced exclusive breast-feeding for at least 5 months. Solid foods were introduced at mean age of 7 months. Daily milk intake was estimated by the test weighing method with corrections for insensible weight loss. Data were collected daily from birth to 14 days, weekly from weeks 3 through 8, and monthly until the study period ended at 1 year after inception. One infant was weaned at 8 months, while all others were weaned on or after the 12 months. Formula was used occasionally (≤ 240 mL/week) after 4 months in three infants. Table 15-10 lists the estimated human milk intakes for this study. Converting values reported as g/day to mL/day, using a conversion factor of 1.03 g/mL, mean human milk intakes were 748 mL/day, 713 mL/day, 744 mL/day, and 391 mL/day at 1, 3, 6, and 12 months of age, respectively.

In comparison to the previously described studies, Neville et al. (1988) collected data on numerous days over a relatively long time period (12 months) and they were corrected for insensible weight loss. However, the intake rates presented in Table 15-10 are estimated based on intake only during a 24-hour period. Consequently, these intake rates are based on short-term data that do not account for day-to-day variability among individual infants. Also, a smaller number of subjects was included than in the previous studies. Three infants were given some formula after 4 months. Without the raw data, these subjects could not be excluded from the study results. Thus, data presented for infants between 5 and 12 months may underestimate the intake of exclusively breast-fed infants.

15.3.5. Dewey et al. (1991b; 1991a)—(a) Maternal Versus Infant Factors Related to Human Milk Intake and Residual Volume: The DARLING Study; (b) Adequacy of Energy Intake Among Breast-Fed Infants in the DARLING Study: Relationships to Growth, Velocity, Morbidity, and Activity Levels

The Davis Area Research on Lactation, Infant Nutrition and Growth (DARLING) study was conducted in 1986 to evaluate growth patterns, nutrient intake, morbidity, and activity levels in infants who were breast-fed for at least their first 12 months of life (Dewey et al., 1991b; Dewey et al., 1991a). Subjects were non-randomly selected through letters to new parents using birth listings. One of the criteria used for selection was that mothers did not plan to feed their infants more than 120 mL/day of other milk or formula for the first 12 months of life. Seventy-three infants aged 3 months were included in the study. At subsequent time intervals, the number of infants included in the study was somewhat lower as a result of attrition. All infants in the study were healthy and of normal gestational age and weight at birth, and they did not consume solid foods until after they were 4 months old. The mothers were highly educated and of “relatively high socioeconomic status.”

Human milk intake was estimated by weighing the infants before and after each feeding and correcting for insensible water loss. Test weighings were conducted over a 4-day period every 3 months. The results of the study indicate that human milk intake declines over the first 12 months of life. This decline is associated with the intake of solid food. When converting values reported as g/day to mL/day, using a conversion factor of 1.03 g/mL, mean human

Chapter 15—Human Milk Intake

milk intake was estimated to be 788 mL/day, 747 mL/day, 627 mL/day, and 435 mL/day at 3, 6, 9, and 12 months, respectively (see Table 15-11). Based on the estimated intakes at 3 months of age, variability between individuals (coefficient of variation [CV] = 16.3%) was higher than the average day-to-day variability ($CV = 8.9 \pm 5.4\%$) for the infants in the study (Dewey et al., 1991a).

The advantages of this study are that data were collected over a relatively long-time (4 days) period at each test interval, which would account for some day-to-day infant variability, and corrections for insensible water loss were made. Data from this study are assumed to represent exclusively breast-fed infants because mothers were specifically recruited for that purpose. It is, however, unclear from the Dewey et al. (1991a) study if this criterion was met throughout the length of the study period.

15.3.6. Butte et al. (2000)—Infant Feeding Mode Affects Early Growth and Body Composition

Butte et al. (2000) conducted a study to assess the effect of infant feeding mode on growth and body composition during the first 2 years of life. The study was conducted in the Houston, TX, area, recruited through the Children's Nutrition Research Center (CNRC) referral system. The study was approved by the Baylor Affiliates Review Boards for Human Subject Research. The overall sample was 76 healthy term infants at 0.5, 3, 6, 9, 12, 18, and 24 months of age. The sample size varied between 71 to 76 infants for each age group. Repeated measurements for body composition and anthropometric were performed. The mothers agreed to either exclusively breast-feed or formula feed the infants for the first 4 months of life.

At 3-month or 6-month study intervals, the feeding history was taken. The mothers or caretakers were questioned about breast-feeding frequency, and the use of formula, milk, juice, solids, water, and vitamin or mineral supplements. Also, infant food intake was quantified at 3, 6, 12, and 24 months with a 3-day weighted intake record completed by the mother or caretaker (Butte et al., 2000). The intake of human milk was assessed by test weighing; the infant weights were calculated before and after each feeding. Using a pre-weighing and post-weighing method, the intake of formula and other foods and beverages was measured for 3 days by the mothers using a digital scale and recorded on predetermined forms.

The average duration of breast-feeding was 11.4 months (standard deviation [SD] = 5.8). Butte et

al. (2000) reported that infants were exclusively breast-fed for at least the first 4 months—except for one who was weaned at 109 days, another who received formula at 102 days, and another who was given cereal at 106 days. Table 15-12 shows the infant feeding characteristics. Table 15-13 shows the intakes of human milk for the infants. When converting values reported as g/day to mL/day, using a conversion factor of 1.03 g/mL, mean human milk intake was estimated to be 728 mL/day at 3 months (weighted average of boys and girls), 637 mL/day at 6 months (weighted average of boys and girls), and 403 mL/day at 12 months (weighted average of boys and girls) (see Table 15-13). Table 15-14 shows feeding practices by percentage for infants. Table 15-15 provides the mean body weights of breast-fed infants.

Advantages of this study are that it provides intake data for breast-fed infants for their first 4 months. The study also provides the mean weights for the infants by feeding type and by sex. The limitations of the study are that the sample size is small and limited to one geographical location. The authors did not indicate if results were corrected for insensible weight loss. Because mothers could introduce formula after 4 months, only the data for the 3-month old infants can be considered exclusively breast-fed.

15.3.7. Arcus-Arth et al. (2005)—Breast Milk and Lipid Intake Distributions for Assessing Cumulative Exposure and Risk

Arcus-Arth et al. (2005) derived population distributions for average daily milk and lipid intakes in g/kg-day for infants age 0–6 months and 0–12 months for infants fed according to the AAP recommendations. The AAP recommends exclusively breast-feeding for the first 6 months of life, with human milk as the only source of milk until age 1 year and the introduction of solid foods after 6 months. The distributions were derived based on data in the peer-reviewed literature and data sets supplied by the publication authors for infants 7 days and older (Arcus-Arth et al., 2005). As cited in Arcus-Arth et al. (2005), data sources included Dewey et al. (1991b; 1991a), Hofvander et al. (1982), Neubauer et al. (1993), Ferris et al. (1993), Salmenpera et al. (1985), and Stuff and Nichols (1989). The authors also evaluated intake rates for infants breast-fed exclusively over the 1st year and provided a regression line of intake versus age for estimating short-term exposures. Arcus-Arth et al. (2005) derived human milk intake rates for the entire infant population (nursing and non-nursing) from

U.S. data on consumption, prevalence and duration. Arcus-Arth et al. (2005) defined *exclusive breast-feeding* (EBF) as “breast milk is the sole source of calories, with no or insignificant calories from other liquid or solid food sources,” and *predominant breast-feeding* as “breast milk is the sole milk source with significant calories from other foods.” The data that were consistent with AAP advice were used to construct the AAP data set (Arcus-Arth et al., 2005). The 0–12 months EBF data set was created using 0–6 month AAP data and data from the EBF infants older than 6 months of age. Because there are no data in the AAP data set for any individual infant followed at regular, frequent intervals during the 12-month period, population distributions were derived with assumptions regarding individual intake variability over time (Arcus-Arth et al., 2005). Two methods were used. In Method 1, the average population daily intake at each age was described by a regression line, assuming normality. Arcus-Arth et al. (2005) noted that age specific intake data were consistent with the assumption of normality. In Method 2, intake over time was simulated for 2,500 hypothetical infants and the distribution intakes derived from 2,500 individual intakes (Arcus-Arth et al., 2005). The population intake distribution was derived following Method 1. Table 15-16 presents the means and standard deviations for intake data at different ages; the variability was greatest for the two youngest and three oldest age groups. The values in Table 15-16 using Method 1 were used to derive the recommendations presented in Table 15-1 because it provides data for the fine age categories. When converting values reported as g/day to mL/day, using a conversion factor of 1.03 g/mL, mean human milk intake was estimated to be 150 mL/kg-day at 1 month, 127 mL/kg-day at 3 months, 101 mL/kg-day at 6 months, and 47 mL/kg-day at 12 months (see Table 15-16). Time weighted average intakes for larger age groups (i.e., 0–6 months, 0–12 months) are presented in Table 15-17.

An advantage of this study is that it was designed to represent the infant population whose mothers follow the AAP recommendations. Intake was calculated on a body weight basis. In addition, the data used to derive the distributions were from peer-reviewed literature and data sets supplied by the publication authors. The distributions were derived from data for infants fed in accordance to AAP recommendations, and they most likely represent daily average milk intake for a significant portion of breast-fed infants today (Arcus-Arth et al., 2005). The limitations of the study are that the data used were from mothers who were predominantly White, well-nourished, and from middle or high

socioeconomic status. Arcus-Arth et al. (2005) also included data from Sweden and Finland. However, human milk volume in mL/day is similar among all women except for severely malnourished women (Arcus-Arth et al., 2005). According to Arcus-Arth et al. (2005): “Although few infants are exclusively breast-fed for 12 months, the EBF distributions may represent a more highly exposed subpopulation of infants exclusively breast-fed in excess of 6 months.”

15.4. KEY STUDIES ON LIPID CONTENT AND LIPID INTAKE FROM HUMAN MILK

Human milk contains more than 200 constituents, including lipids, various proteins, carbohydrates, vitamins, minerals, and trace elements as well as enzymes and hormones. The lipid content of human milk varies according to the length of time that an infant nurses, and it increases from the beginning to the end of a single nursing session (NAS, 1991). The lipid portion accounts for approximately 4% of human milk ($3.9\% \pm 0.4\%$) (NAS, 1991). This value is supported by various studies that evaluated lipid content from human milk (Kent et al., 2006; Arcus-Arth et al., 2005; Mitoulas et al., 2003; Mitoulas et al., 2002; Butte et al., 1984). Several studies also estimated the quantity of lipid consumed by breast-feeding infants. These values are appropriate for performing exposure assessments for nursing infants when the contaminant(s) have residue concentrations that are indexed to the fat portion of human milk.

15.4.1. Butte et al. (1984)—Human Milk Intake and Growth in Exclusively Breast-Fed Infants

Butte et al. (1984) analyzed the lipid content of human milk samples taken from women who participated in a study of human milk intake among exclusively breast-fed infants. The study was conducted with more than 40 women during a 4-month period. Table 15-18 presents the mean lipid content of human milk at various infants’ ages. The overall lipid content for the 4-month study period was $3.43 \pm 0.69\%$ (3.4%). Butte et al. (1984) also calculated lipid intakes from 24-hour human milk intakes and the lipid content of the human milk samples. Lipid intake was estimated to range from 22.9 mL/day (3.7 mL/kg-day) to 27.2 mL/day (5.7 mL/kg-day).

The number of women included in this study was small, and these women were selected primarily from middle to high socioeconomic classes. Thus, data on human milk lipid content from this study may not be entirely representative of human milk lipid content

Chapter 15—Human Milk Intake

among the U.S. population. Also, these estimates are based on short-term data, and day-to-day variability was not characterized.

15.4.2. Mitoulas et al. (2002)—Variation in Fat, Lactose, and Protein in Human Milk Over 24 h and Throughout the First Year of Lactation

Mitoulas et al. (2002) conducted a study of healthy nursing women to determine the volume and composition of human milk during the 1st year of lactation. Nursing mothers were recruited through the Nursing Mothers' Association of Australia. All infants were completely breast-fed on demand for at least 4 months. Complementary solid food was introduced between 4 and 6 months of age. Mothers consumed their own ad libitum diets throughout the study. Seventeen mothers initially provided data for milk production and fat content, whereas lactose, protein, and energy were initially obtained from nine mothers. The number of mothers participating in the study decreased at 6 months because of the cessation of sample collection from 11 mothers, the maximum period of exclusive breast-feeding.

Milk samples were collected before and after each feed from each breast over a 24–28 hour period. Milk yield was determined by weighing the mother before and after each feed from each breast. Insensible water loss was accounted for by weighing the mother 20 minutes after the end of each feeding. The rate of water loss during this 20-minute period was used to calculate insensible water loss during the feeding. Samples of milk produced at the beginning of the feeding (foremilk) and at the end of the feeding (hindmilk) were averaged to provide the fat, protein, lactose, and energy content for each feed. In all cases the left and right breasts were treated separately; therefore, *N* represents the number of individual breasts sampled.

Table 15-19 presents mean human milk production and composition at each age interval. The mean fat, lactose, and protein contents (g/L) were 37.4 (standard error [SE] = 0.6), 61.4 (SE = 0.6), and 9.2 (SE = 0.2), respectively. Composition did not vary between left and right breasts or preferred and non-preferred breasts. Milk production was constant for the first 6 months and thereafter steadily declined. Mitoulas et al. (2002) reported a mean 24-hour milk production from both breasts was 798 (SD = 232) mL. The fat content of milk decreased between 1 and 4 months before increasing to 12 months of lactation. The concentration of protein decreased to 6 months and then remained steady. Lactose remained constant throughout the 12 months of lactation. The decrease

of energy at 2 months and subsequent increase by 9 months can be attributed to changes in fat content. Assuming a density of human milk of 1.03 g/mL, the overall fat content in human milk was 3.6%. Milk production, as well as concentrations of fat, lactose, protein, and energy, differed significantly between women.

The focus of this study was on human milk composition and production, not on infant's human milk intake. The advantage of this study is that it evaluated nursing mothers for a period of 12 months. However, the number of mother-infant pairs in the study was small (17 mothers with infants) and may not be entirely representative of the U.S. population. This study accounted for insensible water loss, which increases the accuracy of the amount of human milk produced.

15.4.3. Mitoulas et al. (2003)—Infant Intake of Fatty Acids From Human Milk Over the First Year of Lactation

Mitoulas et al. (2003) conducted a study of five healthy nursing women to determine the content of fat in human milk and fat intake by infants during the 1st year of lactation. Thirty nursing mothers were recruited through the Australian Breast-feeding Association or from private healthcare facilities. All infants were completely breast-fed on demand for at least 4 months. Complementary solid food was introduced between 4 and 6 months of age. Mothers consumed their own ad libitum diets throughout the study.

Milk samples were collected before and after each feed from each breast over a 24–28 hour period. Fore- and hind-milk samples were averaged to provide the fat content for each feed. Milk yield was determined by weighing the mother before and after each feed from each breast. Insensible water loss was accounted for by weighing the mother 20 minutes after the end of each feeding. The rate of water loss during those 20 minutes was used to calculate insensible water loss during the feeding.

Table 15-20 presents changes in volume of human milk produced and milk fat content over the 1st year of lactation. The mean volumes of milk produced for both breasts combined were 813, 791, 912, 810, 677, and 505 mL/day at 1, 2, 4, 6, 9, and 12 months, respectively. The average daily production over the 12 months was 751 mL/day with a mean fat content of 35.5 g/L. Assuming a density of human milk of 1.03 g/mL, the fat content in human milk was 3.4% over the 12 month period. There was a significant difference in the proportional composition of fatty acids during the course of lactation. Table 15-21

provides average fatty acid composition during the first 12 months of lactation. Additionally, fatty acid composition varied during the course of the day.

The focus of this study was on human milk composition and production—not on infant's human milk intake. The advantage of this study is that it evaluated the human milk composition for a period of 12 months. However, the number of mother-infant pairs in the study was small (five mothers with infants) and may not be entirely representative of the entire U.S. population. This study accounted for insensible water loss, which increases the accuracy of the amount of human milk produced.

15.4.4. Arcus-Arth et al. (2005)—Breast Milk and Lipid Intake Distributions for Assessing Cumulative Exposure and Risk

Arcus-Arth et al. (2005) derived population distributions for average daily milk and lipid intakes in g/kg a day for infants 0–6 months and 0–12 months of age for infants fed according to the AAP recommendations. Lipid intakes were calculated from lipid content and milk intakes measured on the same infant (Arcus-Arth et al., 2005). Table 15-22 provides lipid intakes based on data from Dewey et al. (1991a) and Table 15-23 provides lipid intakes calculated assuming 4% lipid content and milk intake in the AAP data set. The mean measured lipid content ranged from 3.67%–4.16%, with a mean of 3.9% over the 12 month period. Arcus-Arth et al. (2005) noted that the distributions presented are intended to represent the U.S. infant population.

An advantage of this study is that it was designed to represent the population of infants who are breast-fed according to the AAP recommendations. In addition, the data used to derive the distributions were from peer-review literature and data sets supplied by the publication authors. The limitation of the study are that the data used were from mothers that were predominantly white, well-nourished, and from mid- or upper-socioeconomic status; however, human milk volume in mL/day is similar among all women except for severely malnourished women (Arcus-Arth et al., 2005). The authors noted that “although few infants are exclusively breast-fed for 12 months, the exclusively breast-fed distributions may represent a more highly exposed subpopulation of infants exclusively breast-fed in excess of 6 months.” The distributions were derived from data for infants fed in accordance to AAP recommendations, and they most likely represent daily average milk intake for a significant portion of breast-fed infants today (Arcus-Arth et al., 2005).

15.4.5. Kent et al. (2006)—Volume and Frequency of Breast-Feeding and Fat Content of Breast Milk Throughout the Day

Kent et al. (2006) collected data from 71 Australian mothers who were exclusively nursing their 1–6 month-old infants. The study focused on examining the variation of milk consumed from each breast, the degree of fullness of each breast before and after feeding, and the fat content of milk consumed from each breast during daytime and nighttime feedings. The volume of milk was measured using test-weighing procedures with no correction for infant insensible water loss. On average, infants had 11 ± 3 breast-feedings per day (range = 6–18). The interval between feedings was 2 hours and 18 minutes \pm 43 minutes (range = 4 minutes to 10 hours, 58 minutes). The 24-hour average human milk intake was 765 ± 164 mL/day (range = 464–1,317 mL/day). The fat content of milk ranged from 22.3 g/L to 61.6 g/L (2.2%–6.0%) with an average of 41.1 g/L (4.0%).

This study examined breast-feeding practices of volunteer mothers in Australia. Although amounts of milk consumed by Australian infants may be similar to infants in the U.S. population, results could not be broken out by smaller age groups to examine variability with age. The study provides estimates of fat content from a large number of samples.

15.5. RELEVANT STUDY ON LIPID INTAKE FROM HUMAN MILK

15.5.1. Maxwell and Burmaster (1993)—A Simulation Model to Estimate a Distribution of Lipid Intake From Human Milk During the First Year of Life

Maxwell and Burmaster (1993) used a hypothetical population of 5,000 infants between birth and 1 year of age to simulate a distribution of daily lipid intake from human milk. The hypothetical population represented both bottle-fed and breast-fed infants aged 1–365 days. A distribution of daily lipid intake was developed based on data in Dewey et al. (1991b) on human milk intake for infants at 3, 6, 9, and 12 months and human milk lipid content, and survey data in Ryan et al. (1991) on the percentage of breast-fed infants under 12 months (i.e., approximately 22%). A model was used to simulate intake among 1,113 of the 5,000 infants expected to be breast-fed. The results indicated that lipid intake among nursing infants under 12 months can be characterized by a normal distribution with a mean of

Chapter 15—Human Milk Intake

26.0 mL/day and a standard deviation of 7.2 mL/day (see Table 15-24). The model assumes that nursing infants are completely breast-fed and does not account for infants who are breast-fed longer than 1 year. Based on data collected by Dewey et al. (1991b), Maxwell and Burmaster (1993) estimated the lipid content of human milk to be 36.7 g/L at 3 months (35.6 mg/g or 3.6%), 39.2 g/L at 6 months (38.1 mg/g or 3.8%), 41.6 g/L at 9 months (40.4 mg/g or 4.0%), and 40.2 g/L at 12 months (39.0 mg/g or 3.9%).

The limitation of this study is that it provides a snapshot of daily lipid intake from human milk for breast-fed infants. These results also are based on a simulation model and there are uncertainties associated with the assumptions made. Another limitation is that lipid intake was not derived for the U.S. EPA recommended age categories. The estimated mean lipid intake rate represents the average daily intake for nursing infants under 12 months. The study also did not generate new data. A reanalysis of previously reported data on human milk intake and human milk lipid intake were provided.

15.6. OTHER FACTORS

Many factors influence the initiation, continuation, and amount of human milk intake. These factors are complex and may include considerations such as maternal nutritional status, parity, parental involvement, support from lactation consultants, mother's working status, infant's age, weight, sex, food supplementation, the frequency of breast-feeding sessions each day, the duration of breast-feeding for each event, the duration of breast-feeding during childhood, ethnicity, geographic area, and other socioeconomic factors. For example, a study conducted in the United Kingdom found that social and educational factors most influenced the initiation and continuation of lactation (Wright et al., 2006). Prenatal and postnatal lactation consultant intervention was found to be effective in increasing lactation duration and intensity (Bonuck et al., 2005).

15.6.1. Population of Nursing Infants

Breast-feeding rates in the United States have consistently increased since 1993. McDowell et al. (2008) reported that the percentage of infants who were ever breast-fed increased from 60% in 1993–1994 to 77% among infants born in 2005–2006 according to the data from the National Health and Nutrition Examination Surveys (NHANES). This exceeded the goal of 75% set in the Healthy People 2010 McDowell et al. (2008). Rates among non-

Hispanic black women increased significantly from 36% in 1993–1994 to 65% in 2005–2006. Income and age had a significant impact on breast-feeding rates. Breast-feeding rates among higher income women were 74% compared to 57% among lower income women (McDowell et al., 2008).

In another study to monitor progress toward achieving the Centers for Disease Control and Prevention (CDC) *Healthy People 2010* breast-feeding objectives (initiation and duration), Scanlon et al. (2007) analyzed data from the National Immunization Survey (NIS). NIS uses random-digit dialing to survey households to survey age-eligible children, followed by a mail survey to eligible children's vaccination providers to validate the vaccination information. NIS is conducted annually by the CDC to obtain national, state, and selected urban area estimation on vaccinations rates among U.S. children ages 19–35 months. The interview response rate for years 2001–2006 ranged between 64.5% and 76.1%. Questions regarding breast-feeding were added to the NIS survey in 2001. The sample population was infants born during 2000–2004. Scanlon et al. (2007) noted that because data in their analysis are for children ages 19–35 months at the time of the NIS interview, each cross-sectional survey includes children from birth cohorts that span 3 calendar years; the breast-feeding data were analyzed by year-of-birth during 2000–2004 (birth year cohort instead if survey year).

Among infants born in 2000, breast-feeding rates were 70.9% (CI = 69.0–72.8) for the postpartum period (in hospital before discharge), 34.2% (CI = 32.2–36.2) at 6 months, and 15.7 (CI = 14.2–17.2) at 12 months. For infants born in 2004, these rates had increased to 73.8% (CI = 72.8–74.8) for the postpartum period, 41.5% (CI = 40.4–42.6) at 6 months, and 20.9 (CI = 20.0–21.8) at 12 months. Rates of breast-feeding through 3 months were lowest among black infants (19.8%), infants whose mothers were <20 years of age (16.8%), those whose mothers had a high school education or less (22.9% and 23.9%), those whose mothers were unmarried (18.8%), those who resided in rural areas (23.9%), and those whose families had an income-to-poverty ratio of <100% (23.9%). Table 15-25 shows data for exclusive breast-feeding through 3 and 6 months by socioeconomic characteristics for infants born in 2004.

Scanlon et al. (2007) noted the following limitations could affect the utility of these data: (1) breast-feeding behavior was based on retrospective self-report by mothers or other caregivers, whose responses might be subject to recall bias; (2) the NIS question defining early

Chapter 15—Human Milk Intake

postpartum breast-feeding or initiation—"Was [child's name] ever breast-fed or fed breast milk?"—collects information that might differ from the HP2010 objective for initiation; and (3) although survey data were weighted to make them representative of all U.S. children ages 19–35 months, some bias might remain. The advantage of the study is that is representative of the U.S. infant population.

In 2007, CDC released the CDC Breast-feeding Report Card, which has been updated every year since. The CDC National Immunization Program in partnership with the CDC National Center for Health Statistics conducts the NIS within all 50 states, the District of Columbia, and selected geographic areas within the states. Five breast-feeding goals are in the *Healthy People 2010* report. The Breast-feeding Report Card presents data for each state for the following categories of infants: ever breast-fed, breast-fed at 6 months, breast-fed at 12 months, exclusive breast-feeding through 3 months, and exclusive breast-feeding through 6 months (CDC, 2009). These indicators are used to measure a state's ability to promote, protect, and support breast-feeding. Table 15-26 presents these data for the estimated percentage of infants born in 2006. The advantage of this report is that it provides data for each state and is representative of the U.S. infant population.

Analysis of breast-feeding practices in other developing countries also was found in the literature. Marriott et al. (2007) researched feeding practices in developing countries in the first year of life, based on 24-hour recall data. Marriott et al. (2007) used secondary data from the Demographic and Health Surveys (DHS) for more than 35,000 infants in 20 countries. This survey has been conducted since 1986 and was expanded to provide a standardized survey instrument that can be used by developing countries to collect data on maternal-infant health and intake and household variables, as well as to build national health statistics (Marriott et al., 2007). The analysis was based on the responses of the survey mothers for questions on whether they were currently breast-feeding and had fed other liquids and solid foods to their infants in the previous 24 hours. The data incorporated were from between 1999 and 2003. Marriott et al. (2007) selected the youngest infant (i.e., less than 1 year old) in each of the families; multiples were included such as twins or triplets. Separate analyses were conducted for infants less than 6 months old and infants 6 months and older, but less than 12 months old. Food and liquid variables other than water and infant formulas were collapsed into broader food categories for cross-country

comparisons (Marriott et al., 2007). Tinned, powdered, and any other specified animal milks were collapsed. In addition, all other liquids such as herbal teas, fruit juices, and sugar water (excluding unique country-specific liquids) were collapsed into other liquids and the 10 types of solid food groups into an any-solid-foods category (Marriott et al., 2007). Data were pooled from the 20 countries to provide a large sample size and increase statistical power. Table 15-27 and Table 15-28 present the percentage of mothers who were currently breast-feeding and separately had fed their infants other liquids or solid food by age groups. Table 15-29 presents the pooled data summary for the study period. The current breast-feeding was consistent across countries for both age groups; the countries that reported the highest percentages of current breast-feeding for the 0- to 6-month-old infants also reported the highest percentages in the 6- to 12-month-old infants. Pooled data show that 96.6% of the 0- to 6-month-old infants and 87.9% of the 6- to 12-month-old infants were breast-feeding. Feeding of other fluids was lowest in the 0- to 6-month-old infants, with the percentage feeding water the highest of this category. The percentage of mothers feeding commercial infant formulas was the lowest in most countries.

There are other older studies that analyze ethnic and racial differences in breast-feeding practices. Li and Grummer-Strawn (2002) investigated ethnic and racial disparities in lactation in the United States using data from the NHANES III that was conducted between 1988 and 1994. NHANES II participants were ages 2 months and older. The data were collected during a home interview from a parent or a proxy respondent for the child (Li and Grummer-Strawn, 2002). The sample population consisted of children 12–71 months of age at time of interview. The NHANES III response rate for children participating was approximately 94% (Li and Grummer-Strawn, 2002). Data for a total of 2,863 exclusively breast-fed, 6,140 ever breast-fed, and 6,123 continued breast-fed children were included in the analysis (Li and Grummer-Strawn, 2002). The percentage of children ever breast-fed was 60% among non-Hispanic Whites, 26% among non-Hispanic Blacks, and 54% among Mexican Americans. This percentage decreased to 27%, 9%, and 23% respectively by 6 months. The percentage of children fed exclusively human milk at 4 months also was significantly lower for Blacks at 8.5%, compared to 22.6% for Whites and 14.1% for Mexican Americans. The racial and ethnic differences in proportion of children ever breast-fed is presented in Table 15-30, the proportion of children who received any breast milk at 6 months are presented in

Chapter 15—Human Milk Intake

Table 15-31, and the proportion of children exclusively breast-fed at 4 months is presented in Table 15-32.

Li and Grummer-Strawn (2002) noted that there may have been some lag time between birth and the time of the interview. This may have caused misclassification if the predictor variables changed considerably between birth and the time of interview. Also, NHANES III did not collect information on maternal education. Instead, the educational level of the household head was used as a proxy. The advantage of this study is that it is representative of the U.S. children's population.

Data from some older studies provide historical information on breast-feeding practices in the United States. These data are provided in this chapter to show trends in the U.S. population. In 1991, the National Academy of Sciences (NAS) reported that the percentage of breast-feeding women has changed dramatically over the years (NAS, 1991). The Ross Products Division of Abbott Laboratories conducted a large national mail survey in 1995 to determine patterns of breast-feeding during the first 6 months of life. The Ross Laboratory Mothers' Survey was first developed in 1955 and has been expanded to include many more infants. Before 1991, the survey was conducted on a quarterly basis, and approximately 40,000 to 50,000 questionnaires were mailed each quarter (Ryan, 1997). Beginning in 1991, the survey was conducted monthly; 35,000 questionnaires were mailed each month. Over time, the response rate has been consistently in the range of $50 \pm 5\%$. In 1989 and 1995, 196,000 and 720,000 questionnaires were mailed, respectively. Ryan (1997) reported rates of breast-feeding through 1995 and compared them with those in 1989.

The survey demonstrates increases in both the initiation of breast-feeding and continued breast-feeding at 6 months of age between 1989 and 1991. Table 15-33 presents the percentage of breast-feeding in hospitals and at 6 months of age by selected demographic characteristics. In 1995, the incidence of breast-feeding at birth and at 6 months for all infants was approximately 59.7% and 21.6%, respectively. The largest increases in the initiation of breast-feeding between 1989 and 1995 occurred among women who were black, were less than 20 years of age, earned less than \$10,000 per year, had no more than a grade school education, were living in the South Atlantic region of the United States, had infants of low birth weight, were employed full time outside the home at the time they received the survey, and participated in the Women, Infants, and Children program (WIC). In 1995, as in 1989, the initiation of breast-feeding was highest

among women who were more than 35 years of age, earned more than \$25,000 per year, were college-educated, did not participate in the WIC program, and were living in the Mountain and Pacific regions of the United States.

Data on the actual length of time that infants continue to breast-feed beyond 5 or 6 months were limited (NAS, 1991). However, Maxwell and Burmaster (1993) estimated that approximately 22% of infants under 1 year are breast-fed. This estimate was based on a reanalysis by Ryan et al. (1991) of survey data collected by Ross Laboratories (Maxwell and Burmaster, 1993). Studies also have indicated that breast-feeding practices may differ among ethnic and socioeconomic groups and among regions of the United States. More recently, the Ross Products Division of Abbott Laboratories reported the results of their ongoing *Ross Mothers Survey* in 2003 (Abbott Labs, 2003). Table 15-34 presents the percentages of mothers who breast-feed, based on ethnic background and demographic variables. These data update the values presented in the NAS (1991) report.

15.6.2. Intake Rates Based on Nutritional Status

Information on differences in the quality and quantity of human milk on the basis of ethnic or socioeconomic characteristics of the population is limited. Lönnerdal et al. (1976) studied human milk volume and composition (nitrogen, lactose, proteins) among underprivileged and privileged Ethiopian mothers. No significant differences were observed between the data for these two groups. Similar data were observed for well-nourished Swedish mothers. Lönnerdal et al. (1976) stated that these results indicate that human milk quality and quantity are not affected by maternal malnutrition. However, Brown et al. (1986b; 1986a) noted that the lactational capacity and energy concentration of marginally nourished women in Bangladesh were "modestly less than in better nourished mothers." Human milk intake rates for infants of marginally nourished women in this study were 690 ± 122 g/day at 3 months, 722 ± 105 g/day at 6 months, and 719 ± 119 g/day at 9 months (Brown et al., 1986a). Brown et al. (1986a) observed that human milk from women with larger measurements of arm circumference and triceps skinfold thickness had higher concentrations of fat and energy than mothers with less body fat. Positive correlations between maternal weight and milk fat concentrations also were observed. These results suggest that milk composition may be affected by maternal nutritional status.

15.6.3. Frequency and Duration of Feeding

Hofvander et al. (1982) reported on the frequency of feeding among 25 bottle-fed and 25 breast-fed infants at ages 1, 2, and 3 months. The mean number of meals for these age groups was approximately five meals a day (see Table 15-35). Neville et al. (1988) reported slightly higher mean feeding frequencies. The mean number of meals per day for exclusively breast-fed infants was 7.3 at ages 2–5 months and 8.2 at ages 2 weeks to 1 month. Neville et al. (1988) reported that, for infants between the ages of 1 week and 5 months, the average duration of a breast-feeding session is 16–18 minutes.

Buckley (2001) studied the breast-feeding patterns, dietary intake, and growth measurement of children who continued to breast-feed beyond 1 year of age. The sample was 38 mother-child pairs living in the Washington, DC, area. The criteria for inclusion in the study were that infants or their mothers had no hospitalization of either subject 3 months prior to the study and that the mother was currently breast-feeding a 1-year-old or older child (Buckley, 2001). The participants were recruited through local medical consultants and the La Leche League members. The children selected as the final study subjects consisted of 22 boys and 16 girls with ages ranging from 12 to 43 months old. The data were collected using a 7-day breast-feeding diary. The frequency and length of breast-feeding varied with the age of the child (Buckley, 2001). The author noted a statistically significant difference in the mean number of breast-feeding episodes each day and the average total minutes of breast-feeding between the 1-, 2-, and 3-year-old groups. Table 15-36 provides the comparison of breast-feeding patterns between age groups. An advantage of this study is that the frequency and duration data are based primarily on a 7-day diary and some dietary recall. Limitations of the study are the small sample size and that it is limited to one geographical area.

360	8	391 \pm 243	63–748	391 \pm 243

^a Values reported by the author in units of g/day were converted to units of mL/day by dividing by 1.03 g/mL (density of human milk).

^b Multiple data sets were combined by producing simulated data sets fitting the known mean and SD for each age, compositing the data sets to correspond to age groups of 0 to <1 month and 1 to <2 months, and calculating new means and SD's on the composited data.

^c Negative value due to insensible weight loss correction.

SD = Standard deviation.

Chapter 16—Activity Factors

16. ACTIVITY FACTORS**16.1. INTRODUCTION**

Individual or group activities are important determinants of potential exposure. Toxic chemicals introduced into the environment may not cause harm to an individual until an activity is performed that brings the individual into contact with those contaminants. An activity or time spent in a given activity will vary among individuals depending on culture, ethnicity, hobbies, location, sex, age, socioeconomic characteristics, and personal preferences. However, limited information is available regarding ethnic, cultural, and socioeconomic differences in individuals' choice of activities or time spent in a given activity. Children are of special concern because certain activities and behaviors specific to children place them at a higher risk of exposure to certain environmental agents and expose them to higher levels of many chemicals (Chance and Harmsen, 1998). Trends associated with activity patterns include increases in the proportion of the population engaging in sedentary activities and decreases in physical activity in the home and related to work, including walking to work, as there has been a strong trend toward Americans living in the suburbs (Brownson et al., 2005). Recent trends in occupational mobility include the facts that average tenure increases directly with age, and that a large proportion of American workers show substantial job stability (U.S. Census Bureau, 2010). For population mobility, the U.S. Census Bureau reported that the national residential move rate increased to 12.5% in 2009 following a record low of 11.9% in 2008 (U.S. Census Bureau, 2010).

In calculating exposure, a person's average daily dose is determined from a combination of variables including the pollutant concentration, exposure duration, and frequency of exposure (see Chapter 1). These variables can be dependent on human activity patterns and time spent at each activity and/or location.

Time activity data are generally obtained using recall questionnaires and diaries to record the person's activities and microenvironments. Other methods include the use of videotaping and global positioning system technology to provide information on individuals' locations (Elgethun et al., 2003; Phillips et al., 2001).

Obtaining accurate information on time and activities can be challenging. This is especially true for children (Cohen Hubal et al., 2000). Children engage in more contact activities than adults; therefore, a much wider distribution of activities need to be considered when assessing children's exposure

(Cohen Hubal et al., 2000). Mouthing behavior, which includes all activities in which objects, including fingers, are touched by the mouth or put into the mouth are provided in Chapter 4. Chapter 7 provides frequency and duration data for dermal (hand) contact.

This chapter summarizes data on how much time individuals spend participating in various activities in various microenvironments and on the frequency of performing various activities. Information is also provided on occupational mobility and population mobility. The data in this chapter cover a wide range of activities and populations, arranged by age group when such data are available. One of the objectives of this handbook is to provide recommended exposure factor values using a consistent set of age groups. In this chapter, several studies are used as sources for activity pattern data. In some cases, the source data could be retrieved and analyzed using the standard age groupings recommended in *Guidance for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). In other cases, the original source data were not available, and the study results are presented here using the same age groups as the original study, whether or not they conform to the standard age groupings.

The recommendations for activity factors are provided in the next section, along with a summary of the confidence ratings for these recommendations. The recommended values are based on key studies identified by U.S. Environmental Protection Agency (U.S. EPA) for this factor. Following the recommendations, key studies on activity patterns are summarized. Relevant data on activity patterns are also presented to provide the reader with added perspective on the current state-of-knowledge pertaining to activity patterns in adults and children. Additional information on microactivity patterns (i.e., hand-to-mouth, object-to-mouth, and dermal [hand] contact with surfaces and objects) is provided in Chapters 4 and 7.

16.2. RECOMMENDATIONS**16.2.1. Activity Patterns**

Assessors are commonly interested in quantitative information describing several types of time use data for adults and children including the following: time spent indoors and outdoors; time spent bathing, showering, and swimming; and time spent playing on various types of surfaces. Table 16-1 summarizes the recommended values for these factors. Note that, except for swimming, all activity factors are reported in units of minutes/day.

Time spent swimming is reported in units of minutes/month. These data are based on 2 key studies presented in this chapter: a study of children's activity patterns in California (Wiley et al., 1991) and the National Human Activity Pattern Survey (NHAPS) (U.S. EPA, 1996). Both mean and 95th percentile recommended values are provided. However, because these recommendations are based on short-term survey data, 95th percentile values may be misleading for estimating chronic (i.e., long-term) exposures and should be used with caution. Also, the upper percentile values for some activities are truncated as a result of the maximum response included in the survey (e.g., durations of more than 120 minutes/day were reported as 121 minutes/day), and could not be further refined). Table 16-2 presents the confidence ratings for the recommendations.

The recommendations for total time spent indoors and the total time spent outdoors are based on the U.S. EPA re-analysis of the source data from Wiley et al. (1991) for children <1 year of age and U.S. EPA (1996) for childhood age groups >1 year of age. Although Wiley et al. (1991) is a study of California children and the sample size was very small for infants, it provides data for children's activities for the younger age groups. Data from U.S. EPA (1996) are representative of the U.S. general population. In some cases, however, the time spent indoors or outdoors would be better addressed on a site-specific basis since the times are likely to vary depending on the climate, residential setting (i.e., rural versus urban), personal traits (e.g., health status), and personal habits. For children >1 year of age, the recommended values for time spent indoors at a residence, duration of showering and bathing, time spent swimming, and time spent playing on sand, gravel, grass or dirt are based on a U.S. EPA re-analysis of the source data from U.S. EPA (1996). For adults 18 years and older, the recommended values are taken directly from the source document (U.S. EPA, 1996).

16.2.2. Occupational Mobility

Occupational mobility may be an important factor in determining exposure. For example, the duration of exposure to occupationally-related contaminants, such as the chemicals used in an industrial or laboratory setting, will be directly associated with the period of time an individual spends in the occupation.

The median occupational tenure of the working population (109.1 million people) ages 16 years of age and older in January 1987 was 7.9 years for men and 5.4 years for women (Carey, 1988). Since the

occupational tenure varies significantly according to age and sex, the recommended values are given by 5-year age groups separately for males and females in Table 16-3. Section 16.4 provides occupational tenure for males and females combined. Part-time employment, race and the position held are important to consider in determining occupational tenure. These data are also presented in Section 16.4. Table 16-3 also presents recommendations for occupational mobility rate, by age. This rate is the percentage of persons employed in an occupation who had voluntarily entered it from another occupation. The overall percent was 5.3 (Carey, 1990). The ratings indicating confidence in the occupational mobility recommendations are presented in Table 16-4. It should be noted that the recommended values are not for use in evaluating job tenure. These data can be used for determining time spent in an occupation and not for time spent at a specific job site.

16.2.3. Population Mobility

An assessment of population mobility can assist in determining the length of time a household is exposed in a particular location. For example, the duration of exposure to site-specific contamination, such as a polluted stream from which a family fishes or contaminated soil on which children play or vegetables are grown, will be directly related to the period of time residents live near the contaminated site.

There are two key studies from which the population mobility recommendations were derived: the U.S. Census Bureau American Housing Survey, (U.S. Census Bureau, 2008a) and Johnson and Capel (1992). The U.S. Bureau of Census (2008a) provides data on current residence time and Johnson and Capel (1992) provide data on residential occupancy period. Table 16-5 presents the recommendations for population mobility. Table 16-6 presents the confidence ratings for these recommendations.

The 50th and 90th percentiles for current residence time from the U.S. Census Bureau (2008a) are 8 years and 32 years, respectively. The mean and 90th percentile for residential occupancy period from Johnson and Capel (1992) are 12 years and 26 years, respectively.

Chapter 16—Activity Factors

Table 16-1. Recommended Values for Activity Patterns ^a			
Age Group	Mean	95 th Percentile	Source
Time Indoors (total) minutes/day			
Birth to <1 month	1,440	-	U.S. EPA analysis of source data from Wiley et al. (1991) for age groups from birth to <12 months. Average for boys and girls, whole population. See Table 16-14.
1 to <3 months	1,432	-	
3 to <6 months	1,414	-	
6 to <12 months	1,301	-	
1 to <2 years	1,353	-	
2 to <3 years	1,316	-	U.S. EPA re-analysis of source data from U.S. EPA (1996) for age groups from 1 to <21 years, whole population. See Table 16-21.
3 to <6 years	1,278	-	
6 to <11 years	1,244	-	
11 to <16 years	1,260	-	Adults, ≥18 years (U.S. EPA, 1996). Total minutes/24 hours (1,440) minus time outdoors, doers ^b only. See Table 16-22.
16 to <21 years	1,248	-	
18 to <65 years	1,159	-	
≥65 years	1,142	-	
Time Outdoors (total) minutes/day			
Birth to <1 month	0	-	U.S. EPA analysis of source data from Wiley et al. (1991) for age groups from birth to <12 months. Average for boys and girls, whole population. See Table 16-14.
1 to <3 months	8	-	
3 to <6 months	26	-	
6 to <12 months	139	-	
1 to <2 years	36	-	
2 to <3 years	76	-	U.S. EPA re-analysis of source data from U.S. EPA (1996) for age groups from 1 to <21 years, whole population. See Table 16-21.
3 to <6 years	107	-	
6 to <11 years	132	-	
11 to <16 years	100	-	Adults, ≥18 years (U.S. EPA, 1996). Sum of minutes spent outdoors away from the residence and minutes spent outdoors at the residence. Doers ^b only. See Table 16-22.
16 to <21 years	102	-	
18 to <65 years	281	-	
≥65 years	298	-	
Time Indoors (at residence) minutes/day			
Birth to <1year	1,108	1,440	Children, Birth to <21 years: U.S. EPA re-analysis of source data from U.S. EPA (1996). Doers ^b only. See Table 16-15.
1 to <2 years	1,065	1,440	
2 to <3 years	979	1,296	
3 to <6 years	957	1,355	
6 to <11 years	893	1,275	
11 to <16 years	889	1,315	Adults, ≥18 years (U.S. EPA, 1996). Doers ^b only. See Table 16-16.
16 to <21 years	833	1,288	
18 to <65 years	948	1,428	
≥65 years	1,175	1,440	
Showering minutes/day			
Birth to <1year	15	-	U.S. EPA re-analysis of source data from U.S. EPA (1996). Doers ^b only. See Table 16-29.
1 to <2 years	20	-	
2 to <3 years	22	44	
3 to <6 years	17	34	
6 to <11 years	18	41	
11 to <16 years	18	40	
16 to <21 years	20	45

Chapter 16—Activity Factors

Table 16-1. Recommended Values for Activity Patterns (continued)			
Age Group	Mean	95 th Percentile	Source
		Playing on Dirt minutes/day	
Birth to <1 year	33	-	Children, <21 years: U.S. EPA re-analysis of source data from U.S. EPA (1996). Doers ^b only. See Table 16-43.
1 to <2 years	56	121	
2 to <3 years	47	121	
3 to <6 years	63	121	
6 to <11 years	63	121	
11 to <16 years	49	120	Adults, ≥18 years (U.S. EPA, 1996). Doers ^b only. See Table 16-44.
16 to <21 years	30	-	
18 to <65 years	0 ^c	120	
≥65 years	0 ^c	-	

- Percentiles were not calculated for sample sizes less than 10 or in cases where the mean was calculated by summing the means from multiple locations or activities.

^a These activities are averaged over seasons.

^b Doers are those respondents who engaged or participated in the activity.

^c Median value, mean not available in U.S. EPA (1996).

Note: All activities are reported in units of minutes/day, except swimming, which is reported in units of minutes/month. There are 1,440 minutes in a day. Time indoors and outdoors may not add up to 1,440 minutes due to activities that could not be classified as either indoors or outdoors.

Table 16-2. Confidence in Recommendations for Activity Patterns

General Assessment Factors	Rationale	Rating
Soundness		High
<i>Adequacy of Approach</i>	The survey methodologies and data analyses were adequate. For the reanalysis of U.S. EPA (1996) study data, responses were weighted; however, adult data were not reanalyzed. The California children's activity pattern survey design (Wiley et al., 1991) and NHAPS (U.S. EPA, 1996) consisted of large overall sample sizes that varied with age. Data were collected via questionnaires and interviews.	
<i>Minimal (or Defined) Bias</i>	Measurement or recording error may have occurred since the diaries were based on 24 hour recall. The sample sizes for some age groups were small for some activity factors. The upper ends of the distributions were truncated for some factors. The data were based on short-term data.	
Applicability and Utility		Medium
<i>Exposure Factor of Interest</i>	The key studies focused on activities of children and adults.	
<i>Representativeness</i>	U.S. EPA (1996) was a nationally representative survey of the U.S. population and the reanalysis was weighted; the Wiley et al. (1991) survey was conducted in California and it was not representative of the U.S. population.	
<i>Currency</i>	The Wiley et al. (1991) study was conducted between April 1989 and February 1990; the U.S. EPA (1996) study was conducted between October 1992 and September 1994.	
<i>Data Collection Period</i>	Data were collected for a 24-hour period.	
Clarity and Completeness		Medium
<i>Accessibility</i>	The original studies are widely available to the public; U.S. EPA analysis of the original raw data from U.S. EPA (1996) is available upon request.	
<i>Reproducibility</i>	The methodologies were clearly presented; enough information was included to reproduce the results.	
<i>Quality Assurance</i>	Quality assurance methods were not well described in study reports.	
Variability and Uncertainty		Medium
<i>Variability in Population</i>	Variability was characterized across various age categories of children and adults.	
<i>Uncertainty</i>	The studies were based on short term recall data, and the upper ends of the distributions were truncated.	
Evaluation and Review		Medium
<i>Peer Review</i>	The original studies received a high level of peer review. The re-analysis of the U.S. EPA (1996) data to conform to the standardized age categories was not peer-reviewed.	
<i>Number and Agreement of Studies</i>	There were 2 key studies.	
Overall Rating		Medium for the mean; low for upper percentile

Table 16-3. Recommended Values for Occupational Mobility

	Median Tenure (years)	Median Tenure (years)	
Age Group	Men	Women	Source
All ages, ≥16 years	7.9	5.4	(Carey, 1988). See Table 16-103
16 to 24 years	2.0	1.9	
25 to 29 years	4.6	4.1	
30 to 34 years	7.6	6.0	
35 to 39 years	10.4	7.0	
40 to 44 years	13.8	8.0	
45 to 49 years	17.5	10.0	
50 to 54 years	20.0	10.8	
55 to 59 years	21.9	12.4	
60 to 64 years	23.9	14.5	
65 to 69 years	26.9	15.6	
≥70 years	30.5	18.8	
	Occupational Mobility Rate ^a		Source
Age Group	(percent)		
16 to 24 years	12.7		(Carey, 1990). See Table 16-107
25 to 34 years	6.6		
35 to 44 years	4.0		
45 to 54 years	1.9		
55 to 64 years	1.0		
≥64 years	0.3		
Total, ≥16 years	5.3		
^a Occupational mobility rate = percentage of persons employed in an occupation who had voluntarily entered it from another occupation.			

^a Occupational mobility rate = percentage of persons employed in an occupation who had voluntarily entered it from another occupation.

Table 16-4. Confidence in Recommendations for Occupational Mobility

General Assessment Factors	Rationale	Rating
Soundness		Medium
<i>Adequacy of Approach</i>	Both studies are based on the U.S. Census Bureau's Current Population Survey which uses valid methodologies and approaches and is representative of the U.S. population with sample sizes of approximately 50,000 a month. Both studies are secondary analyses based on supplemental data to the January, 1987, Current Population Survey (a U.S. Census publication).	
<i>Minimal (or Defined) Bias</i>	Much of the original study data is not available. Only median values are reported. There is minimal concern about sampling and non-sampling error and non-response bias as in all surveys based on statistical samples.	
Applicability and Utility		Medium
<i>Exposure Factor of Interest</i>	Occupational tenure was the focus of both key studies.	
<i>Representativeness</i>	The data are statistically representative of the U.S. population.	
<i>Currency</i>	The data were collected over 20 years ago in 1986 and 1987. It is questionable whether the results would be the same if current data were analyzed based on changes in the economy that have occurred since the study was conducted.	
<i>Data Collection Period</i>	Data were collected in 1986–1987.	
Clarity and Completeness		Medium
<i>Accessibility</i>	The studies are widely available to the public. The Current Population Survey January, 1987: Occupational Mobility and Job Tenure data are available from the U.S. Census Bureau.	
<i>Reproducibility</i>	Results can be reproduced and methodology can be followed and evaluated.	
<i>Quality Assurance</i>	Quality assurance methods were not well described.	
Variability and Uncertainty		High
<i>Variability in Population</i>	The study provided averages according to sex, race, and education; age averages and percentiles were provided.	
<i>Uncertainty</i>	The studies are based on recall data.	
Evaluation and Review		Medium
<i>Peer Review</i>	The studies received a high level of peer review.	
<i>Number and Agreement of Studies</i>	There are 2 key studies based on the same data source.	
Overall Rating		Medium

Table 16-5. Recommended Values for Population Mobility

	Mean	95 th Percentile	Source
Residential Occupancy Period	12 years	33 years	(Johnson and Capel, 1992). See Table 16-108.
Current Residence Time	13 years	46 years	(U.S. Census Bureau, 2008a). See Table 16-111.

Chapter 16—Activity Factors

Table 16-6. Confidence in Recommendations for Population Mobility		
General Assessment Factors	Rationale	Rating
Soundness		Medium
<i>Adequacy of Approach</i>	Both key studies are based on U.S. Census Bureau studies which used valid data collection methodologies and approaches and are representative of the U.S. population.	
<i>Minimal (or Defined) Bias</i>	Data do not account for each member of the household; values are more realistic estimates for the individual's total residence time than the average time a household has been living at its current residence. The moving process was modeled in Johnson and Capel (1992). For the mean and percentile calculations of U.S. Census Bureau (2008a) data, an even distribution was assumed within different ranges which may bias the statistics.	
Applicability and Utility		Medium
<i>Exposure Factor of Interest</i>	The Census data provided length of time at current residence. The other study used modeling to estimate total time.	
<i>Representativeness</i>	The sample surveyed was statistically representative of the U.S. population.	
<i>Currency</i>	The data were collected in 2007 and 1985–1987, and reported in 2008 and 1992, respectively.	
<i>Data Collection Period</i>	Data were collected throughout the calendar year.	
Clarity and Completeness		High
<i>Accessibility</i>	The studies are widely available to the public.	
<i>Reproducibility</i>	Results can be reproduced or methodology can be followed and evaluated.	
<i>Quality Assurance</i>	Quality assurance is discussed in the documentation on the U.S. Census Bureau studies.	
Variability and Uncertainty		Medium
<i>Variability in Population</i>	The study provided data by age and sex. Variability across several geographic regions was noted. Type of ownership was also addressed.	
<i>Uncertainty</i>	The U.S. Census Bureau data was truncated at 65 years.	
Evaluation and Review		High
<i>Peer Review</i>	The studies received high levels of peer review and appear in publications.	
<i>Number and Agreement of Studies</i>	The 2 studies produced similar results.	
Overall Rating		Medium

16.3. ACTIVITY PATTERNS

16.3.1. Key Activity Pattern Studies

16.3.1.1. Wiley et al. (1991)—*Study of Children's Activity Patterns*

The California Study of Children's Activity Patterns survey (Wiley et al., 1991) provided estimates of the time children spent in various activities and locations (microenvironments) on a typical day. The sample population consisted of 1,200 children, under 12 years of age, selected from English-speaking households using Random Digit Dial (RDD) methods. This represented a survey response rate of 77.9%. One child was selected from each household. If the selected child was less than 9 years old, the adult in the household who spent the most time with the child responded. However, if the selected child was between 9 and 11 years old, that child responded. The population was also stratified to provide representative estimates for major regions of the state. The survey questionnaire included a time diary which provided information on the children's activity and location patterns based on a 24-hour recall period. In addition, the survey questionnaire included questions about potential exposure to sources of indoor air pollution (e.g., presence of smokers) on the diary day, and the socio-demographic characteristics of children and adult respondents. The questionnaires and the time diaries were administered via a computer-assisted telephone interviewing (CATI) technology (Wiley et al., 1991). The telephone interviews were conducted during April 1989 to February 1990 over 4 seasons: spring (April to June 1989), summer (July to September 1989), fall (October to December 1989), and winter (January to February 1990).

The data obtained from the survey interviews resulted in 10 major activity categories, 113 detailed activity codes, 6 major categories of locations, and 63 detailed location codes. The time respondents under 12 years of age spent in the 10 activity categories (plus a "don't know" or non-coded activity category) are presented in Table 16-7. For each of the 10 activity categories, this table presents the mean duration for all survey participants, the percentage of respondents who reported participating in the activity (i.e., percent doers), and the mean, median, and maximum duration for only those survey respondents who engaged in the activity (i.e., doers). It also includes the detailed activity with the highest mean duration of time for each activity category. The activity category with the highest time expenditure was personal needs and care, with a mean of 794 minutes/day (13.2 hours/day). Night sleep was the detailed activity that had the highest mean

duration in that activity category. The activity category "don't know" had a mean duration of about 2 minutes/day and only 4% of the respondents reported missing activity time.

Table 16-8 presents the mean time spent in the 10 activity categories by age and sex. Because the original source data were available, U.S. EPA re-analyzed the data according to the standardized age categories used in this handbook. Differences between activity patterns in boys and girls tended to be small. Table 16-9 presents the mean time spent in the 10 activity categories grouped by season and geographic region in the state of California. There were seasonal differences for 5 activity categories: personal needs and care, education, entertainment/social, recreation, and communication/passive leisure. Time expenditure differences in various regions of the state were minimal for childcare, work-related, goods/services, personal needs and care, education, entertainment/social, and recreation.

Table 16-10 presents the distribution of time across 6 location categories. The mean duration for all survey participants, the percent of respondents engaging in the activity (i.e., percent doers); the mean, median, and maximum duration for doers only; and the detailed locations with the highest average time expenditure are shown. For all survey respondents, the largest mean amount of time spent was at home (1,078 minutes/day); 99% of respondents spent time at home (mean of 1,086 minutes/day for these individuals only). Table 16-11 and Table 16-12 show the average time spent in the 6 locations grouped by age and sex, and season and region, respectively. Again, because the original source data were available, the age categories used by Wiley et al. (1991) have been replaced in Table 16-11 by the standardized age categories used in this handbook. There were relatively large differences among the age groups in time expenditure for educational settings (see Table 16-11). There were small differences in time expenditure at the 6 locations by region, but time spent in school decreased in the summer months compared with other seasons (see Table 16-12).

Table 16-13 shows the average time children spent in proximity to gasoline fumes and gas oven fumes. In general, the sampled children spent more time closer to gasoline fumes than to gas oven fumes. The age categories in Table 16-13 have been modified to conform to the standardized categories used in this handbook.

Chapter 16—Activity Factors

The U.S. EPA estimated the total time indoors and outdoors using the data from the Wiley et al. (1991) study. Activities performed indoors were assumed to include household work, child care, personal needs and care, education, and communication/passive leisure. The average times spent in these indoor activities and half the time spent in each activity which could have occurred either indoors or outdoors (i.e., work-related, goods/services, organizational activities, entertainment/social, don't know/not coded) were summed. Table 16-14 summarizes the results of this analysis using the standard age groups.

A limitation of this study is that the sampling population was restricted to only English-speaking households; therefore, the data obtained do not represent the diverse population group present in California. Another limitation is that time use values obtained from this survey were based on short-term recall (24-hour) data; therefore, the data set obtained may be biased. Other limitations are as follows: the survey was conducted in California and is not representative of the national population, and the significance of the observed differences in the data obtained (i.e., sex, age, seasons, and regions) were not tested statistically. An advantage of this study is that time expenditure in various activities and locations were presented for children grouped by age, sex, and season. Also, potential exposures of respondents to pollutants were explored in the survey. Another advantage is the use of the CATI program in obtaining time diaries, which allows automatic coding of activities and locations onto a computer tape, and allows activities forgotten by respondents to be inserted into their appropriate position during interviewing.

**16.3.1.2. U.S. EPA (1996)—Descriptive Statistics
Tables From a Detailed Analysis of the
National Human Activity Pattern Survey
(NHAPS) Data**

U.S. EPA (1996) analyzed data collected by the National Human Activity Pattern Survey. This survey was conducted by U.S. EPA and is the largest and most current human activity pattern survey available (U.S. EPA, 1996). Data for 9,386 respondents in the 48 contiguous United States were collected via minute-by-minute 24-hour diaries. NHAPS was conducted from October 1992 through September 1994 by the University of Maryland's Survey Research Center using CATI technology to collect 24-hour retrospective diaries and answers to a number of personal and exposure related questions from each respondent. Detailed data were collected

for a maximum of 82 different possible locations, and a maximum of 91 different activities. Participants were selected using a RDD method. The response rate was 63% overall. If the chosen respondent was a child less than 10 years of age, an adult in the household gave a proxy interview. Each participant was asked to recount their entire daily routine from midnight to midnight immediately previous to the day that they were interviewed. The survey collected information on duration and frequency of selected activities and of the time spent in selected microenvironments. In addition, demographic information was collected for each respondent to allow for statistical summaries to be generated according to specific groups of the U.S. population (i.e., by sex, age, race, employment status, census region, season, etc.). Saturdays and Sundays were over sampled to ensure an adequate weekend sample.

For children, the source data from U.S. EPA for selected locations, both indoors and outdoors, and activities have been reviewed and re-analyzed by U.S. EPA to conform to the age categories recommended in *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). This analysis was weighted according to geographic, socioeconomic, time/season, and other demographic factors to ensure that results were representative of the U.S. population. The weighted sample matched the 1990 U.S. census population for each sex, age group, census region, and the day-of-week and seasonal responses were equally distributed.

Table 16-15 through Table 16-64 provide data from the NHAPS study. Because no data were available on subjects' age in months, age groups less than 1 year old were consolidated into a single group. These tables provide statistics for 24-hour cumulative time spent (mean, minimum, percentiles, and maximum) in selected locations or engaging in selected activities. The original analysis generated statistics for the subset of the survey population that reported being in the location or doing the activity in question (i.e., doers only). For the reanalysis, statistics were calculated for the entire survey population (i.e., whole population) and for doers only. When the sample size was 10 persons or fewer, percentile values were not calculated.

Re-analyzed data are presented for the time children, aged birth to less than 21 years, spent in selected locations both indoors and outdoors and doing various selected activities. Each children only table is followed by a table for the whole population which presents data for specific populations (i.e., by sex, age, race, ethnicity, employment, education, Census region, day of the week, season, asthma

status, and bronchitis/emphysema status) and includes the time adults, aged 18 years and older, spent in various locations and doing various activities. Table 16-15 and Table 16-16 present data for time spent in rooms of the house (e.g., kitchen, bathroom, bedroom, and garage), and all rooms combined, for children and by demographic characteristics (including adulthood) respectively. Table 16-17 and Table 16-18 present data for time spent in other indoor locations (e.g., restaurants, indoors at school, and grocery/convenience stores). Table 16-19 and Table 16-20 present data for the time survey participants spent outdoors on school grounds/playgrounds, parks or golf courses, or pool rivers, or lakes.

Table 16-21 provides data on time spent in indoor and outdoor environments for children birth to <21 years of age. The U.S. EPA estimated the time spent indoors by adding the average times spent indoors at the respondents' home (kitchen, living room, bathroom, etc.), at other houses, and inside other locations such as school, restaurants, etc. Time outdoors was estimated by adding the average time spent outdoors at the respondents' pool and yard, others' pool and yard, and outside other locations such as sidewalk, street, neighborhood, parking lot, service station/gas station, school grounds, park/golf course, pool, river, lake, farm, etc. Table 16-22 provides data on time spent in outdoor and indoor environments for adults aged 18 years and older. The average time spent outdoors was estimated by summing the average time spent outdoors away from the residence and the average time spent outdoors at the residence. Note that these averages are for doers only and thus over-estimate the total time spent in the environments for the population.

Table 16-23 and Table 16-24 present data for the time spent in various types of vehicles and mass transit (i.e., car, truck/van, bus, trains, airplanes), and in all vehicles combined. Table 16-25 and Table 16-26 present data for the time children and adults spent in various major activity categories (e.g., sleeping, napping, eating, attending school, outdoor recreation, active sports, exercise, and walking). Table 16-27 presents data for activities associated with time spent working.

Table 16-28 through Table 16-36 provide data related to showering and bathing. Data on handwashing activities are in Table 16-37 and Table 16-38. Table 16-39 and Table 16-40 provide data for children on monthly swimming (in a freshwater pool) frequency and swimming duration, respectively. Table 16-41 and Table 16-42 provide data by demographic characteristics (including adulthood) on monthly swimming (in a freshwater

pool) frequency and swimming duration, respectively. Table 16-43 provides data on the time children spent playing on dirt, sand/gravel, or grass, and Table 16-44 displays these data by demographic characteristics (including adulthood).

Table 16-45 and Table 16-46 provide data on the number of minutes spent near excessive dust. Table 16-47 and Table 16-48 provide information on frequency of sweeping or vacuuming. Table 16-49 through Table 16-51 provide information on time spent in the presence of smokers and time spent smoking. Table 16-52 through Table 16-64 provide information on activities that may be related to specific sources of pollution (e.g., time spent near open flames, time spent near heavy traffic, frequency of use of dishwashers and washing machines). For this data set, the authors' original age categories for children were used because the methodology used to generate these data could not be reproduced.

The advantages of the NHAPS data set are that it is representative of the U.S. population. The reanalysis done by U.S. EPA to get estimates for childhood age groups that correspond to the *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005) was weighted and thus the results presented are balanced geographically, seasonally, and for day/time. Also, the NHAPS is inclusive of all ages, sexes, and races. A disadvantage of the study is that for the standard age categories, the number of respondents is small for the "doers" of many activities. In addition, the durations exceeding 60, 120, and 181 minutes were not collected for some activities. Therefore, the actual time spent at the high end of the distribution for these activities could not be accurately estimated. In addition, some of the activities were not necessarily mutually exclusive (e.g., time spent in active sports likely overlaps with exercise time).

16.3.2. Relevant Activity Pattern Studies

16.3.2.1. Hill (1985)—Patterns of Time Use

Hill (1985) investigated the total amount of time American adults spend in 1 year performing various activities and the variation in time use across 3 different dimensions: demographic characteristics, geographical location, and seasonal characteristics. In this study, time estimates were based on data collected from time diaries in 4 waves (1/season) of a survey conducted in the fall of 1975 through the fall of 1976 for the 1975–1976 Time Allocation Study. The sampling periods included 2 weekdays, 1 Saturday and 1 Sunday. The information gathered was in response to the survey question "What were

Chapter 16—Activity Factors

you doing?” The survey also provided information on secondary activities (i.e., respondents performing more than 1 activity at the same time). Hill (1985) analyzed time estimates from 971 individuals for 10 broad categories of activities based on data collected from 87 activities. These estimates included seasonal variation in time use patterns and comparisons of time use patterns for different days of the week.

Analysis of the 1975–1976 survey data revealed very small regional differences in time use among the broad activity patterns (Hill, 1985). The weighted mean hours/week spent performing the 10 major activity categories presented by region are shown in Table 16-65. Table 16-66 presents the time spent per day, by the day of the week for the 10 major activity categories. Adult time use was dominated in descending order by personal care (including sleep), market work, passive leisure, and housework. Collectively, these activities represent about 80% of available time (Hill, 1985).

According to Hill (1985), sleep (included in personal care) was the single most dominant activity averaging about 56.3 hours/week. Television watching (included in passive leisure) averaged about 21.8 hours/week, and housework activities averaged about 14.7 hours/week. Weekdays were predominantly market-work oriented. Weekends (Saturday and Sunday) were predominantly devoted to household tasks (“sleeping in,” socializing, and active leisure) (Hill, 1985). Table 16-67 presents the mean time spent performing these 10 groups of activities during each wave of interview (fall, winter, spring, and summer). Adjustments were made to the data to assure equal distributions of weekdays, Saturdays, and Sundays (Hill, 1985). The data indicate that the time periods adults spent performing market work, child care, shopping, organizational activities, and active leisure were fairly constant throughout the year (Hill, 1985). The mean hours spent per week in performing the 10 major activity patterns are presented by sex in Table 16-68. These data indicate that time use patterns determined by data collected for the mid-1970’s survey show sex differences. Men spent more time on activities related to labor market work and education, and women spent more time on household work activities.

A limitation associated with this study is that the time use data were obtained from an old survey conducted in the mid-1970s. Because of fairly rapid changes in American society, applying these data to current exposure assessments may result in some biases. Another limitation is that time use data were not presented for children. An advantage of this study is that time diaries were kept and data were not based

on recall. The former approach may result in a more accurate data set. Another advantage of this study is that the survey is seasonally balanced since it was conducted throughout the year and the data are from a large survey sample.

16.3.2.2. Timmer et al. (1985)—How Children Use Time

Timmer et al. (1985) conducted a study using the data obtained on children’s time use from a 1981–1982 panel study. Data were obtained for 389 children between 3 and 17 years of age. Data were collected using a time diary and a standardized interview. The time diary involved children reporting their activities beginning at 12:00 a.m. the previous night, the duration and location of each activity, the presence of another individual, and whether they were performing other activities at the same time. The standardized interview was administered to the children to gather information about their psychological, intellectual (using reading comprehension tests), and emotional well-being; their hopes and goals; their family environment; and their attitudes and beliefs.

For preschool children, parents provided information about the child’s previous day’s activities. Children in first through third grades completed the time diary with their parents’ assistance and, in addition, completed reading tests. Children in 4th grade and above provided their own diary information and participated in the interview. Parents were asked to assess their children’s socioemotional and intellectual development, and a survey form was sent to a teacher of each school-age child to evaluate their socioemotional and intellectual development. The activity descriptor codes used in this study were developed by Juster et al. (1983).

The mean time spent performing major activities on weekdays and weekends by age, sex, and type of day is presented in Table 16-69. On weekdays, children spend about 40% of their time sleeping, 20% in school, and 10% eating, and performing personal care activities (Timmer et al., 1985). The data in Table 16-69 indicate that girls spent more time than boys performing household work and personal care activities and less time playing sports. Also, the children spent most of their free time watching television.

Table 16-70 presents the mean time children spent during weekdays and weekends performing major activities by 5 different age groups. The significant effects of each variable (i.e., age and sex) are also shown. Older children spent more time performing household and market work, studying,

and watching television and less time eating, sleeping, and playing. The authors estimated that, on average, boys spent 19.4 hours a week and girls spent 17.8 hours/week watching television.

U.S. EPA estimated the total time indoors and outdoors using the Timmer et al. (1985) data. Activities performed indoors were assumed to include household work, personal care, eating, sleeping, attending school, studying, attending church, watching television, and engaging in household conversations. The average times spent in these indoor activities and half the time spent in each activity which could have occurred indoors or outdoors (e.g., market work, sports, hobbies, art activities, playing, reading, and other passive leisure) were summed. Table 16-71 summarizes the results of this analysis by age group and day of the week.

A limitation associated with this study is that it was conducted in 1981. It is likely that activity patterns of children have changed from 1981 to the present. Thus, the application of these data to current exposure assessments may bias their results. Another limitation is that the data do not provide overall annual estimates of children's time use since data were collected only during the time of the year when children attended school and not during school vacations. An advantage of this survey is that diary recordings of activity patterns were kept and the data obtained were not based entirely on recall. Another advantage is that parents assisted younger children with keeping their diaries and with interviews, minimizing any bias that may have been created by having younger children record their own data.

16.3.2.3. Robinson and Thomas (1991)—Time Spent in Activities, Locations, and Microenvironments: A California-National Comparison

Robinson and Thomas (1991) reviewed and compared data from the 1987–1988 California Air Resources Board (CARB) time-activity study for California residents and from a similar 1985 national study, *Americans' Use of Time*, conducted at the University of Maryland. Both studies used the diary approach to collect data. Time-use patterns were collected for individuals aged 12 years and older. Telephone interviews based on the RDD procedure were conducted for 1,762 and 2,762 respondents for the CARB study and the national study, respectively. Robinson and Thomas (1991) defined a set of 16 microenvironments based on the activity and location codes employed in the 2 studies. The mean durations of time spent in the 16 microenvironments by age, are presented in Table 16-72. In both studies,

children and adults spent the majority of their time sleeping, and engaging in leisure and work/study-related activities.

Table 16-73 shows the mean time spent in the 10 major activities by sex and for all respondents between the ages of 18-64 years. Table 16-74 presents the mean time spent at 3 major locations for the CARB and national study grouped by total sample and sex, ages 18-64 years. The mean duration of time spent in locations for total sample population, 12 years and older, across 3 types of locations is presented in Table 16-75 for both studies.

The limitations associated with the Robinson and Thomas (1991) study are that the CARB survey was performed in California only and may not be representative of the U.S. population as a whole, and the studies were conducted in the 1980s and activity patterns may have changed over time. Another limitation is that the data are based on short-term studies. Finally, the available data could not be re-analyzed to conform to the standardized age categories used in this handbook.

16.3.2.4. Funk et al. (1998)—Quantifying the Distribution of Inhalation Exposure in Human Populations: Distribution of Time Spent by Adults, Adolescents, and Children at Home, at Work, and at School

Funk et al. (1998) used the data from the CARB study to determine distributions of exposure time by tracking the time spent participating in daily activities for male and female children, adolescents, and adults. CARB performed 2 studies from 1987 to 1990; the first was focused on adults (18 years and older) and adolescents (12 to 17 years old), and the second focused on children (6 to 11 years old). The targeted groups were non-institutionalized English speaking Californians with telephones in their residences. Individuals were contacted by telephone and asked to account for every minute within the previous 24 hours, including the amount of time spent on an activity and the location of the activity. The surveys were conducted on different days of the week as well as different seasons of the year.

Using the location descriptors provided in the CARB study, Funk et al. (1998) categorized the activities into 2 groups, “at home” (any activity at principal residence) and “away.” Each activity was assigned to 1 of 3 inhalation rate levels (low, moderate, or high) based on the level of exertion expected from the activity. Ambiguous activities were assigned to moderate inhalation rate levels. Among the adolescents and children studied, means

Chapter 16—Activity Factors

were determined for the aggregate age groups. Sample sizes are shown in Table 16-76.

Funk et al. (1998) used several statistical methods, such as Chi-square, Kolmogorov-Smirnov, and Anderson-Darling, to determine whether the time spent in an activity group had a known distribution. Most of the activities performed by all individuals were assigned a low or moderate inhalation rate (see Table 16-77).

The aggregate time periods spent at home in each activity are shown in Table 16-78. Aggregate time spent at home performing different activities was compared between sexes. There were no significant differences between adolescent males and females in any of the activity groups (see Table 16-79). There were significant differences between males and females among adults in all activity groups except for the low activity group (see Table 16-58). In children, ages 6 to 11 years, differences between sex and age were observed at the low inhalation rate levels. There were significant differences ($p < 0.05$) between 2 age groups (6 to 8 years, and 9 to 11 years) and sex at the moderate inhalation rate level (see Table 16-80).

A limitation of this study was that large proportions of the respondents in the study did not participate in high-inhalation rate-level activities. The Funk et al. (1998) study was based on data from 1 geographic location, collected more than a decade ago. Thus, it may not be representative of current activities among the general population of the United States.

16.3.2.5. Cohen Hubal et al. (2000)—Children's Exposure Assessment: A Review of Factors Influencing Children's Exposure and the Data Available to Characterize and Assess That Exposure

Cohen Hubal et al. (2000) reviewed available data from the Consolidated Human Activity Database [CHAD, U.S. EPA (2009)], including activity pattern data, to characterize and assess environmental exposures to children. Data from the 2 key studies in this chapter (U.S. EPA, 1996; Wiley et al., 1991) are included in CHAD. CHAD was developed by the U.S. EPA's National Exposure Research Laboratory to provide access to existing human activity pattern data for use in exposure and risk assessment efforts. It is available online at <http://www.epa.gov/chadnet1/>. Data from twelve activity pattern studies conducted at the city, state, and national levels are included in CHAD. CHAD contains both the original raw data from each study and data modified based on predefined format

requirements. Modifications made to data included: recoding of variables to fit into them a common activity/location code system, and standardization of time diaries to an exact 24-hour length. Detailed information on the coding system and the studies included in CHAD is available in the CHAD User Manual, available at [http://oaspub.epa.gov/chad/CHAD_Datafiles\\$.startup#Manual](http://oaspub.epa.gov/chad/CHAD_Datafiles$.startup#Manual), and in McCurdy et al. (2000).

A total of 144 activity codes and 115 location codes were used in CHAD (McCurdy et al., 2000). Although some participants in a study conducted multiple activities, many activities were only conducted within a few studies. The same is true for activity locations. The selection of exposure estimates for a particular activity or particular location should be based on study parameters that closely relate to the exposure scenario being assessed. The maximum amount of time, on average, within a majority of the studies was sleeping or taking a nap, while the maximum amount of time spent at a particular location was at home or at work, depending on the study.

Many of the limitations of CHAD data arise from the incorporation of multiple studies into the time diary functions specified in CHAD. Activities and locations were coded similarly to the NHAPS study; studies with differing coding systems were modified to fit the NHAPS codes. In some cases start times and end times from a study had to be adjusted to fit a 24-hour period. Respondents were not randomly distributed in CHAD. For example, some cities or states were over sampled because entire studies were carried out in those places. Other studies excluded large groups of people such as smokers, or non-English speakers, or people without telephones. Many surveys were age restricted, or they preferentially sampled certain target groups. As a result, users are cautioned against using random individuals in CHAD to represent the U.S. population as a whole (Stallings et al., 2002).

CHAD contains 3,009 person-days of macroactivity data for 2,640 children less than 12 years of age (Cohen Hubal et al., 2000) (see Table 16-81). The number of hours these children spent in various microenvironments are shown in Table 16-82 and the time they spent in various activities indoors at home is shown in Table 16-83.

Cohen Hubal et al. (2000) noted that CHAD contains approximately "140 activity codes and 110 location codes, but the data generally are not available for all activity locations for any single respondent. In fact, not all of the codes were used for most of the studies. Even though many codes are used in macroactivity studies, many of the activity

codes do not adequately capture the richness of what children actually do. They are much too broadly defined and ignore many child-oriented behaviors. Thus, there is a need for more and better-focused research into children's activities."

U.S. EPA updated the analysis performed by Cohen Hubal et al. (2000) using CHAD data downloaded in 2000, sorted according to the age groups recommended in *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005). Table 16-84 and Table 16-85 show the results. In this analysis, individual study participants within CHAD whose behavior patterns were measured over multiple days were treated as multiple 1-day activity patterns. This is a potential source of error or bias in the results because a single individual may contribute multiple data sets to the aggregate population being studied.

Advantages of the CHAD database are that it includes data from 12 activity pattern studies and is a fairly comprehensive tool for cohort development and for simulating individuals within exposure assessments. However, because the database is comprised of separate studies, issues such as quality assurance and consistency between the studies are difficult to assess. In addition, current human activity pattern surveys do not collect data on microactivities that are important to understanding exposures, especially for children, nor do they discriminate sufficiently among activities important to developing energy expenditure estimates.

16.3.2.6. Wong et al. (2000)—Adult Proxy Responses to a Survey of Children's Dermal Soil Contact Activities

Wong et al. (2000) conducted telephone surveys to gather information on children's activity patterns as related to dermal contact with soil during outdoor play on bare dirt or mixed grass and dirt surfaces. This study, the second Soil Contact Survey (SCS-II), was a follow-up to the initial Soil Contact Survey (SCS-I), conducted in 1996, that primarily focused on assessing adult behavior related to dermal contact with soil and dust (Garlock et al., 1999). As part of SCS-I, information was gathered on the behavior of children under the age of 18 years, however, the questions were limited to clothing choices and the length of time between soil contact and hand washing. Questions were posed for SCS-II to further define children's outdoor activities and hand washing and bathing frequency. For both soil contact surveys households were randomly phoned in order to obtain nationally representative results. The adult

respondents were questioned as surrogates for 1 randomly chosen child under the age of 18 residing within the household.

In the SCS-II, of 680 total adult respondents with a child in their household, 500 (73.5%) reported that their child played outdoors on bare dirt or mixed grass and dirt surfaces (identified as "players"). Those children that reportedly did not play outdoors ("non-players") were typically very young (≤ 1 year) or relatively older (≥ 14 years). Of the 500 children that played outdoors, 497 played outdoors in warm weather months (April through October) and 390 were reported to play outdoors during cold weather months (November through March). These results are presented in Table 16-86. The frequency (days/week), duration (hours/day), and total hours/week spent playing outdoors was determined for those children identified as "players" (see Table 16-87). The responses indicated that children spent a relatively high percentage of time outdoors during the warmer months, and a lesser amount of time outdoors in cold weather. The median play frequency reported was 7 days/week in warm weather and 3 days/week in cold weather. Median play duration was 3 hours/day in warm weather and 1 hour/day during cold weather months.

Adult respondents were then questioned as to how many times per day their child washed his/her hands and how many times the child bathed or showered per week, during both warm and cold weather months. This information provided an estimate of the time between skin contact with soil and removal of soil by washing (i.e., exposure time). Hand washing and bathing frequencies for child players are reported in Table 16-88. Based on these results, hand washing occurred a median of 4 times per day during both warm and cold weather months. The median frequency for baths and showers was estimated to be 7 times per week for both warm and cold weather.

Based on reported household incomes, the respondents sampled in SCS-II tended to have higher incomes than that of the general population. This may be explained by the fact that phone surveys cannot sample households without telephones. Additional uncertainty or error in the study results may have occurred as a result of the use of surrogate respondents. Adult respondents were questioned regarding child activities that may have occurred in prior seasons, introducing the chance of recall error. In some instances, a respondent did not know the answer to a question or refused to answer. Table 16-89 compares mean play duration data from SCS-II to similar activities identified in NHAPS (U.S. EPA, 1996). Table 16-90 compares the number

Chapter 16—Activity Factors

of times per day a child washed his or her hands, based on data from SCS-II and NHAPS. As indicated in Table 16-89 and Table 16-90, where comparison is possible, NHAPS and SCS-II results showed similarities in observed behaviors.

An advantage of this study includes the fact that a random household survey was conducted to obtain nationally representative results. A limitation of the study is that questions were limited to clothing choices and the length of time between soil contact and hand washing. In addition, the participants were questioned about events from prior seasons, which may have introduced recall error.

**16.3.2.7. Graham and McCurdy (2004)—
Developing Meaningful Cohorts for
Human Exposure Models**

Graham and McCurdy (2004) used a statistical model (general linear model and analysis of variance [GLM/ANOVA]) to assess the significance of various factors in explaining variation in time spent outdoors, indoors and in motor vehicles. These factors, which are commonly used in developing cohorts for exposure modeling, included age, sex, weather, ethnicity, day type, and precipitation. Activity pattern data from CHAD, containing 30 or more records per day, were used in the analysis (Graham and McCurdy, 2004). Data from the 2 key studies in this chapter (U.S. EPA, 1996; Wiley et al., 1991) are included in CHAD.

Table 16-91 presents data on time spent outdoors for people who spent >0 time outdoors (i.e., doers). Graham and McCurdy (2004) found that all the factors evaluated were significant ($p < 0.001$) in explaining differences in time spent outdoors (Graham and McCurdy, 2004). An evaluation of sex differences in time spent outdoors by age cohorts was also conducted. Table 16-92 presents descriptive statistics and the results of the 2-sample Kolmogorov-Smirnov (K-S) test for this evaluation. As shown in Table 16-92, there were statistically significant sex differences in time spent outdoors starting with the 6 to 10 year old age category and continuing through all age groups, up to and including >64 years of age. In addition, Graham and McCurdy (2004) evaluated the effect of physical activity and concluded that this was the most important factor in explaining time spent outdoors. For time spent indoors (see Table 16-93), there were statistically significant effects for all the factors evaluated, with sex, weather, and day type being the most important variables. Regarding time spent in motor vehicles (see Table 16-94), precipitation was

the only factor found to have no significant effects (Graham and McCurdy, 2004).

Based on the results of these analyses, Graham and McCurdy (2004) noted that “besides age and sex, other important attributes for defining cohorts are the physical activity level of individuals, weather factors such as daily maximum temperature in combination with months of the year, and combined weekday/weekend with employment status.” The authors also noted that even though the factors evaluated were found to be statistically significant in explaining differences in time spent outdoors, indoors, and in motor vehicles, “parameters such as lifestyle and life stages that are absent from CHAD might have reduced the amount of unexplained variance.” The authors recommended that, in defining cohorts for exposure modeling, age and sex should be used as “first-order” attributes, followed by physical activity level, daily maximum temperature, and day type (weekend/weekday or day-of-the-week/working status) (Graham and McCurdy, 2004).

The CHAD database is a fairly comprehensive tool for cohort development and for simulating individuals within exposure assessments. However, the database is comprised of 12 separate studies, and because of this, issues such as quality assurance and consistency between the studies are difficult to assess. In addition, current human activity pattern surveys do not collect data on microactivities that are important to understanding exposures, especially for children, nor do they discriminate sufficiently among activities important to developing energy expenditure estimates. Other limitations of the CHAD database are described earlier in this chapter by Cohen Hubal et al. (2000) in Section 16.3.2.5.

**16.3.2.8. Juster et al. (2004)—Changing Times of
American Youth: 1983–2003**

Juster et al. (2004) evaluated changes in time use patterns of children by comparing data collected in a 1981–1982 pilot study of children ages 6 to 17 to data from the 2002–2003 Child Development Supplement (CDS) to the Panel Study of Income Dynamics (PSID). The 1981–1982 pilot study is the same study described in Timmer et al. (1985). The 2002–2003 CDS gathered 24-hour time diary data on 2,908 children ages 6 to 17; as was done in the 1997 CDS, information was collected on 1 randomly selected weekday and 1 randomly selected weekend day (Juster et al., 2004).

Table 16-95 and Table 16-96 present the mean time children spent (in minutes/day) performing major activities on weekdays and weekend days,

respectively, for the years 1981–1982 and 2002–2003. Table 16-97 shows the weekly time spent in these activities for the years 1981–1982 and 2002–2003. Juster et al. (2004) noted that the time spent in school and studying increased while time spent in active sports and outdoors activities decreased during the period studied.

An advantage of this survey is that diary recordings of activity patterns were kept and the data obtained were not based entirely on recall. Another advantage is that because parents assisted younger children with keeping their diaries and with interviews, minimizing any bias that may have been created by having younger children record their own data. A limitation associated with this study is that the data from the Timmer et al. (1985) study were collected in 1981 and it is likely that the activity patterns of children have changed from 1981 to the present. Another limitation is that the data from the CDS study do not provide overall annual estimates of children's time use since data were collected only during the time of the year when children attended school and not during school vacations.

16.3.2.9. Vandewater et al. (2004)—Linking Obesity and Activity Level With Children's Television and Video Game Use

Vandewater et al. (2004) evaluated children's media use and participation in active and sedentary activities using 24-hour time-use diaries collected in 1997, as part of the Child Development Supplement to the Panel Study of Income Dynamics. The PSID is an ongoing, longitudinal study of U.S. individuals and their families conducted by the Survey Research Center of the University of Michigan. In 1997, PSID families with children younger than 12 years of age completed the CDS and reported all activities performed by the children on 1 randomly selected weekday and 1 randomly selected weekend day. Since minorities, low-income families, and less educated individuals were oversampled in the PSID, sample weights were applied to the data (Vandewater et al., 2004). More information on the CDS can be found [on-line](http://psidonline.isr.umich.edu/CDS/) at <http://psidonline.isr.umich.edu/CDS/>.

Using time use diary data from 2,831 children participating in the CDS, Vandewater et al. (2004) estimated the time in minutes over the 2-day study period (i.e., sum of time spent on 1 weekday and 1 weekend day) that children spent watching television, playing games on video games consoles or computers, reading, and using computers for other purposes besides playing games. In addition, the time

spent participating in highly active (i.e., playing sports), moderately active (i.e., fishing, boating, camping, taking music lessons, and singing), and sedentary (i.e., using the phone, doing puzzles, playing board games, and relaxing) activities was determined. Table 16-98 presents the means and standard deviations for the time spent in the selected activities by age and sex.

A limitation of this study is that the survey was not designed for exposure assessment purposes. Therefore, the time use data set may be biased. However, the survey provides a database of current information on various human activities. This information can be used to assess various exposure pathways and scenarios associated with these activities.

16.3.2.10. U.S. Department of Labor (2007)—American Time Use Survey, 2006 Results

The American Time Use Study has been conducted annually since 2003 by the U.S. Department of Labor's (DOL) Bureau of Labor Statistics (U.S. Department of Labor, 2007). The purpose of the study is to collect "data on what activities people do during the day and how much time they spend doing them." In 2006, the survey focused on "the time Americans worked, did household activities, cared for household children, participated in educational activities, and engaged in leisure and sports activities." Approximately 13,000 individuals, 15 years of age and older, were interviewed during 2006. Participants were randomly selected and interviewed using the CATI method and were asked to recall their activities on the day before the interview. The survey response rate was 55.1% (U.S. Department of Labor, 2007). Data were collected for all days of the week, including weekends (i.e., 10% of the individuals were interviewed about their activities on 1 of the 5 weekdays, and 25% of the individuals were interviewed about their activities on 1 of the 2 weekend days). Demographic information, including age, sex, race/ethnicity, marital status, and educational level were also collected, and sample weights were applied to records to "reduce bias in the estimates due to differences in sampling and response rates across populations and days of the week." Data were collected for 17 major activities, which were subsequently combined into 12 categories for publication of the results. Table 16-99 provides information on the average amount of time spent in the 12 major time use categories by sex, age, race/ethnicity, marital status, and educational level (U.S. Department of Labor, 2007). Estimates of time

Chapter 16—Activity Factors

use in sub-categories of the 12 major categories are presented in Table 16-100. The majority of time was spent engaging in personal care activities (9.41 hours/day) which included sleeping (8.63 hours/day), followed by leisure and sports activities (5.09 hours/day), and work activities (3.75 hours/day). Note that because these data are averaged over both weekdays and weekends for the entire year, the amount of time spent daily on work-related activities does not reflect that of a typical work day.

Table 16-101 provides estimates of time use for all children ages 15 to 19 years by sex. It also provides a more detailed breakdown of the Leisure and Sports category for all children, ages 15 to 19 years old.

The limitation of this study is that it did not account for all activities during the day and therefore estimates about total time indoors and outdoors could not be calculated. The advantages are the large sample size, the representativeness of the sample, and the currency of the data.

16.3.2.11. Nader et al. (2008)—Moderate-to-Vigorous Physical Activity From Ages 9 to 15 Years

Nader et al. (2008) conducted a longitudinal study of 1,032 children from ages 9 to 15 years. The purpose of the study was to determine the amount of time children 9 to 15 years of age engaged in moderate-to-vigorous physical activities (MVPA) and compare results with the recommendations issued by the U.S. Department of Health and Human Services and the U.S. Department of Agriculture (USDA, 2005) of a minimum of 60 minutes/day. Participants were recruited from university-based community hospitals located in Arkansas, California, Kansas, Massachusetts, Pennsylvania, Virginia, Washington, North Carolina, and Wisconsin. Children's activity levels were recorded for 4 to 7 days using an accelerometer, set so that it recorded minute-by-minute movement counts. The study participants included 517 boys and 515 girls.

The study found that at age nine years, children engaged in 3 hours of MVPA/day. By age 15 years, the amount of time engaged in MVPA was dropped to 49 minutes/day on weekdays and 35 minutes/day on weekends. Boys spent 18 more minutes/day of MVPA than girls on weekdays and 13 more minutes/day on weekends. Estimates of the mean time spent in MVPA by various age groups are presented in Table 16-102.

Advantages of this study include the fact that both weekdays and weekends were included in the

study and the use of an accelerometer to measure physical activity. A limitation of the study is the fact that the sample of children was not nationally representative of the U.S. population. In addition, the study did not provide information about the amount of time spent at specific activities.

16.4. OCCUPATIONAL MOBILITY

16.4.1. Key Occupational Mobility Studies

16.4.1.1. Carey (1988)—Occupational Tenure in 1987: Many Workers Have Remained in Their Fields

Carey (1988) presented median occupational and employer tenure for different age groups, sex, earnings, ethnicity, and educational attainment. Occupational tenure was defined as “the cumulative number of years a person worked in his or her current occupation, regardless of number of employers, interruptions in employment, or time spent in other occupations” (Carey, 1988). The information presented was obtained from supplemental data to the January 1987 Current Population Study, a U.S. Census Bureau publication. Carey (1988) did not present information on the survey design.

The median occupational tenure by age and sex, race, and employment status are presented in Table 16-103, Table 16-104, and Table 16-105, respectively. The median occupational tenure of the working population (109.1 million people) 16 years of age and older in January of 1987 was 6.6 years (see Table 16-103). Table 16-103 also shows that median occupational tenure increased from 1.9 years for workers 16 to 24 years old to 21.9 years for workers 70 years and older. The median occupational tenure for men 16 years and older was higher (7.9 years) than for women of the same age group (5.4 years). Table 16-104 indicates that Whites had longer occupational tenure (6.7 years) than Blacks (5.8 years), and Hispanics (4.5 years). Full-time workers had more occupational tenure than part-time workers 7.2 years and 3.1 years, respectively (see Table 16-105).

Table 16-106 presents the median occupational tenure among major occupational groups. The median tenure ranged from 4.1 years for service workers to 10.4 years for people employed in farming, forestry, and fishing.

The strength of an individual's attachment to a specific occupation has been attributed to the individual's investment in education (Carey, 1988). Carey (1988) reported the median occupational tenure for the surveyed working population by age and educational level. Workers with 5 or more years of college had the highest median occupational tenure

of 10.1 years. Workers that were 65 years and older with 5 or more years of college had the highest occupational tenure level of 33.8 years. The median occupational tenure was 10.6 years for self-employed workers and 6.2 years for wage and salary workers (Carey, 1988).

A limitation associated with this study is that the survey design employed in the data collection was not presented, though it can be found on the U.S. Census Bureau's website. Therefore, the validity and accuracy of the data set cannot be determined. Another limitation is that only median values were reported in the study. An advantage of this study is that occupational tenure (years spent in a specific occupation) was obtained for various age groups by sex, ethnicity, employment status, and educational level. Another advantage of this study is that the data were based on a survey population which appears to represent the general U.S. population.

16.4.1.2. Carey (1990)—Occupational Tenure, Employer Tenure, and Occupational Mobility

Carey (1990) conducted another study that was similar in scope to the study of Carey (1988). The January 1987 Current Population Study was used. This study provided data on occupational mobility and employer tenure in addition to occupational tenure. Occupational tenure was defined in Carey (1988) as the “the cumulative number of years a person worked in his or her current occupation, regardless of number of employees, interruptions in employment, or time spent in other locations.” Employer tenure was defined as “the length of time a worker has been with the same employer,” while occupational mobility was defined as “the number of workers who change from 1 occupation to another” (Carey, 1990). Occupational mobility was measured by asking individuals who were employed in both January 1986 and January 1987 if they were doing the same kind of work in each of these months (Carey, 1990). Carey (1990) further analyzed the occupational mobility data and obtained information on entry and exit rates for occupations. These rates were defined as “the percentage of persons employed in an occupation who had voluntarily entered it from another occupation” and an exit rate was defined as “the percentage of persons employed in an occupation who had voluntarily left for a new occupation” (Carey, 1990).

Table 16-107 shows the voluntary occupational mobility rates in January 1987 for workers 16 years and older. For all workers, the overall voluntary occupational mobility rate during that year was 5.3%.

These data also show that younger workers left occupations at a higher rate than older workers. Carey (1990) reported that 10 million of the 100.1 million individuals employed in January 1986 and in January 1987 had changed occupations during that period, resulting in an overall mobility rate of 9.9%. Executive, administrative, and managerial occupations had the highest entry rate of 5.3%, followed by administrative support (including clerical) at 4.9%. Sales had the highest exit rate of 5.3% and service had the 2nd highest exit rate of 4.8% (Carey, 1990). In January 1987, the median employer tenure for all workers was 4.2 years. The median employee tenure was 12.4 years for those workers that were 65 years of age and older (Carey, 1990).

Because the study was conducted by Carey (1990) in a manner similar to that of the previous study (Carey, 1988), the same advantages and disadvantages associated with Carey (1988) also apply to this data set.

16.5. POPULATION MOBILITY

16.5.1. Key Population Mobility Studies

16.5.1.1. Johnson and Capel (1992)—A Monte Carlo Approach to Simulating Residential Occupancy Periods and Its Application to the General U.S. Population

Johnson and Capel (1992) developed a methodology to estimate the distribution of the residential occupancy period (ROP) in the national population. ROP denotes the time (years) between a person moving into a residence and the time the person moves out or dies. The methodology used a Monte Carlo approach to simulate a distribution of ROP for 500,000 persons using data on population, mobility, and mortality.

The methodology consisted of 6 steps. The 1st step defined the population of interest and categorized them by location, sex, age, sex, and race. Next the demographic groups were selected and the fraction of the specified population that fell into each group was developed using U.S. Census Bureau data. A mobility table was developed based on census data, which provided the probability that a person with specified demographics did not move during the previous year. The fifth step used data on vital statistics published by the National Center for Health Statistics and developed a mortality table which provided the probability that individuals with specific demographic characteristics would die during the upcoming year. As a final step, a computer based algorithm was used to apply a Monte Carlo approach to a series of persons selected at random from the population being analyzed.

Chapter 16—Activity Factors

Table 16-108 presents the results for residential occupancy periods for the total population, by sex. The estimated mean ROP for the total population was 11.7 years. The distribution was skewed (Johnson and Capel, 1992): the 25th, 50th, and 75th percentiles were 3, 9, and 16 years, respectively. The 90th, 95th, and 99th percentiles were 26, 33, and 47 years, respectively. The mean ROP was 11.1 years for males and 12.3 years for females, and the median value was 8 years for males and 9 years for females.

Descriptive statistics for groups defined by current ages were also calculated. These data, presented by sex, are shown in Table 16-109. The mean ROP increases from age 3 to age 12 years and there is a noticeable decrease at age 24 years. However, there is a steady increase from age 24 through age 81 years.

There are a few biases within this methodology that have been noted by the authors. The probability of not moving is estimated as a function only of sex and age. The Monte Carlo process assumes that this probability is independent of (1) the calendar year to which it is applied, and (2) the past history of the person being simulated. These assumptions, according to Johnson and Capel (1992), are not entirely correct. They believe that extreme values are a function of sample size and will, for the most part, increase as the number of simulated persons increases.

16.5.1.2. U.S. Census Bureau (2008a)—American Housing Survey for the United States in 2007

This survey is a national sample of 55,000 interviews in which data were collected from present owners, renters, Black householders, and Hispanic householders. The data reflect the number of years a unit has been occupied and represent all occupied housing units that the residents' rented or owned at the time of the survey.

The results of the survey pertaining to residence time of owner/renter occupied units in the United States are presented in Table 16-110. Using the data in Table 16-110, the percentages of householders living in houses for specified time ranges were determined and are presented in Table 16-111. Based on the U.S. Census Bureau data in Table 16-111, the 50th percentile and the 90th percentile values were calculated for the number of years lived in the householder's current house. These values were calculated by apportioning the total sample size (110,692 households) to the indicated percentile associated with the applicable range of years lived in the current home. Assuming an even distribution

within the appropriate range, the 50th and 90th percentile values for years living in the current home were determined to be 8.0 and 32.0 years, respectively. Based on the above data, 8 and 32 years are assumed to best represent a central tendency estimate of length of residence and upper percentile estimate of residence time, respectively.

A limitation associated with the above analysis is the assumption that there is an even distribution within the different ranges. As a result, the 50th and 90th percentile values may be biased.

16.5.2. Relevant Population Mobility Studies

16.5.2.1. Israeli and Nelson (1992)—Distribution and Expected Time of Residence for U.S. Households

In risk assessments, the average current residence time (time since moving into current residence) has often been used as a substitute for the average total residence time (time between moving into and out of a residence) (Israeli and Nelson, 1992). Israeli and Nelson (1992) have estimated distributions of expected time of residence for U.S. households. Distributions and averages for both current and total residence times were calculated for several housing categories using the 1985 and 1987 U.S. Census Bureau housing survey data. The total residence time distribution was estimated from current residence time data by modeling the moving process (Israeli and Nelson, 1992). Israeli and Nelson (1992) estimated the average total residence time for a household to be approximately 4.6 years or 1/6 of the expected life span (see Table 16-112). The maximal total residence time that a given fraction of households will live in the same residence is presented in Table 16-113. For example, only 5% of the individuals in the "All Households" category will live in the same residence for 23 years and 95% will move in less than 23 years.

The authors note that the data presented are for the expected time a household will stay in the same residence. The data do not predict the expected residence time for each member of the household, which is generally expected to be smaller (Israeli and Nelson, 1992). These values are more realistic estimates for the individual total residence time, than the average time a household has been living at its current residence. The expected total residence time for a household is consistently less than the average current residence time. This is the result of greater weighting of short residence time when calculating the average total residence time than when calculating the average current residence time (Israeli and Nelson, 1992). When averaging total residence

over a time interval, frequent movers may appear several times, but when averaging current residence times, each household appears only once (Israeli and Nelson, 1992). According to Israeli and Nelson (1992), the residence time distribution developed by the model is skewed and the median values are considerably less than the means, which are less than the average current residence times.

Advantages of this study are the large sample size and its representativeness to the U.S. population, since it was based on U.S. Census Bureau housing survey data. Several limitations of the study have been noted by Israeli and Nelson (1992) above. An additional limitation is the age of the study and the fact that the U.S. Census Bureau housing survey is based on recall data.

16.5.2.2. National Association of Realtors (NAR) (1993)—The Home Buying and Selling Process

The NAR survey was conducted by mailing a questionnaire to 15,000 home buyers throughout the United States who purchased homes during the second half of 1993. The survey was conducted in December 1993 and 1,763 usable responses were received, equaling a response rate of 12% (NAR, 1993). Of the respondents, 41% were first time buyers. Home buyer names and addresses were obtained from Dataman Information Services (DIS). DIS compiles information on residential real estate transactions from more than 600 counties throughout the United States using courthouse deed records. Most of the 250 Metropolitan Statistical Areas are also covered in the DIS data compilation.

The home buyers were questioned on the length of time they owned their previous home. The typical homebuyer (40%) was found to have lived in their previous home between 4 and 7 years (see Table 16-114). The survey results indicate that the average tenure of home buyers is 7.1 years based on an overall residence history of the respondents (NAR, 1993). In addition, the median length of residence in respondents' previous homes was found to be 6 years (see Table 16-115).

The distances the respondents moved to their new homes were typically short distances. Data presented in Table 16-116 indicate that the mean distances range from 230 miles for new home buyers and 270 miles for repeat buyers to 110 miles for first time buyers and 190 for existing home buyers. Seventeen percent (17%) of respondents purchased homes over 100 miles from their previous homes and 49% purchased homes less than 10 miles away.

Advantages of this study are the large sample size and its representativeness to the U.S. population, since it was based on 15,000 home buyers throughout the United States. A limitation of the study is the fact that the data are over 17 years old.

16.5.2.3. U.S. Census Bureau (2008b)—Current Population Survey 2007, Annual Social and Economic Supplement

The Current Population Survey is conducted monthly by the U.S. Census Bureau. The sample is selected to be statistically representative of the civilian non-institutionalized U.S. population. The data presented in Table 16-117 and Table 16-118 are yearly averages for the year 2006–2007. Approximately 50,000 people are surveyed each month.

Table 16-117 presents data on general mobility by demographic factors (i.e., sex, age, education, marital status, nativity, tenure, and poverty status). “Movers” are respondents who did not report living at the same residence 1 year earlier than the date of interview. Of the total number of respondents, 13% had moved residences. Of those, 65% moved within the same county. Table 16-118 presents data on these intercounty moves and shows that of these intercounty moves, over 60% moved less than 200 miles.

Advantages of this study are the large sample size, the currency of the data set, and its representativeness to the U.S. population. Limitations are that the study is based on recall data and that due to the Current Population Survey design, data for states are not as reliable as nationwide estimates.

Chapter 16—Activity Factors

Table 16-7. Mean Time (minutes/day) Children Under 12 Years of Age Spent in Ten Major Activity Categories, for All Respondents and Doers						
Activity Category	Mean Duration (All)	% Doers ^a	Mean Duration (Doers) ^a	Median Duration (Doers) ^a	Maximum Duration (Doers) ^a	Detailed Activity with Highest Average Minutes
Work-related ^b	10	25	39	30	405	Eating at Work/School/Daycare
Household ^c	53	86	61	40	602	Travel to Household
Childcare ^d	<1	<1	83	30	290	Other Child Care
Good/Service ^e	21	26	81	60	450	Errands
Personal Needs and Care ^f	794	100	794	770	1,440	Night Sleep
Education ^g	110	35	316	335	790	School Classes
Organizational Activities ^h	4	4	111	105	435	Attend Meetings
Entertain/Social ⁱ	15	17	87	60	490	Visiting with Others
Recreation ^j	239	92	260	240	835	Games
Communication/Passive Leisure ^k	192	93	205	180	898	TV Use
Don't know/Not coded	2	4	41	15	600	-
All Activities	1,440	-	-	-	-	-
^a	Doers indicate the respondents who reported participating in each activity category.					
^b	Includes: travel to and during work/school; children's paid work; eating at work/school/daycare; and accompanying or watching adult at work.					
^c	Includes: food preparation; meal cleanup; cleaning; clothes care; car and home repair/painting; building a fire; plant and pet care; and traveling to household.					
^d	Includes: baby and child care; helping/teaching children; talking and reading; playing while caring for children; medical care; travel related to child care; and other care.					
^e	Includes: shopping; medical appointments; obtaining personal care services (e.g., haircuts), government and financial services, and repairs; travel related to goods and services; and errands.					
^f	Includes: bathing, showering, and going to bathroom; medical care; help and care; meals; night sleep and daytime naps, dressing and grooming; and travel for personal care.					
^g	Includes: student and other classes; daycare; homework; library; and travel for education.					
^h	Includes: attending meetings and associated travel.					
ⁱ	Includes: sports events; eating and amusements; movies and theater; visiting museums, zoos, art galleries, etc.; visiting others; parties and other social events; and travel to social activities.					
^j	Includes: active sports; leisure; hobbies; crafts; art; music/drama/dance; games; playing; and travel to leisure activities.					
^k	Includes: radio and television use; reading; conversation; paperwork; other passive leisure; and travel to passive leisure activities.

Table 16-14. Mean Time (minutes/day) Children Under 12 Years of Age Spent Indoors and Outdoors, Grouped by Age and Sex

Age Group	N	Boys		N	Girls	
		Indoor ^a	Outdoor ^b		Indoor ^a	Outdoor ^b
Birth to <1 Month	3	1,440	0	4	1,440	0
1 to <3 Months	7	1,432	8	10	1,431	9
3 to <6 Months	15	1,407	33	11	1,421	19
6 to <12 Months	31	1,322	118	23	1,280	160
1 to <2 Years	54	1,101	339	43	1,164	276
2 to <3 Years	62	1,121	319	50	1,102	338
3 to <6 Years	151	1,117	323	151	1,140	300
6 to <11 Years	239	1,145	295	225	1,183	255
11 Years ^c	62	1,166	274	59	1,215	225
All Ages	624	1,181	258	576	1,181	258

^a Time indoors was estimated by adding the average times spent performing indoor activities (household work, child care, personal needs and care, education, and communication/passive leisure) and half the time spent in each activity which could have occurred either indoors or outdoors (i.e., work-related, goods/services, organizational activities, entertainment/social, don't know/not coded).

^b Time outdoors was estimated by adding the average time spent in recreation activities and half the time spent in each activity which could have occurred either indoors or outdoors (i.e., work-related, goods/services, organizational activities, entertainment/social, don't know/not coded).

^c The source data end at 11 years of age, so the 11 to <16 year category is truncated and the 16 to <21 year category is not included.

N = Sample size.

Note: Indoor and outdoor minutes/day may not sum to 1,440 minutes/day due to rounding.

Source: U.S. EPA analysis of source data used by Wiley et al. (1991).

Chapter 16—Activity Factors

**Table 16-16. Time Spent (minutes/day) in Various Rooms at Home and in All Rooms Combined, Doers Only
(continued)**

-	= Indicates missing data.
DK	= The respondent replied “don’t know”.
Refused	= Refused data.
N	= Doer sample size.
Mean	= Mean 24-hour cumulative number of minutes for doers.
SD	= Standard deviation.
SE	= Standard error.
Min	= Minimum number of minutes.
Max	= Maximum number of minutes. Percentiles are the percentage of doers below or equal to a given number of minutes.
Source:	U.S. EPA (1996).

11 to <16	449	1,260	100	80
16 to <21	493	1,248	102	90
^a Time indoors was estimating by adding the average times spent indoors at the respondents' home (kitchen, living room, bathroom, etc.), at other houses, and inside other locations such as school, restaurants, etc. ^b Time outdoors was estimated by adding the average time spent outdoors at the respondents' pool and yard, others' pool and yard, and outside other locations such as sidewalk, street, neighborhood, parking lot, service station/gas station, school grounds, park/golf course, pool, river, lake, farm, etc. ^c Includes time spent in vehicles or in activities that could not be assigned an indoor or outdoor location. N = Sample size.				
Source: U.S. EPA re-analysis of source data from U.S. EPA (1996).

- = Indicates missing data.
 DK = The respondent replied "don't know".
 Refused = Refused data.
 N = Doer sample size.
 SD = Standard deviation.
 SE = Standard error.
 Min = Minimum number of minutes.
 Max = Maximum number of minutes.

N = Sample size.

Min = Minimum.

Max = Maximum.

- = Percentiles were not calculated for sample sizes less than 10.

Chapter 16—Activity Factors

Table 16-26. Time Spent (minutes/day) in Selected Activities, Doers Only (continued)	
-	= Indicates missing data.
DK	= The respondent replied “don’t know”.
Refused	= Refused data.
N	= Doer sample size.
SD	= Standard deviation.
SE	= Standard error.
Min	= Minimum number of minutes.
Max	= Maximum number of minutes.
^a	Includes cleaning house, other repairs, and household work.
^b	Includes car repair services, other repairs services, outdoor cleaning, car repair maintenance, other repairs, plant care, other household work, domestic crafts, domestic arts.
Source:	U.S. EPA (1996).

16 to <21	207	28	4	5	7	10	10	15	25	35	50	60	74	89	121
N	= Doer sample size.														
Min	= Minimum.														
Max	= Maximum.														
-	= Percentiles were not calculated for sample sizes less than 10.														
Note:	A value of “61” was used for any shower, bath, or bathroom stay longer than 60 minutes. A value of “121” for the sum of shower duration and time spent in bathroom following shower (or the sum of bath duration and time spent in bathroom following bath) signifies that more than 120 minutes were spent.														
Source:	U.S. EPA re-analysis of source data from U.S. EPA (1996).														

Table 16-30. Mean Time Spent (minutes/day) and Bathing/Showering, Adults 18 Years and Older, Doers Only			
Age (years)	Mean No. Baths/Showers per Day ^a	Median Time Spent in Shower/Bath ^b (minutes/bath)	Time Spent in Shower/Bath ^c (minutes/day)
18 to 64	1.27	13.5	17.1
>64	1.14	15.0	17.1
^a	For additional statistics see Table 16-30. Calculated by averaging the reported number of baths/showers taken per day (truncated at 11), by the number of respondents. Respondents responding Missing and Don't Know were excluded (<i>N</i> = 5).		
^b	For additional statistics see Table 16-31.		
^c	Calculated by multiplying the mean number of showers/baths per day by the median time spent in shower/bath.		
Source: U.S. EPA (1996).

Table 16-40. Time Spent (minutes/month) Swimming in Freshwater Swimming Pool, Children <21 Years

Age (years)	N	Mean	Min	Percentiles											Max
				1	2	5	10	25	50	75	90	95	98	99	
Birth to <1	10	96	6	-	-	-	-	-	-	-	-	-	-	-	181
1 to <2	7	105	45	-	-	-	-	-	-	-	-	-	-	-	181
2 to <3	18	116	15	16	17	19	27	60	120	181	181	181	181	181	181
3 to <6	42	137	6	8	9	12	40	83	181	181	181	181	181	181	181
6 to <11	72	151	8	13	17	30	60	150	181	181	181	181	181	181	181
11 to <16	65	139	4	8	11	20	30	90	181	181	181	181	181	181	181
16 to <21	50	145	2	3	5	25	39	124	181	181	181	181	181	181	181

N = Doer sample size.

Min = Minimum.

Max = Maximum.

- = Percentiles were not calculated for sample sizes of 10 or fewer.

Note: A value of 181 for number of minutes signifies that more than 180 minutes were spent.

N = Sample size.

Min = Minimum.

Max = Maximum.

- = Percentiles were not calculated for sample sizes of 10 or fewer.

Note: A value of "121" for number of minutes signifies that more than 120 minutes were spent.

Table 16-71. Mean Time Spent (hours/day) Indoors and Outdoors, by Age and Day of the Week

Age Group	Indoors ^a		Outdoors ^b	
	Weekday	Weekend	Weekday	Weekend
3 to 5 years	19.4	18.9	2.5	3.1
6 to 8 years	20.7	18.6	1.8	2.5
9 to 11 years	20.8	18.6	1.3	2.3
12 to 14 years	20.7	18.5	1.6	1.9
15 to 17 years	19.9	17.9	1.4	2.3

^a Time indoors was estimated by adding the average times spent performing indoor activities (household work, personal care, eating, sleeping, attending school, studying, attending church, watching television, and engaging in conversation) and half the time spent in each activity which could have occurred either indoors or outdoors (i.e., market work, sports, hobbies, art activities, playing, reading, and other passive leisure).

^b Time outdoors was estimated by adding the average time spent in outdoor activities and half the time spent in each activity which could have occurred either indoors or outdoors (i.e., market work, sports, hobbies, art activities, playing, reading, and other passive leisure).

Chapter 17—Consumer Products

17. CONSUMER PRODUCTS**17.1. INTRODUCTION****17.1.1. Background**

Consumer products may contain toxic or potentially toxic chemical constituents to which people may be exposed as a result of their use. For example, household cleaners can contain ammonia, alcohols, acids, and/or organic solvents that may pose health concerns. Potential routes of exposure to consumer products or chemicals released from consumer products during use include ingestion, inhalation, and dermal contact. These household consumer products include cleaners, solvents, and paints. Non-users, including children, can be passively exposed to chemicals in these products. Because people spend a large amount of time indoors, the use of household chemicals in the indoor environment can be a principal source of exposure ([Franklin, 2008](#)).

Very little information is available about the exact way the different kinds of products are used by consumers, including the many ways in which these products are handled, the frequency and duration of contact, and the measures consumers may take to minimize exposure or risk ([Steenbekkers, 2001](#)). In addition, the factors that influence these behaviors are not well studied, but some studies have shown that a large variation exists in behavior between persons ([Steenbekkers, 2001](#)).

This chapter presents information on the amount of product used, the frequency of use, and the duration of use for various consumer products typically found in consumer households. All tables that present information for these consumer products are located at the end of this chapter.

Note that this chapter does not provide an exhaustive treatment of all consumer products, but rather, it provides some background and data that can be used in an exposure assessment. Also, the data presented may not capture the information needed to assess the highly exposed population (i.e., consumers who use commercial and industrial strength products at home). The studies presented in the following sections represent readily available surveys for which data were collected on the frequency and duration of use and the amount of use of cleaning products, painting products, household solvent products, cosmetic and other personal care products, household equipment, pesticides, and tobacco. Also note that some of the data in this chapter comes from corporate, consortia, or trade organizations.

17.1.2. Additional Sources of Information

There are several sources of information on data relevant to consumer products. Table 17-1 provides a list of household consumer products found in some U.S. households ([U.S. EPA, 1987](#)). It should be noted, however, that this list was compiled by the U.S. Environmental Protection Agency (EPA) in 1987, and consumer use of some products listed may have changed (e.g., aerosol product use has declined). Therefore, refer to the Household Product Database of the National Library of Medicine database as a source of more current information on the types of products used. This database contains over 7,000 consumer brands including auto products; products used inside the home; pesticides; landscape and yard; personal care; home maintenance, arts, and crafts; pet care; and home office. The information includes chemical ingredients, specific brands that contain those ingredients, and acute and chronic health effects associated with specific ingredients. The database does not contain any information on frequency or amount of product used.

The Soaps and Detergent Association (SDA) developed a peer-reviewed document that presents methodologies and specific exposure information that can be used for screening-level risk assessments from exposures to high production volume chemicals. The document addresses the use of consumer products, including laundry, cleaning, and personal care products. It includes data for daily frequency of use and the amount of product used. The data used were compiled from a number of sources including cosmetic associations and data from the SDA. The document *Exposure and Risk Screening Methods for Consumer Product Ingredients* can be found on the SDA Web site at http://www.cleaning101.com/files/Exposure_and_Risk_Screening_Methods_for_Consumer_Product_Ingredients.pdf.

Another document has been developed by the U.S. EPA Office of Toxic Substances ([1986a, b](#)): *Standard Scenarios for Estimating Exposure to Chemical Substances During Use of Consumer Products – Volumes I and II*. This document presents data and supporting information required to assess consumer exposure to constituents in household cleaners and components of adhesives. Its information includes a description of standard scenarios selected to represent upper bound exposures for each product. Values also are presented for parameters needed to estimate exposure for defined exposure routes and pathways assumed for each scenario.

An additional reference is the Simmons Market Research Bureau's (SMRB's) *Simmons Study of*

Chapter 17—Consumer Products

Media and Markets. This document provides an example of available marketing data that may be useful in assessing exposure to selected products. The report is published biannually. Data are collected on the buying habits of the U.S. population during the previous 12 months for more than 1,000 consumer products. Data are presented on frequency of use, total number of buyers in each use category, and selected demographics. The consumer product data are presented according to the buyer and not necessarily according to the user (i.e., actively exposed person). Therefore, it may be necessary to adjust the data to reflect potential uses. The reports are available for purchase from the SMRB. Table 17-2 presents a list of product categories in the *Simmons Study of Media and Markets* for which information is available.

17.2. RECOMMENDATIONS

Because of the large range and variation among consumer products and their exposure pathways, it is not feasible to recommend specific exposure values as has been done in other chapters of this handbook. Refer to the information provided by the references of this chapter to derive appropriate exposure factors. The following sections of this chapter provide summaries of data from surveys involving the use of consumer products.

17.3. CONSUMER PRODUCTS USE STUDIES

17.3.1. CTFA (1983)—Cosmetic, Toiletry, and Fragrance Association, Inc.—Summary of Results of Surveys of the Amount and Frequency of Use of Cosmetic Products by Women

The Cosmetic, Toiletry, and Fragrance Association, Inc. (CTFA, 1983), a major manufacturer and a market research bureau, published three surveys that collected data on the frequency of use of various cosmetic products and selected baby products. In the first survey, CTFA (1983) conducted a 1-week prospective survey of 47 female employees and relatives of employees between ages 13 and 61 years. In the second survey, a cosmetic manufacturer conducted a retrospective survey of 1,129 of its customers. In the third survey, a market research bureau sampled 19,035 female consumers nationwide over a 9½-month period. Of the 19,035 females interviewed, responses from only 9,684 females were tabulated (CTFA, 1983). The respondents in all three surveys were asked to record the number of times they used the various products in a given time period (i.e., a week, a day, a month, or a

year). The third survey also was designed to reflect the socio-demographic (e.g., age, income) characteristics of the entire U.S. population.

To obtain the average frequency of use for each cosmetic product, responses were averaged for each product in each survey. Averages were calculated by adding the reported number of uses per given time period for each product, dividing by the total number of respondents in the survey, and then dividing again by the number of days in the given time period (CTFA, 1983). The average frequency of use of cosmetic products was determined for both users and non-users. The frequency of use of baby products was determined among users only. The upper 90th percentile frequency of use values were determined by eliminating the top 10% most extreme frequencies of use. Therefore, the highest remaining frequency of use was recorded as the upper 90th percentile value. Table 17-3 presents the amount of product used per application (grams) and the average and 90th percentile frequency of use per day for various cosmetic products for all the surveys. Note that Table 17-3 reports values provided by cosmetic companies, associations, or market research firms.

An advantage of the frequency data obtained from the third survey (by the market research bureau) is that the sample population was more likely to be representative of the U.S. population. Another advantage of the third data set is that the survey was conducted over a longer period of time when compared with the other two frequency datasets. Also, the study provided empirical data that may be useful in generating more accurate estimates of consumer exposure to cosmetic products. In contrast to the large market research bureau survey, the CTFA employee survey is very small, and both that survey and the cosmetic company survey are likely to be biased toward high-end users. Therefore, data from these two surveys should be used with caution. The limitations of these surveys are that data were not tabulated by age, are more than 20 years old, and are only representative of products used by babies and female consumers. Another limitation is that these data may not be representative of long-term use patterns.

17.3.2. Westat (1987a)—Household Solvent Products: A National Usage Survey

Westat (1987a) conducted a nationwide survey to determine consumer exposure to common household products believed to contain methylene chloride or its substitutes (i.e., carbon tetrachloride, trichloroethane, trichloroethylene, perchloroethylene, and 1,1,1,2,2,2 -

Chapter 17—Consumer Products

trichlorotrifluoroethane). The survey methodology was comprised of two phases. In the first phase, the sample population was generated by using a random digit dialing (RDD) procedure, in which telephone numbers of households nationwide were randomly selected by using an unbiased, equal probability of selection method, known as the Waksberg Method ([Westat, 1987a](#)). After the respondents in the selected households (18 years and older) agreed to participate in the survey, questionnaires and product pictures were mailed to each respondent. Finally, telephone follow-up calls were made to those respondents who did not respond to the mailed questionnaire within a 4-week period to administer the same questionnaire. Of the 6,700 individuals contacted for the survey, 4,920 individuals either responded to the mailed questionnaire or to a telephone interview (a response rate of 73%). Survey questions included how often the products were used in the last 12 months, when they were last used, how much time was spent using a product (per occasion or year), how long the respondent remained in the room after use, how much of a product was used per occasion or year, and what protective measures were used ([Westat, 1987a](#)).

Thirty-two categories of common household products were included in the survey and are presented in Table 17-4. Table 17-4, Table 17-5, Table 17-6, and Table 17-7 provide means, medians, and percentile rankings for the following variables: frequency of use, exposure time, amount of use, and time exposed after use.

An advantage of this study is that the RDD procedure (i.e., Waksberg Method) to identify participants enabled a diverse selection of a representative, unbiased sample of the U.S. population ([Westat, 1987a](#)). Also, empirical data on consumer household product use are provided. However, a limitation associated with this study is that the data generated were based on recall behavior. Another limitation is that extrapolation of these data to long-term use patterns may be difficult; the data are more than 20 years old and cannot be broken out by age groups.

17.3.3. Westat ([1987c](#))—National Usage Survey of Household Cleaning Products

Westat ([1987c](#)) collected usage data from a nationwide survey to assess the magnitude of exposure of consumers to various products used when performing certain household cleaning tasks. The survey was conducted from the middle of November 1985 to the middle of January 1986. Telephone interviews were conducted with 193 households. According to Westat ([1987c](#)), the

resulting response rate for this survey was 78%. The Waksberg Method discussed in the Westat ([1987a](#)) study also was used in randomly selecting telephone numbers employed in this survey. The survey was designed to obtain information on cleaning activities performed in the interior of the home during the previous year. The person who did the majority of the cleaning in the kitchen and bathroom areas of each household was interviewed. Of those respondents, the primary cleaner was female in 160 households (83%) and male in 30 households (16%); the sex of the respondents in the three remaining households was not ascertained ([Westat, 1987c](#)). Data obtained from the survey included the frequency of performing 14 different cleaning tasks, the amount of time (duration) spent at each task, the cleaning product most frequently used, the type of product (i.e., liquid, powder, aerosol, or spray pump) used, and the protective measures taken during cleaning, such as wearing rubber gloves or having a window open or an exhaust fan on ([Westat, 1987c](#)).

Table 17-8 through Table 17-12 present the survey data. Table 17-8 presents the mean and median total exposure time of use for each cleaning task and the product type preferred for each task. Table 17-9 presents the percentile rankings for the total time exposed to the products used for 14 cleaning tasks. Table 17-10 presents the mean and percentile rankings of the frequency in performing each task. Table 17-11 shows the mean and percentile rankings for exposure time per event of performing household tasks. Table 17-12 presents the mean and percentile rankings for total number of hours spent per year using the top 10 product groups.

Westat ([1987c](#)) randomly selected a subset of 30 respondents from the original survey and re-interviewed them during the first 2 weeks of March 1986 as a reliability check on the recall data from the original phone survey. Frequency and duration data for 3 of the original 14 cleaning tasks were obtained from the re-interviews. In a second effort to validate the phone survey, 50 respondents of the original phone survey participated in a 4-week diary study (between February and March 1986) of 8 of the 14 cleaning tasks originally studied. The diary approach assessed the validity of using a 1-time telephone survey to determine usual cleaning behavior ([Westat, 1987c](#)). The data (i.e., frequency and duration) obtained from the re-interviews and the diary approach were lower than the data from the original telephone survey, but were more consistent with one other. Westat ([1987c](#)) attributed the significant differences in the data obtained from these surveys to seasonal changes rather than methodological problems.

A limitation of this survey is evident from the reliability and validity check of the data collected by Westat (1987c). The data obtained from the telephone survey may reflect heavier seasonal cleaning because the survey was conducted during the holidays (November through January). Therefore, usage data obtained in this study may be biased and may represent upper bound estimates. Other limitations of this study include the small size of the sample population, the age of the data set, and that the data cannot be broken out by age groups. An advantage of this survey is that the RDD procedure (Waksberg Method) used provides unbiased results of sample selection and reduces the number of unproductive calls. Another advantage of this study is that it provides empirical data on frequency and duration of consumer use.

17.3.4. Westat (1987b)—National Household Survey of Interior Painters

Westat (1987b) conducted a nationwide study between November 1985 and January 1986 to obtain usage information that estimates the magnitude of exposure of consumers to different types of painting and painting-related products used while painting the interior of the home. The study sampled 777 households to determine whether any household member had painted the interior of the home during the 12 months prior to the survey date. Of the sampled households, 208 households (27%) had a household member who had painted during the past 12 months. Based on the households with primary painters, the response rate was 90% (Westat, 1987b). The person in each household who did most of the interior painting during the past 12 months was interviewed over the telephone. The RDD procedure (Waksberg Method) previously described in Westat (1987a) was used to generate sample blocks of telephone numbers in this survey. Questions were asked about the frequency and time spent for interior painting activities, the amount of paint used, and the protective measures used (i.e., wearing gloves, hats, and masks or keeping a window open) (Westat, 1987b). Fifty-three percent of the primary painters in the households interviewed were male, 46% were female, and the sex of the remaining 1% was not ascertained. Three types of painting products were used in this study: latex paint, oil-based paint, and wood stains and varnishes. Of the respondents, 94.7% used latex paint, 16.8% used oil-based paint, and 20.2% used wood stains and varnishes.

Table 17-13, Table 17-14, and Table 17-15 summarize data generated from this survey. Table 17-13 presents the mean, standard deviation, and

percentile rankings for the total exposure time for painting activity by paint type. Table 17-14 presents the mean and median exposure times for each painting activity per occasion for each paint type. A painting occasion is defined as a time period from start to cleanup (Westat, 1987b). Table 17-14 also presents the frequency and percentile rankings of painting occasions per year. Table 17-15 presents the total amount of paint used by interior painters.

In addition, 30 respondents from the original survey were re-interviewed in April 1986 as a reliability check on the recall data. There were no significant differences between the data obtained from the re-interviews and the original painting survey (Westat, 1987b).

An advantage of this survey, based on the reliability check conducted by Westat (1987b), is the stability in the painting data obtained. Another advantage of this survey is that the response rate was high (90%), thus minimizing non-response bias. Also, the Waksberg Method employed provides an unbiased equal probability method of RDD. The limitations of the survey are that the data are based on 12-month recall and may not accurately reflect long-term use patterns and the age of the data set.

17.3.5. Abt (1992)—Methylene Chloride Consumer Use Study Survey Findings

As part of a plan to assess the effectiveness of labeling of consumer products containing methylene chloride, Abt (1992) conducted a nationwide telephone survey of nearly 5,000 households. The survey was conducted in April and May of 1991. Three classes of products were included: (1) paint strippers, (2) non-automotive spray paint, and (3) adhesive removers. The survey paralleled a 1986 consumer use survey conducted by Abt for the U.S. EPA.

The survey was conducted to estimate the percentage of the U.S. adult population using paint remover, adhesive remover, and non-automotive spray paint. In addition, an estimate of the population using these products containing methylene chloride was determined. A survey questionnaire was developed to collect product usage data and demographic data. The survey sample was generated using a RDD technique.

A total of 4,997 product screener interviews were conducted for the product interview sections. The number of respondents was 381 for paint strippers, 58 for adhesive removers, and 791 for non-automotive spray paint. Survey responses were weighted to allow estimation at the level of the total U.S. population (Abt, 1992). A follow-up mail survey

Chapter 17—Consumer Products

also was conducted by using a short questionnaire. Respondents who had used the product in the past year or had purchased the product in the past 2 years and still had the container were asked to respond to the questionnaire (Abt, 1992). Of the 527 mailed questionnaires, 259 were returned. The questionnaire responses included 67 on paint strippers, 6 on adhesive removers, and 186 on non-automotive spray paint. Table 17-16 through Table 17-21 (*Ns* are unweighted) present the results of the survey. Data are presented for recent users, who were defined as persons who have used the product within the last year of the survey or who have purchased the product in the past 2 years.

Abt (1992) found the following results when comparing the new data to the 1986 findings:

- A significantly smaller proportion of current survey respondents used a paint stripper, spray paint, or adhesive remover.
- The proportion of the population who used the three products recently (within the past year) decreased substantially.
- Those who used the products reported a significantly longer time since their last use. For all three products, the reported amount used per year was significantly higher in the current survey.

An advantage of this survey is that the survey population was large, and the survey responses were weighted to represent the U.S. population. In addition, the survey was designed to collect data for frequency of product use and amount of product used by sex. Limitations of the survey are that the information may be dated, and that the data were generated based on recall behavior. Extrapolation of these data to accurately reflect long-term use patterns may be difficult.

17.3.6. U.S. EPA (1996)—National Human Activity Pattern Survey (NHAPS)

U.S. EPA (1996) collected data on the duration and frequency of selected activities and the time spent in selected microenvironments via 24-hour diaries as part of the National Human Activity Pattern Survey (NHAPS). More than 9,000 individuals from various age groups in 48 contiguous states participated in NHAPS, including 2,000 children. The survey was conducted between October 1992 and September 1994. Individuals were interviewed to categorize their 24-hour routines (diaries) and/or to

answer follow-up questions that were related to exposure events. Demographic, including socioeconomic (e.g., sex, age, race, education), geographic (e.g., census region, state), and temporal (i.e., day of week, month, season) data were included in the study. Data were collected for a maximum of 82 possible microenvironments and 91 different activities.

As part of the survey, data also were collected on duration and frequency of use of selected consumer products. Table 17-22 through Table 17-30 present data on the number of minutes that survey respondents spent in activities working with or being near certain consumer products, including microwave ovens; freshly applied paints; household cleaning agents such as scouring powders or ammonia; floor wax, furniture wax, or shoe polish; glue; solvents, fumes, or strong-smelling chemicals; stain or spot removers; gasoline, diesel-powered equipment, or automobiles; and pesticides, bug sprays, or bug strips. Table 17-31 through Table 17-35 present data on the number of respondents in these age categories that used fragrances, aerosol sprays, humidifiers, and pesticides (professionally-applied and consumer-applied). Because the age categories used by the study authors did not coincide with the standardized age categories recommended in U.S. EPA (2005) and used elsewhere in this handbook, the source data from NHAPS on pesticide use (professionally applied and consumer-applied) were reanalyzed by U.S. EPA to generate data for the standardized age categories. Data for subsets of the 1st year of life (e.g., 1 to 2 months, 3 to 5 months, etc.) were not available.

As discussed in previous chapters that used NHAPS as a data source, the primary advantage is that the data were collected for a large number of individuals, and the survey was designed to be representative of the U.S. general population. However, due to the wording of questions in the survey, precise data were not available for consumers who spent more than 60 or 120 minutes (depending on the activity) using some consumer products. This prevents accurate characterization of the high end of the distribution and also may introduce error into the calculation of the mean. Another limitation is that the adult data were not broken down into finer age categories. These data are also based on 24-hour diaries and may not be representative of long-term use patterns.

17.3.7. Bass et al. (2001)—What's Being Used at Home: A Household Pesticide Survey

Bass et al. (2001) conducted a survey to assess the use of pesticide products in homes with

children in March 1999. The study obtained information on what pesticides were used, where they were used, and how frequently they were used. A total of 107 households in Arizona that had a least one child less than 10 years old in the household and had used a pesticide within the last 6 months were surveyed ([Bass et al., 2001](#)). The survey population was composed predominantly of Hispanic females and represented a survey response rate of approximately 74%. Study participants were selected by systematic random sampling. Pesticide use was assessed by a one-on-one interview in the home. Survey questions pertained to household pesticides used inside the house for insect control and outside the house for controlling weeds in the garden and repelling animals from the garden. As part of the interview, information was gathered on the pesticides' frequency of use.

Table 17-36 presents information on the type, characteristics, and frequency of pesticide use, as well as information on the demographics of the survey population. A total of 148 pesticide products were used in the 107 households surveyed. Respondents had used pesticides in the kitchen, bathroom, floors, baseboards, and cabinets with dishes or cookware. The frequency of use data showed the following: about 32% of the households used pesticides once per week or more; about 44% used the products once per month or once in 3 months; and about 19% used the products once in 6 months or once per year ([Bass et al., 2001](#)).

Although this study was limited to a selected area in Arizona, it provides useful information on the frequency of use of pesticides among households with children. This may be useful for populations in similar geographical locations where site-specific data are not available. However, these data are the result of a community-based survey and are not representative of the U.S. general population.

17.3.8. Weegels and van Veen (2001)—Variation of Consumer Contact With Household Products: A Preliminary Investigation

Weegels and van Veen ([2001](#)) conducted a survey to determine consumer exposure to common household products used once a day or every other day. Thirty households participated in the study, including 10 families with children, 10 couples, 9 individuals, and 1 household of 6 adults from the city of Delft in The Netherlands. Households were recruited through the Usability Panel of the School of Industrial Design and through public notices and pamphlets.

Three types of products were studied: dishwashing detergent, all-purpose cleaners, and hair-styling products. Three activities in which these products are commonly used were studied in more detail: dishwashing, toilet cleaning, and styling hair. In-home observations, diaries, and measurement of the amount of product utilized were used to collect data. Subjects were visited in their homes and videotaped performing the activities. After 3 weeks, subjects were again visited in their homes and videotaped performing activities, diaries were collected, and the amount of product used was measured.

Table 17-37 presents the survey data. During toilet cleaning, 22 of 29 subjects observed used at least two different products (e.g., toilet cleaner, all-purpose cleaner, and/or abrasive cleaner). The large variation in duration of toilet cleaning was due to the diverse ways in which toilet cleaner was used: some subjects left the toilet cleaner to soak overnight, some left it in the bowl while cleaning the remainder of the toilet, others flushed the toilet immediately after cleaning. The authors noted that the findings of the study suggest that "...individuals have a consistent way of using a product for a particular activity, but there is a large variety in product usage among consumers, with relations among frequency, durations and amount. If this conclusion is confirmed by future research, it suggests that there will be people who exhibit high-end use of products and will, most likely follow their own routine, which may have consequences for the definition of worst-case use of consumer products."

An advantage of this study is that the empirical data generated provide more accurate calculations of exposure than studies relying on recall data. Limitations of the study are the small study population (30 households) and that The Netherlands may not be representative of U.S. population behaviors. Another limitation is that the short duration (3 weeks) may not accurately reflect long-term or seasonal usage patterns.

17.3.9. Loretz et al. (2005)—Exposure Data for Cosmetic Products: Lipstick, Body Lotion, and Face Cream

Loretz et al. ([2005](#)) conducted a nationwide survey to estimate the usage (i.e., frequency of application and amount used per application) of lipstick, body lotion, and face cream. The study was conducted in 2000 and included 360 study subjects recruited in 10 U.S. cities (i.e., Atlanta, GA; Boston, MA; Chicago, IL; Denver, CO; Houston, TX; Minneapolis, MN; St. Louis, MO; San Bernardino,

Chapter 17—Consumer Products

CA; Tampa Bay, FL; and Seattle, WA). The survey participants were women, ages 19 to 65 years, who regularly used the products of interest. Typical cosmetic formulations of the three product types were weighed and provided to the women for use over a 2-week period. Subjects recorded information on product usage (e.g., whether the product was used, number of applications, time of applications) on a daily basis in a diary provided to them. At the end of the 2-week period, unused portions of product were returned and weighed. The amount of product used was estimated as the difference between the weight of product at the beginning and end of the survey period. Of the 360 subjects, 86.4%, 83.3%, and 85.6% completed the study and returned the diaries for lipstick, body lotion, and face cream, respectively ([Loretz et al., 2005](#)).

Table 17-38 and Table 17-39 present the survey data. Table 17-38 provides the mean, median, and standard deviations for the frequency of use. Table 17-39 provides distribution data for the total amount applied, the average amount applied per use day, and the average amount applied per application.

An advantage of this study is that the survey population covered a diverse geographical area of the United States and that it was not based on recall data. A limitation of the study is that the short duration (2 weeks) may not accurately reflect long-term usage patterns. Another limitation is that the study only included women who already used the products; therefore, the usage patterns are not representative of the entire female population. Also, the data are not presented by age group.

17.3.10. Loretz et al. (2006)—Exposure Data for Personal Care Products: Hairspray, Spray Perfume, Liquid Foundation, Shampoo, Body Wash, and Solid Antiperspirant

Loretz et al. (2006) conducted a nationwide survey to determine the usage (i.e., frequency of use and amount used) of hairspray, spray perfume, liquid foundation, shampoo, body wash, and solid antiperspirant. The survey was similar to that described by Loretz et al. (2005). This study was conducted in 2000 and 2001. A total of 360 women were recruited from 10 U.S. cities (Atlanta, GA; Boston, MA; Chicago, IL; Denver, CO; Houston, TX; Minneapolis, MN; St. Louis, MO; San Bernardino, CA; Tampa Bay, FL; and Seattle, WA). The survey participants were women, ages 19 to 65 years old, who regularly used the test products. Subjects kept daily records on product usage (e.g., whether the product was used, number of applications, time of

applications) in a diary. For spray perfume, liquid foundation, and body wash, subjects recorded the body areas where these products were applied. For shampoo, subjects recorded information on their hair type (i.e., length, thickness, oiliness, straight or curly, and color treated or not). At the end of the 2-week period, unused portions of products were returned and weighed. Of the 360 subjects recruited per product, the study was completed by 91% of participants for hairspray, 91% for spray perfume, 94% for liquid foundation, and 94% for shampoo, body wash, and solid antiperspirant.

Table 17-40 through Table 17-42 present the survey data. Table 17-40 provides the minimum, maximum, mean, and standard deviations for the frequency of use. Table 17-41 provides percentile values for the amount of product applied per application. Table 17-42 provides distribution data for the amount applied per use day.

An advantage of this study is that the survey population covered a diverse geographical range of the United States and that it did not rely on recall data. A limitation of the study is that the short duration (2 weeks) may not accurately reflect long-term usage patterns. Another limitation is that the study only included women who already used these products; therefore, the usage patterns are not entirely representative of the entire female population. Also, the data are not presented by age group.

17.3.11. Hall et al. (2007)—European Consumer Exposure to Cosmetic Products, a Framework for Conducting Population Exposure Assessments

European cosmetic manufacturers constructed a probabilistic European population model of exposure for six cosmetic products: body lotion, deodorant/antiperspirant, lipstick, facial moisturizer, shampoo, and toothpaste ([Hall et al., 2007](#)). Data were collected by using both market information databases and a controlled product use study from 44,100 households and 18,057 individual consumers, creating a sample of the 249 million inhabitants of the 15 countries in the European Union. Tables Table 17-43 through Table 17-50 show the amount used in g/day and mg/kg-day. The study found an inverse correlation between frequency of product use and quantity used per application for body lotion, facial moisturizer, toothpaste, and shampoo, and so the authors cautioned against calculating daily exposure to these products by multiplying the maximum frequency value by the maximum quantity per event value.

The advantage of this study is that it included a large sample size. However, behaviors and activities in the European population may not be representative of the U.S. population, and results were not broken out by age groups.

17.3.12. Loretz et al. (2008)—Exposure Data for Cosmetic Products: Facial Cleanser, Hair Conditioner, and Eye Shadow

Loretz et al. (2008) used the data from a study conducted in 2005 to estimate frequency of use and usage amount for facial cleanser, hair conditioner, and eye shadow. The study was conducted in a similar manner as Loretz et al. (2006; 2005). A total of 360 women, ages 18 to 69 years, were recruited by telephone to provide diary records of product use during a 2-week period. The study subjects were representative of four U.S. Census regions (i.e., Northeast, Midwest, South, and West). A total of 295, 297, and 299 women completed the study for facial cleanser, hair conditioner, and eye shadow, respectively.

The participants recorded daily in a diary whether the product was used that day, the number of applications, and the time of applications during a 2-week period. Products were weighed at the start and completion of the study to determine the amount used. A statistical analysis of the data was conducted to provide summary distributions of use patterns, including number of applications, amount used per day, and amount of product used per application for each product. Table 17-51 provides data on the number of applications per use day. Table 17-52 shows the average amounts of product applied per use day, while Table 17-53 shows the average amounts of product applied per application.

The advantages of this study are that it is representative of the U.S. female population for users of the products studied, it provides data for frequency of use and amount used, and it provides distribution data. A limitation of the study is that the data were not provided by age group. In addition, the participants were regular users of the product, so the amount applied and the frequency of use may be higher than for other individuals who may use the products. According to Loretz et al. (2008), "...variability in amount used by the different subjects is high, but consistent with the data from other cosmetic and personal care studies." The authors also noted that it was not clear if the high-end users of products represented true usage. Data were also collected over a 2-week period and may not be representative of long-term usage patterns.

17.3.13. Sathyanarayana et al. (2008)—Baby Care Products; Possible Sources of Infant Phthalate Exposure

Sathyanarayana et al. (2008) investigated dermal exposure to phthalates via the dermal application of personal care products. The study was conducted on 163 infants born between 2000 and 2005. The products studied were baby lotion, baby powder, baby shampoo, diaper cream, and baby wipes. Infants were recruited through Future Families, a multicenter pregnancy cohort study, at prenatal clinics in Los Angeles, CA; Minneapolis, MN; and Columbia, MO. Although the study was designed to assess exposure to phthalates, the authors collected information on the percentage of the total participants who used the baby products. Data were collected from questionnaire responses of the mothers and at study visits. Table 17-54 shows the characteristics and the percentage of the population using the studied baby products. Of the 163 infants studied, 94% of the participants used baby wipes, and 54% used infant shampoo.

The advantages of this study are that it specifically targeted consumer products used by children, it captured the percentage of the study population using these products, and it collected the data from a diverse ethnic population. The limitation is that these data may not be entirely representative of the U.S. population because the study population was from only three states and the sample size was small. Also, this study did not contain any information on amount or frequency of product use.

Table 17-2. List of Product Categories in the Simmons Study of Media and Markets

The volumes included in the Media series are as follows:	
M1	Publications: Total Audiences
M2	Publications: Qualitative Measurements and In-Home Audiences
M3	Publications: Duplication of Audiences
M4	Multi-Media Audiences: Adults
M5	Multi-Media Audiences: Males
M6	Multi-Media Audiences: Females and Mothers
M7	Business to Business
M8	Multi-Media Reach and Frequency and Television Attentiveness and Special Events
The following volumes are included in the Product series:	
P1	Automobiles, Cycles, Trucks and Vans
P2	Automotive Products and Services
P3	Travel
P4	Banking, Investments, Insurance, Credit Cards and Contributions, Memberships and Public Activities
P5	Games and Toys, Children's and Babies' Apparel and Specialty Products
P6	Computers, Books, Discs, Records, Tapes, Stereo, Telephones, TV and Video
P7	Appliances, Garden Care, Sewing and Photography
P8	Home Furnishings and Home Improvements
P9	Sports and Leisure
P10	Restaurants, Stores and Grocery Shopping
P11	Direct Mail and Other In-Home Shopping, Yellow Pages, Florist, Telegrams, Faxes and Greeting Cards
P12	Jewelry, Watches, Luggage, Writing Tools and Men's Apparel
P13	Women's Apparel
P14	Distilled Spirits, Mixed Drinks, Malt Beverages, Wine and Tobacco Products
P15	Coffee, Tea, Cocoa, Milk, Soft Drinks, Juices and Bottled Water
P16	Dairy Products, Desserts, Baking and Bread Products
P17	Cereals and Spreads, Rice, Pasta, Pizza, Mexican Foods, Fruits and Vegetables
P18	Soup, Meat, Fish, Poultry, Condiments and Dressings
P19	Chewing Gum, Candy, Cookies and Snacks
P20	Soap, Laundry, Paper Products and Kitchen Wraps
P21	Household Cleaners, Room Deodorizers, Pest Controls and Pet Foods
P22	Health Care Products and Remedies
P23	Oral Hygiene Products, Skin Care, Deodorants and Drug Stores
P24	Hair Care, Shaving Products and Fragrances
P25	Women's Beauty Aids, Cosmetics and Personal Products
P26	Relative Volume of Consumption

Chapter 17—Consumer Products

Table 17-3. Amount and Frequency of Use of Various Cosmetic and Baby Products (continued)							
Product Type	Amount of Product per Application ^a (grams)	Average Frequency of Use (per day)			Upper 90 th Percentile Frequency of Use (per day)		
		Survey Type			Survey Type		
		CTFA	Cosmetic Co.	Market ^b Research Bureau	CTFA	Cosmetic Co.	Market Research Bureau
Face, Body and Hand Preps (excluding shaving preps)	3.5	0.65	—	1.12	2.0	—	2.14
Foot Powder and Sprays	—	0.061	0.079	—	0.57 ^e	0.29	—
Hormones	—	0.012	0.028	—	0.57 ^e	0.14 ^e	—
Moisturizers	0.5	0.98	0.88	0.63	2.0	1.71	1.5
Night Skin Care Products	1.3	0.18	0.50	—	1.0	1.0	—
Paste Masks (mud packs)	3.7	0.027	0.20	—	0.14	0.43	—
Skin Lighteners	—	—	0.024	—	— ^e	0.14 ^e	—
Skin Fresheners and Astringents	2.0	0.33	0.56	—	1.0	1.43	—
Wrinkle Smoothers (removers)	0.4	0.021	0.15	—	1.0 ^d	1.0	—
Facial Cream	0.6	0.0061	—	—	0.0061	—	—
Permanent Wave	101	0.003	—	0.001	0.0082	—	0.005
Hair Straighteners	0.2	0.0007	—	—	0.005 ^e	—	—
Hair Dye	—	0.001	—	0.005	0.004 ^e	—	0.014
Hair Lighteners	—	0.0003	—	—	0.005 ^e	—	—
Hair Bleaches	—	0.0005	—	—	0.02 ^e	—	—
Hair Tints	—	0.0001	—	—	0.005 ^e	—	—
Hair Rinse (coloring)	—	0.0004	—	—	0.02 ^e	—	—
Shampoo (coloring)	—	0.0005	—	—	0.02 ^e	—	—
Hair Color Spray	—	—	—	—	— ^e	—	—
Shave Cream	1.73	—	—	0.082	—	—	0.36
^a	Values reported are the averages of the responses reported by the 20 companies interviewed.						
^b	The averages shown for the Market Research Bureau are not true averages - this is due to the fact that in many cases the class of most frequent users is indicated by "1 or more"; also, ranges are used in many cases (i.e., "10-12"). The average, therefore, is underestimated slightly. The "1 or more" designation also skews the 90 th percentile figures in many instances. The 90 th percentile values may, in actuality, be somewhat higher for many products.						
^c	Average usage among users only for baby products.						
^d	Usage data reflects entire household use for both baby lotion and baby oil.						
^e	Fewer than 10% of individuals surveyed used these products. Value listed is lowest frequency among individuals reporting usage. In the case of wave sets, skin lighteners, and hair color spray, none of the individuals surveyed by the CTFA used this product during the period of the study.						
^f	Usage data reflects entire household use.						
^g	Usage data reflects total bath product usage.						
^h	None of the individuals surveyed reported using this product.						
(—)	indicate no data available.

Chapter 18—Lifetime

18. LIFETIME**18.1. INTRODUCTION**

The length of an individual's life is an important factor to consider when evaluating cancer risk because the dose estimate is averaged over an individual's lifetime. The recommendations for life expectancy are provided in the next section, along with a summary of the confidence rating for this recommendation. Because the averaging time is found in the denominator of the dose equation, a shorter lifetime would result in a higher potential risk estimate, and, conversely, a longer life expectancy would produce a lower potential risk estimate.

The recommended values are based on one key study identified by the U.S. Environmental Protection Agency (EPA) for this factor. Following the recommendations, the key study is summarized.

18.2. RECOMMENDATIONS

Current data suggest that 78 years would be an appropriate value to reflect the average life expectancy of the general population and is the

recommended value. If sex is a factor considered in the assessment, note that the average life expectancy value for females is higher than that for males. It is recommended that the assessor use the appropriate value of 75 years for males and 80 years for females, based on life expectancy data from 2007 (Xu et al., 2010). If race is a consideration in assessing exposure for individuals, note that the life expectancy is longer for Whites than for Blacks. Therefore, assessors are encouraged to use values that most reflect the exposed population. Table 18-1 and Table 18-2 present the recommendations and confidence ratings for life expectancy, respectively.

This recommended value is different than the 70 years commonly assumed for the general population in U.S. EPA risk assessments. The Integrated Risk Information System does not use a 70-year lifetime assumption in the derivation of reference concentration and reference dose, cancer slope factors, or unit risks. Therefore, using a value different than 70 years will not result in an inconsistency with the toxicity data.

Table 18-1. Recommended Values for Expectation of Life at Birth: 2007		
Population	Life Expectancy (years)	Source
Total	78	Xu et al. (2010)
Males	75	
Females	80	

Table 18-2. Confidence in Lifetime Expectancy Recommendations

Considerations	Rationale	Rating
Soundness		High
<i>Adequacy of Approach</i>	Recommendations are based on data from death certificates filed in the 50 states in the United States and District of Columbia.	
<i>Minimal (or defined) Bias</i>	There are no apparent biases.	
Applicability and Utility		High
<i>Exposure Factor of Interest</i>	Death certificate data were used to calculate life expectancy for various population groups born between 1940 and 2007.	
<i>Representativeness</i>	The data are representative of the U.S. population.	
<i>Currency</i>	The study was published in 2010 based on data collected in 2007.	
<i>Data Collection Period</i>	Data were collected in 2007.	
Clarity and Completeness		High
<i>Accessibility</i>	The key study is widely available to the public.	
<i>Reproducibility</i>	Results can be reproduced by analyzing death certificate data.	
<i>Quality Assurance</i>	Information on ensuring data quality are available publicly.	
Variability and Uncertainty		Medium
<i>Variability in Population</i>	Data were averaged by sex and race—but only for Blacks and Whites; no other nationalities were represented within the study.	
<i>Uncertainty</i>	Data were based on death certificates filed in the 50 states in the United States and District of Columbia.	
Evaluation and Review		High
<i>Peer Review</i>	Data are published and have been peer reviewed.	
<i>Number and Agreement of Studies</i>	Recommendations for expectation of life at birth were based on only one study.	
Overall Rating		High

Chapter 18—Lifetime

18.3. KEY LIFETIME STUDY**18.3.1. Xu et al. (2010)—Deaths: Final Data for 2007**

Xu et al. (2010) used information compiled from death certificates filed in the 50 states of the United States and District of Columbia and calculated life expectancy for various population groups born between 1940 and 2007. “Life expectancy at birth represents the average number of years that a group of infants would live if the group was to experience throughout life the age-specific death rates present in the year of birth” (Xu et al., 2010).

Table 18-3 shows life expectancy data by sex, age, and race (i.e., Whites and Blacks). Although data for other ethnic groups were collected, they were not considered as reliable because of inconsistencies between the race reported in the death certificates and in the censuses and surveys. Data for 2007 show that the life expectancy for an average person born in the United States is 77.9 years (Xu et al., 2010). The average life expectancy for males in 2007 was 75.4 years and 80.4 years for females. Whereas the gap between males and females was about 7 years in 1970, it has now narrowed to about 5 years. Table 18-3 also indicates that life expectancy for White males and females is consistently longer than for Black males and females. Table 18-4 presents data for the expectation of life for persons at a specific age in year 2007 (Xu et al., 2010). The advantages of this study are that it is representative of the United States and provides life expectancy data based on death certificates and calculations of death rates. A disadvantage is that the data were averaged by sex and race—but only for Blacks and Whites.

18.4. RELEVANT LIFETIME STUDY**18.4.1. U.S. Census Bureau (2008)—U.S. Population Projections: Projected Life Expectancy at Birth by Sex, Race, and Hispanic Origin for the United States: 2010 to 2050**

Statistical data on life expectancy are published annually by the U.S. Department of Commerce in the publication, *Statistical Abstract of the United States*. Data are collected for the 50 states and the District of Columbia. The *Statistical Abstract of the United States* has been published by the U.S. Census Bureau since 1878 (U.S. Census Bureau, 2010). The U.S. Census Bureau (2008) computed life expectancy projections for 2010 through 2050, by decade. This analysis uses historical mortality trend data collected by the National Center for Health Statistics and applies forecast models to estimate projected life

expectancy at birth. These data are provided, by sex and race in Table 18-5.

The advantage of this survey is that it is representative of the United States, and it provides projections by sex and race. A disadvantage is that life expectancy estimates are based on future projections.

19. BUILDING CHARACTERISTICS

19.1. INTRODUCTION

This document is an update to Chapter 19 (Building Characteristics) of the *Exposure Factors Handbook; 2011 Edition*. New information that has become available since 2011 has been added, and the recommended values have been revised, as needed to reflect the additional information. The chapter includes a comprehensive review of the scientific literature through 2017. The new literature was identified via formal literature searches conducted by EPA library services as well as targeted internet searches conducted by the authors of this chapter. Appendix A provides a list of the key terms that were used in the literature searches. Revisions to this chapter have been made in accordance with the approved quality assurance plan for the *Exposure Factors Handbook*.

As described in Chapter 1 of the *Exposure Factors Handbook: 2011 Edition* (U.S. EPA, 2011), key studies represent the most up-to-date and scientifically sound for deriving recommendations for exposure factors, whereas other studies are designated “relevant,” meaning applicable or pertinent, but not necessarily the most important. For example, studies that provide supporting data or information related to the factor of interest (e.g., building materials, building foundation types), or have study designs or approaches that make the data less applicable to the population of interest (e.g., studies not conducted in the United States) have been designated as relevant rather than key. Key studies were selected based on the general assessment factors described in Chapter 1 of the Handbook.

Unlike previous chapters in this handbook, which focus on human behavior or characteristics that affect exposure, this chapter focuses on building characteristics. Assessment of exposure in indoor settings requires information on the availability of the chemical(s) of concern at the point of exposure, characteristics of the structure and microenvironment that affect exposure, and human presence within the building. The purpose of this chapter is to provide data that are available on building characteristics that affect exposure in an indoor environment. This chapter addresses residential and nonresidential building characteristics (volumes, surface areas, mechanical systems, and types of foundations), transport phenomena that affect chemical transport within a building (airflow, chemical-specific deposition and filtration, and soil tracking), information on indoor water uses, and on various types of indoor building-related sources associated with airborne exposure and soil/house dust sources. Source-receptor

relationships in indoor exposure scenarios can be complex due to interactions among sources, and transport/transformation processes that result from chemical-specific and building-specific factors.

There are many factors that affect indoor air exposures. Indoor air models generally require data on several parameters. This chapter provides recommendations on two parameters, volume and air exchange rates. Other factors that affect indoor air quality are furnishings, siting, weather, ventilation and infiltration, environmental control systems, material durability, operation and maintenance, occupants and their activities, and building structure. Available relevant information on some of these other factors is provided in this chapter, but specific recommendations are not provided, as site-specific parameters are preferred.

Figure 19-1 illustrates the complex factors that must be considered when conducting exposure assessments in an indoor setting. The primary cause of indoor pollution is the release of gases or particles into the air from indoor and outdoor sources. In addition to sources within the building, chemicals of concern may enter the indoor environment from outdoor air, soil, gas, water supply, tracked-in soil, and industrial work clothes worn by the residents. Indoor concentrations are affected by loss mechanisms, also illustrated in Figure 19-1, involving chemical reactions, deposition to and re-emission from surfaces, and transport out of the building. Particle-bound chemicals can enter indoor air through resuspension. Indoor air concentrations of gas-phase organic chemicals are affected by the presence of reversible sinks formed by a wide range of indoor materials. In addition, the activity of human receptors greatly affects their exposure as they move from room to room, entering and leaving areas with different levels and types of chemicals. Data on human activities, such as time spent at various rooms in the house, can be found in Chapter 16 of this handbook.

Inhalation of airborne chemicals in indoor settings are typically modeled by considering the building as an assemblage of one or more well-mixed zones. A zone is defined as one room, a group of interconnected rooms, or an entire building. At this macroscopic level, well-mixed assumptions form the basis for interpretation of measurement data as well as simulation of hypothetical scenarios. Exposure assessment models on a macroscopic level incorporate important physical factors and processes. These well-mixed, macroscopic models have been used to perform indoor air quality simulations (Axley, 1989), as well as indoor air exposure assessments (McKone, 1989; Ryan, 1991). Nazaroff and Cass (1986) and Wilkes et al. (1992) have used computer programs

featuring finite difference or finite element numerical techniques to model mass balance. A simplified approach using desktop spreadsheet programs has been used by Jennings et al. (1987a). U.S. Environmental Protection Agency (EPA) has created two useful indoor air quality models: the (I-BEAM) (<https://www.epa.gov/indoor-air-quality-iaq/indoor-air-quality-building-education-and-assessment-model>), which estimates indoor air quality in commercial buildings and the *Multi-Chamber Concentration and Exposure Model* (MCCEM) (<https://www.epa.gov/tsca-screening-tools/multi-chamber-concentration-and-exposure-model-mccem-version-12>), which estimates average and peak indoor air concentrations of chemicals released from residences.

Major air transport pathways for airborne substances in buildings include the following:

- Air exchange across the building envelope—Air leakage through windows, doorways, intakes and exhausts, and “adventitious openings” (i.e., cracks and seams) that combine to form the leakage configuration of the building envelope plus natural and mechanical ventilation;
- Interzonal airflows—Transport through doorways, ductwork, and service chaseways that interconnect rooms or zones within a building; and
- Local circulation—Convective and advective air circulation and mixing within a room or within a zone.

The air exchange rate is generally expressed in terms of air changes per hour (ACH), with units of (hour^{-1}). It is defined as the ratio of the airflow ($\text{m}^3 \text{ hour}^{-1}$) to the volume (m^3). The distribution of airflows across the building envelope that contributes to air exchange and the interzonal airflows along interior flowpaths is determined by the interior pressure distribution. The forces causing the airflows are temperature differences, the actions of wind, and natural and mechanical ventilation systems. Basic concepts on distributions and airflows have been reviewed by the American Society of Heating Refrigerating & Air Conditioning Engineers (ASHRAE, 2013). Indoor-outdoor and room-to-room temperature differences create density differences that help determine basic patterns of air motion. During the heating season, warmer indoor air tends to rise to exit the building at upper levels by stack action. Exiting air is replaced at lower levels by an influx of colder

outdoor air. During the cooling season, this pattern is reversed: stack forces during the cooling season are generally not as strong as in the heating season because the indoor-outdoor temperature differences are not as pronounced.

The position of the neutral pressure level (i.e., the point where indoor-outdoor pressures are equal) depends on the leakage configuration of the building envelope. The stack effect arising from indoor-outdoor temperature differences is also influenced by the partitioning of the building interior. When there is free communication between floors or stories, the building behaves as a single volume affected by a generally rising current during the heating season and a generally falling current during the cooling season. When vertical communication is restricted, each level essentially becomes an independent zone. As the wind flows past a building, regions of positive and negative pressure (relative to indoors) are created within the building; positive pressures induce an influx of air, whereas negative pressures induce an outflow. Wind effects and stack effects combine to determine a net inflow or outflow.

The final element of indoor transport involves the actions of natural and mechanical ventilation systems. Natural ventilation uses pressure differences indoors and outdoors that arise from natural forces through openings such as windows, while mechanical systems circulate indoor air through the use of fans. There are generally three air distribution methods used for room ventilation: mixed ventilation, displacement ventilation, and stratum ventilation (Cheng and Lin, 2015). A mixed ventilation results in a uniform environment since air is supplied by jets. Displacement ventilation uses gravity to form a stratified environment. In stratum ventilation, the air is directly delivered to occupants’ head level.

Mechanical ventilation systems may be connected to heating/cooling systems that, depending on the type of building, recirculate thermally treated indoor air or a mixture of fresh air and recirculated air. Mechanical systems also may be solely dedicated to exhausting air from a designated area, as with some kitchen range hoods and bath exhausts, or to recirculating air in designated areas as with a room fan. Local air circulation also is influenced by the movement of people and the operation of local heat sources.

19.2. RECOMMENDATIONS

Table 19-1 presents the recommendations for residential building volumes and air exchange rates. Table 19-2 presents the confidence ratings for the recommended residential building volumes. The 2009 Residential Energy Consumption Survey (RECS) data

indicates a 446 m³ average living space (approximately 2000 ft² area, assuming an 8 ft ceiling height) (U.S. DOE, 2013). However, these values vary depending on the type of housing (see Section 19.3.1.1). The recommended lower end of housing volume is 154 m³ (approximately 675 ft² area assuming ceiling height of 8 ft). The 10th percentile is based on EPA's analysis of the data from the 2005 RECS survey. Other percentiles are available in Section 19.3.1.1.

Residential air exchange rates vary by region of the country and seasonally. The recommended median air exchange rate for all regions combined is 0.45 ACH. The arithmetic mean is not preferred because it is influenced fairly heavily by extreme values at the upper tail of the distribution. This value was derived by Koontz and Rector (1995) using the perfluorocarbon tracer (PFT) database and is supported by Persily et al. (2010). Although Persily et al. (2010) provides more recent information on air exchange rates, the data were based on modeling data from two databases including the RECS database and the U.S. Census Bureau American Housing Survey (AHS) database. Koontz and Rector (1995) also has an advantage over Persily et al. (2010) in that it provides data for the various regions of the country. Section 19.5.1.1.1 presents distributions for the various regions of the country. For a conservative value, the 10th percentile for the PFT database (0.18 ACH) is recommended (see Section 19.5.1.1.1).

Table 19-3 presents the recommended values for nonresidential building volumes and air exchange rates. Volumes of nonresidential buildings vary with type of building (e.g., office space, malls). They range from 1,889 m³ for food services to 287,978 m³ for enclosed malls. The mean for all buildings combined is 5,575 m³. These data come from the Commercial Buildings Energy Consumption Survey (CBECS) (U.S. DOE, 2008b). The last CBECS for which data are publicly available was conducted in 2012. However, microdata from this survey year have not been analyzed by EPA. Instead, analyses of the 2003 data were conducted by EPA to derive recommendations for nonresidential building volume and air exchange rates. Table 19-4 presents the confidence ratings for the nonresidential building volume recommendations. The mean air exchange rate for all nonresidential buildings combined is 1.5 ACH. The 10th percentile air exchange rate for all buildings combined is 0.60 ACH. These data come from Turk et al. (1987).

Table 19-5 presents the confidence ratings for the air exchange rate recommendations for both residential and nonresidential buildings. Air exchange rate data presented in the studies are extremely limited.

Therefore, the recommended values have been assigned a "low" overall confidence rating, and these values should be used with caution.

Volume and air exchange rates can be used by exposure assessors in modeling indoor-air concentrations as one of the inputs to exposure estimation. Other inputs to the modeling effort include rates of indoor pollutant generation and losses to (and, in some cases, re-emissions from) indoor sinks. Other things being equal (i.e., holding constant the pollutant generation rate and effect of indoor sinks), lower values for either the indoor volume or the air exchange rate will result in higher indoor-air concentrations. Thus, values near the lower end of the distribution (e.g., 10th percentile) for either parameter are appropriate in developing conservative estimates of exposure.

There are some uncertainties in, or limitations on, the distribution for volumes and air exchange rates that are presented in this chapter. In addition, there are no systematic survey studies of air exchange rate. For example, the RECS contains information on floor area rather than total volume. The PFT database did not base its measurements on a sample that was statistically representative of the national housing stock or balanced by time of the year. PFT has been found to underpredict seasonal average air exchange by 15 to 35% Sherman (1989). Using PFT to determine air exchange can produce significant errors when conditions during the measurements greatly deviate from idealizations calling for constant, well-mixed conditions. Principal concerns focus on the effects of naturally varying air exchange and the effects of temperature in the permeation source. Some researchers have found that failing to use a time-weighted average temperature can greatly affect air exchange rate estimates (Leaderer et al., 1985). A final difficulty in estimating air exchange rates for any particular zone results from interconnectedness of multizone models and the effect of neighboring zones as demonstrated by Sinden (1978) and Sandberg (1984).

Table 19-1. Summary of Recommended Values for Residential Building Parameters			
	Mean	10 th Percentile	Source
Volume of residence ^a	446 m ³ (central estimate) ^b	154 m ³ (lower percentile) ^c	EPA analysis of U.S. DOE, (2013, 2008a)
Air exchange rate	0.45 ACH (central estimate) ^d	0.18 ACH (lower percentile) ^e	Koontz and Rector (1995); Persily et al. (2010)
^a	Volumes vary with type of housing. For specific housing type volumes, see Tables 19-6 and 19-7.		
^b	Mean value presented in Table 19-6 recommended for use as a central estimate for all single family homes, including mobile homes and multifamily units.		
^c	10 th percentile value from Table 19-9 recommended to be used as a lower percentile estimate.		
^d	Median value recommended to be used as a central estimate based across all U.S. census regions and various housing types (see Tables 19-25 and 19-26).		
^e	10 th percentile value across all U.S. census regions recommended to be used as a lower percentile value (see Table 19-25).		
ACH	= Air changes per hour.

Table 19-4. Confidence in Nonresidential Volume Recommendations ^a		
General Assessment Factors	Rationale	Rating
Soundness <i>Adequacy of approach</i>	All nonresidential data were based on one study: CBECS (U.S. DOE, 2008b). Volumes were estimated assuming a 20-foot ceiling height assumption for warehouses and a 12-foot height assumption for all other nonresidential buildings based on scant anecdotal information. Although Murray (1997) found that the impact of an 8-foot ceiling assumption was insignificant for residential structures, the impact of these ceiling height assumptions for nonresidential buildings is unknown.	Medium
<i>Minimal (or defined) bias</i>	Selection of residences was random for CBECS.	
Applicability and utility <i>Exposure factor of interest</i>	CBECS (U.S. DOE, 2008b) contained ample building size data, which were used as the basis provided for volume estimates.	High
<i>Representativeness</i>	CBECS (U.S. DOE, 2008b) was a nationwide study that generated weighted nationwide data based upon a large random sample.	
<i>Currency, data collection period</i>	The data were collected in 2003.	
Clarity and completeness <i>Accessibility</i>	The data are available online in both summary tables and raw data. http://www.eia.doe.gov/emeu/cbeecs/contents.html .	High
<i>Reproducibility</i>	Direct measurements were made.	
<i>Quality assurance</i>	Not applicable.	
Variability and uncertainty <i>Variability in population</i>	Distributions are presented by building type, heating and cooling system type, and employment, but a few subcategory sample sizes were small.	Medium
<i>Uncertainty</i>	Volumes were calculated using speculative assumptions for building height. The impact of such assumptions may or may not be significant.	
Evaluation and review <i>Peer review</i>	There are no studies from the peer-reviewed literature.	Low
<i>Number and agreement of studies</i>	All data are based upon one study: CBECS (U.S. DOE, 2008b).	
Overall Rating		Medium

19.3. RESIDENTIAL BUILDING CHARACTERISTICS STUDIES

19.3.1. Key Study of Volumes of Residences

19.3.1.1. U.S. DOE (2017, 2013, 2008a)—Residential Energy Consumption Survey (RECS)

Measurement surveys have not been conducted to directly characterize the range and distribution of volumes for a random sample of U.S. residences. Related data, however, are regularly collected through the U.S. Department of Energy's (DOE) RECS. In addition to collecting information on energy use, this survey collects data on housing characteristics including direct measurements of total and heated floor space for buildings visited by survey specialists. The last three surveys were conducted in 2005, 2009, and 2015. Data from these survey years were made available in 2008, 2013, and 2017, respectively. For the most recent survey conducted in 2015, a multistage probability sample of more than 5,600 residences was surveyed, representing 118.2 million housing units nationwide

(www.eia.gov/consumption/residential/about.php).

However, not all of the data from the 2015 survey were available in time for the revisions to this chapter. For example, the floor space area from the residences surveyed in 2015 is not available yet. In 2009, the survey consisted of a multistage probability sample of 12,083 residences, representing 113.6 million housing units nationwide. The 2009 survey response rate was 79% (U.S. DOE, 2013). Housing volumes were estimated using the RECS 2009 data since the data from the 2015 were not available. These were estimated by multiplying the heated floor space area by an assumed ceiling height of 8 feet. The data and data tables were released to the public in 2013 and are available from

<https://www.eia.gov/consumption/residential/data/2009/index.php?view=characteristics>.

Table 19-6 presents results for average residential volume by type of residence, census region, and urbanicity (i.e., urban vs. rural). The predominant housing type—single-family detached homes—also had the largest average volume. Multifamily units and mobile homes had volumes averaging about half that of single-family detached homes, with single-family attached homes about halfway between these extremes. The average house volume for all types of units for all years was estimated to be 446 m³. Table 19-7 presents the average residential volume for single family homes, multifamily homes, and mobile homes by housing unit type, census region, and urbanicity. Data on the relationship of residential

volume to year of construction are provided in Table 19-8 and indicate a slight decrease in residential volumes between 1950 and 1979, followed by an increasing trend. A ceiling height of 8 feet was assumed in estimating the average volumes, whereas there may have been some time-related trends in ceiling height. It is important to note that the available data used to derive volumes included all basements, finished or conditioned (heated or cooled) areas of attics, and conditioned garage space that is attached to the home. Unconditioned and unfinished areas in attics and attached garages are excluded.

In 2010, the EPA conducted an analysis of the RECS 2005 survey microdata files. The RECS 2005 survey consisted of a sample of 4,382 residences representing 111 million housing units nationwide. The response rate in the 2005 RECS survey was 71% (U.S. DOE 2008a). Table 19-9 presents distributions of residential volumes for all house types and all units estimated by the EPA using the 2005 microdata. Similar analysis has not been conducted with the more recent data sets from 2009 and 2015.

The advantages of this study were that the sample size was large, and it was representative of houses in the United States. Also, it included various housing types. A limitation of this analysis is that volumes were estimated assuming a ceiling height of 8 feet. Volumes of individual rooms in the house cannot be estimated. In addition, not all the data from the most recent survey years have been released.

19.3.2. Relevant Studies of Volumes of Residences

19.3.2.1. Versar (1990)—Database on Perfluorocarbon Tracer (PFT) Ventilation Measurements

Versar (1990) compiled a database of time-averaged air exchange and interzonal airflow measurements in more than 4,000 residences. These data were collected between 1982 and 1987. The residences that appear in this database are not a random sample of U.S. homes. However, they represent a compilation of homes visited in about 100 different field studies, some of which involved random sampling. In each study, the house volumes were directly measured or estimated. The collective homes visited in these field projects are not geographically balanced. A large fraction of these homes are located in southern California. Statistical weighting techniques were applied in developing estimates of nationwide distributions to compensate for the geographic imbalance. The Versar (1990) PFT database found a mean value of 369 m³ (see Table 19-10).

The advantage of this study is that it provides a distribution of house volumes. However, more up-to-date data are available from RECS 2009 (U.S. DOE, 2013).

19.3.2.2. Murray (1997)—Analysis of RECS and PFT Databases

Using a database from the 1993 RECS and an assumed ceiling height of 8 feet, Murray (1997) estimated a mean residential volume of 382 m³ using RECS estimates of heated floor space. This estimate is slightly different from the mean of 369 m³ given in Table 19-10. Murray's (1997) sensitivity analysis indicated that when a fixed ceiling height of 8 feet was replaced with a randomly varying height with a mean of 8 feet, there was little effect on the standard deviation of the estimated distribution. From a separate analysis of the PFT database, based on 1,751 individual household measurements, Murray (1997) estimated an average volume of 369 m³, the same as previously given in Table 19-10. In performing this analysis, the author carefully reviewed the PFT database in an effort to use each residence only once, for those residences thought to have multiple PFT measurements.

Murray (1997) analyzed the distribution of selected residential zones (i.e., a series of connected rooms) using the PFT database. The author analyzed the "kitchen zone" and the "bedroom zone" for houses in the Los Angeles area that were labeled in this manner by field researchers, and "basement," "first floor," and "second floor" zones for houses outside of Los Angeles for which the researchers labeled individual floors as zones. The kitchen zone contained the kitchen in addition to any of the following associated spaces: utility room, dining room, living room, and family room. The bedroom zone contained all the bedrooms plus any bathrooms and hallways associated with the bedrooms. The following summary statistics (mean \pm standard deviation) were reported by Murray (1997) for the volumes of the zones described above: 199 \pm 115 m³ for the kitchen zone, 128 \pm 67 m³ for the bedroom zone, 205 \pm 64 m³ for the basement, 233 \pm 72 m³ for the first floor, and 233 \pm 111 m³ for the second floor.

The advantage of this study is that the data are representative of homes in the United States. However, more up-to-date data are available from the RECS 2009 (U.S. DOE, 2013).

19.3.2.3. U.S. Census Bureau (2017)—American Housing Survey for the United States: 2015

The American Housing Survey (AHS) is conducted by the Census Bureau for the Department of Housing and Urban Development. It collects data on the Nation's housing, including apartments, single-family homes, mobile homes, vacant housing units, household characteristics, housing quality, foundation type, drinking water source, equipment and fuels, and housing unit size. National data are collected biennially between May and September in odd-numbered years. The 2015 survey was comprised of a national sample of 5,686 housing units representing 118.2 million occupied primary households in the United States. The U.S. Census Bureau (2017) lists the number of residential single detached and manufactured/mobile homes in the United States within the owner or renter categories, based on the AHS (see Table 19-11). Assuming an 8-foot ceiling, these units have a median size of 340 m³; however, these values do not include multifamily units, but include single detached and manufactured/mobile homes. It should be mentioned that 8 feet is the most common assumed ceiling height, and Murray (1997) has shown that the effect of the 8-foot ceiling height assumption is not significant.

The advantage of this study is that it was a large national sample and, therefore, representative of the United States. The limitations of these data are that distributions were not provided by the authors, and the analysis did not include multifamily units.

19.3.3. Other Factors

19.3.3.1. Surface Area and Room Volumes

The surface areas of floors are commonly considered in relation to the room or house volume, and their relative loadings are expressed as a surface area-to-volume, or loading ratio. Table 19-12 provides the basis for calculating loading ratios for typical-sized rooms. Constant features in the examples are a room width of 12 feet and a ceiling height of 8 feet (typical for residential buildings), or a ceiling height of 12 feet (typical for some types of commercial buildings).

Volumes of individual rooms are dependent on the building size and configuration, but summary data are not readily available. The exposure assessor is advised to define specific rooms, or assemblies of rooms, that best fit the scenario of interest. Most models for predicting indoor air concentrations specify airflows in m³ per hour and, correspondingly, express volumes in m³. A measurement in ft³ can be converted to m³ by multiplying the value in ft³ by

0.0283 m³/ft³. For example, a bedroom that is 9 feet wide by 12 feet long by 8 feet high has a volume of 864 ft³ or 24.5 m³. Similarly, a living room with dimensions of 12 feet wide by 20 feet long by 8 feet high has a volume of 1,920 ft³ or 54.3 m³, and a bathroom with dimensions of 5 feet by 12 feet by 8 feet has a volume of 480 ft³ or 13.6 m³.

19.3.3.2. *Products and Materials*

Table 19-13 presents examples of assumed amounts of selected products and materials used in constructing or finishing residential surfaces (Tucker, 1991). Products used for floor surfaces include adhesive, varnish, and wood stain; and materials used for walls include paneling, painted gypsum board, and wallpaper. Particleboard and chipboard are commonly used for interior furnishings such as shelves or cabinets but could also be used for decking or underlayment. It should be noted that numbers presented in the table for surface area are based on typical values for residences, and they are presented as examples. In contrast to the concept of loading ratios presented above (as a surface area), the numbers in the table also are not scaled to any particular residential volume. In some cases, it may be preferable for the exposure assessor to use professional judgment in combination with the loading ratios given above. For example, if the exposure scenario involves residential wall to wall carpeting in a room of 3 × 4 m with a ceiling height of 2.5 m (approximately 8 feet), it will have a loading ratio of 0.4 m²m⁻³ (Tichenor, 2006). This can be multiplied by an assumed residential volume and assumed fractional coverage of carpeting to derive an estimate of the surface area. More specifically, a residence with a volume of 300 m³, a loading ratio of 0.4 m²m⁻³, and coverage of 80%, would have 96 m² of carpeting. The estimates discussed here relate to macroscopic surfaces; the true surface area for carpeting, for example, would be considerably larger because of the nature of its fibrous material.

19.3.3.3. *Mechanical System Configurations*

Mechanical systems for air movement in residences can affect the migration and mixing of pollutants released indoors and the rate of pollutant removal. Three types of mechanical systems are (1) systems associated with heating, ventilating, and air conditioning (HVAC); (2) systems whose primary function is providing localized exhaust; and (3) systems intended to increase the overall air exchange rate of the residence.

Portable space heaters intended to serve a single room, or a series of adjacent rooms, may or may not

be equipped with blowers that promote air movement and mixing. Without a blower, these heaters still have the ability to induce mixing through convective heat transfer. If the heater is a source of combustion pollutants, as with unvented gas or kerosene space heaters, then the combination of convective heat transfer and thermal buoyancy of combustion products will result in fairly rapid dispersal of such pollutants. The pollutants will disperse throughout the floor where the heater is located and to floors above the heater, but may not disperse to floors below.

Central forced-air HVAC systems are common in many residences. Such systems, through a network of supply/return ducts and registers, can achieve fairly complete mixing within 20 to 30 minutes (Koontz et al., 1988). The air handler for such systems is commonly equipped with a filter (see Figure 19-2) that can remove particle-phase contaminants. Further removal of particles, via deposition on various room surfaces (see Section 19.5.5), is accomplished through increased air movement when the air handler is operating.

Figure 19-2 also distinguishes forced-air HVAC systems by the return layout in relation to supply registers. The return layout shown in the upper portion of the figure is the type most commonly found in residential settings. On any floor of the residence, it is typical to find one or more supply registers to individual rooms, with one or two centralized return registers. With this layout, supply/return imbalances can often occur in individual rooms, particularly if the interior doors to rooms are closed. In comparison, the supply/return layout shown in the lower portion of the figure by design tends to achieve a balance in individual rooms or zones. Airflow imbalances can also be caused by inadvertent duct leakage to unconditioned spaces such as attics, basements, and crawl spaces. Such imbalances usually depressurize the house, thereby increasing the likelihood of contaminant entry via soil-gas transport or through spillage of combustion products from vented fossil-fuel appliances such as fireplaces and gas/oil furnaces.

Mechanical devices such as kitchen fans, bathroom fans, and clothes dryers are intended primarily to provide localized removal of unwanted heat, moisture, or odors. Operation of these devices tends to increase the air exchange rate between the indoors and outdoors. Because local exhaust devices are designed to be near certain indoor sources, their effective removal rate for locally generated pollutants is greater than would be expected from the dilution effect of increased air exchange. Operation of these devices also tends to depressurize the house, because

replacement air usually is not provided to balance the exhausted air.

An alternative approach to pollutant removal is one which relies on an increase in air exchange to dilute pollutants generated indoors. This approach can be accomplished using heat recovery ventilators (HRVs) or energy recovery ventilators (ERVs). Both types of ventilators are designed to provide balanced supply and exhaust airflows and are intended to recover most of the energy that normally is lost when additional outdoor air is introduced. Although ventilators can provide for more rapid dilution of internally generated pollutants, they also increase the rate at which outdoor pollutants are brought into the house. A distinguishing feature of the two types is that ERVs provide for recovery of latent heat (moisture) in addition to sensible heat. Moreover, ERVs typically recover latent heat using a moisture-transfer device such as a desiccant wheel. It has been observed in some studies that the transfer of moisture between outbound and inbound air streams can result in some re-entrainment of indoor pollutants that otherwise would have been exhausted from the house (Andersson et al., 1993). Inadvertent air communication between the supply and exhaust air streams can have a similar effect.

Studies quantifying the effect of mechanical devices on air exchange using tracer-gas measurements are uncommon and typically provide only anecdotal data. The common approach is for the expected increment in the air exchange rate to be estimated from the rated airflow capacity of the device(s). For example, if a device with a rated capacity of 100 ft³ per minute, or 170 m³ per hour, is operated continuously in a house with a volume of 400 m³, then the expected increment in the air exchange rate of the house would be 170 m³ hour⁻¹/400 m³, or approximately 0.4 ACH.

U.S. DOE RECS contains data on residential heating characteristics. The data show that most homes in the United States have some kind of heating and air conditioning system (U.S. DOE, 2017). The types of system vary regionally within the United States. Table 19-14 shows the type of primary and secondary heating systems found in U.S. residences. The predominant primary heating system in the Midwest is natural gas (used by 67.0% of homes there) while most homes in the South (60.1%) primarily heat with electricity. Nationwide, 36.6% of residences have a secondary heating source, typically an electric source.

Table 19-15 shows the type of heating systems found in the United States by climate region. It is noteworthy that 51.4% of residences in very cold/cold

climate use central heating compared to 19.7% in hot humid climate.

Table 19-16 shows that 87.2% of U.S. residences have some type of cooling system: 65.2% have central air while 26.7% use individual air conditioning units. Like heating systems, cooling system type varies regionally as well. In the South, 95.3% of residences have either central or room air conditioning units whereas only 54.9% of residences in the Western United States have air conditioning.

19.3.3.4. Type of Foundation

The type of foundation of a residence is of interest in residential exposure assessment. It provides some indication of the number of stories and house configuration, as well as an indication of the relative potential for soil-gas transport. For example, such transport can occur readily in homes with enclosed crawl spaces. Homes with basements provide some resistance, but still have numerous pathways for soil-gas entry. By comparison, homes with crawl spaces open to the outside have significant opportunities for dilution of soil gases prior to transport into the house. Using data from the 2015 AHS, of total housing units in the United States, 31% have a basement under the entire building, 11% have a basement under part of the building, 22% have a crawl space, and 36% are on a concrete slab (U.S. Census Bureau, 2017).

19.3.3.4.1. Lucas et al. (1992)—National Residential Radon Survey

The estimated percentage of homes with a full or partial basement according to the National Residential Radon Survey of 5,700 households nationwide was 44% (see Table 19-17) (Lucas et al., 1992). The National Residential Radon Survey provides data for more refined geographical areas, with a breakdown by the 10 EPA Regions. The New England region (i.e., EPA Region 1), which includes Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, and Vermont, had the highest prevalence of basements (93%). The lowest prevalence (4%) was for the South Central region (i.e., EPA Region 6), which includes Arkansas, Louisiana, New Mexico, Oklahoma, and Texas. Section 19.3.3.4.2 presents the states associated with each census region and EPA region.

19.3.3.4.2. U.S. DOE (2008a, 2013, 2017)—Residential Energy Consumption Survey (RECS)

The three most recent RECS (described in Section 19.3.1.1) were administered in 2005, 2009,

and 2015 (U.S. DOE, 2008a, 2013, 2017). The type of information requested by the survey questionnaire included the type of foundation for the residence (i.e., basement, enclosed crawl space, crawl space open to outside, or concrete slab). This information was not obtained for multifamily structures with five or more dwelling units or for mobile homes. EPA analyzed the RECS 2015 data (U.S. DOE, 2017) to estimate the percentage of residences with basements by census region. Table 19-18 indicates that 43.5% of residences have basements nationwide. Table 19-19 shows the states associated with each EPA region and census region. Table 19-20 presents the percentage of residences with each foundation type, by census region, and for the entire United States. The foundation type data (other than basements) were not included in the RECS 2015 survey. Therefore, the values presented in Table 19-20 are based on data from the RECS 2009 survey (U.S. DOE, 2013). The percentages can add up to more than 100% because some residences have more than one type of foundation; for example, many split-level structures have a partial basement combined with some crawlspace that typically is enclosed. The data in Table 19-20 indicate that 39.9% of residences nationwide have a basement. It also shows that a large fraction of homes have concrete slabs (46.5%). There are also variations by census region. For example, around 74.7 and 72.5% of the residences in the Northeast and Midwest regions, respectively, have basements. In the South and West regions, the predominant foundation type is concrete slab.

The advantage of this study is that it had a large sample size, and it was representative of houses in the United States. Also, it included various housing types. A limitation of this analysis is that homes have multiple foundation types, and the analysis does not provide estimates of square footage for each type of foundation. Also, the information collected varied slightly across survey years and the data from the most recent survey were not available to be analyzed.

19.4. NONRESIDENTIAL BUILDING CHARACTERISTICS STUDIES

19.4.1. U.S. DOE (2008b, 2016)—Nonresidential Building Characteristics—Commercial Buildings Energy Consumption Survey (CBECS)

The U.S. Department of Energy conducts the CBECS to collect data on the characteristics and energy use of commercial buildings. CBECS is a national survey of U.S. buildings that DOE first conducted in 1979. The survey is conducted every 4 years. In 2010, EPA conducted an analysis of the

U.S. DOE CBECS 2003 data, released in 2008. CBECS defines “Commercial” buildings as all buildings in which at least half of the floorspace is used for a purpose that is not residential, industrial, or agricultural, so they include building types that might not traditionally be considered commercial, such as schools, correctional institutions, and buildings used for religious worship.

The 2003 CBECS provided nationwide estimates for the United States based upon a weighted statistical sample of 5,215 buildings. DOE releases a data set about the sample buildings for public use. The 2003 CBECS Public Use Microdata set includes data for 4,820 nonmall commercial buildings (U.S. DOE, 2008b). A second data set is available that includes information on malls, lacks building characteristics data. Building characteristics data provided by CBECS includes floor area, number of floors, census division, heating and cooling design, principal building activity, number of employees, and weighting factors. Although DOE released the Microdata from the 2012 survey in 2016, EPA did not analyze these data to estimate volumes of commercial buildings, the number of hours per week they are open, and the number of employees during the main shift because of the amount of effort involved and the likelihood that values have not changed considerably.

Table 19-21 shows that nonresidential buildings vary greatly in volumes. The table shows average volume for a numbers of structures including offices (5,036 m³), restaurants (food services) (1,889 m³), schools (education) (8,694 m³), hotels (lodging) (11,559 m³), and enclosed shopping malls (287,978 m³). Each of these structures varies considerably in size as well. The large shopping malls are over 500,000 m³ (90th percentile). The most numerous of the nonresidential buildings are office buildings (17%), nonfood service buildings (13%), and warehouses (12%).

Table 19-22 presents data on the number of hours various types of nonresidential buildings are open for business and the number of employees that work in such buildings. In general, places of worship have the most limited hours. The average place of worship is open 32 hours per week. On the other extreme are healthcare facilities, which are open 168 hours a week (24 hours per day, 7 days per week). The average restaurant is open 86 hours per week. Hours vary considerably by building type. Some offices, labs, warehouses, restaurants, police stations, and hotels are also open 24 hours per day, 7 days per week, as reflected by the 90th percentiles. Table 19-22 also presents the number of employees typically employed in such buildings during the main shift. Overall, the average building houses 16 workers during its primary

shift, but some facilities employ many more. The average hospital employs 471 workers during its main shift, although those in the 10th percentile employ only 175, and those in the 90th employ 2,250.

EPA used the 2012 CBECS, however, to update the information on the heating and cooling sources using the summary tables tabulated by the U.S. Energy Information Administration of the U.S. DOE and released to the public in 2016 (U.S. DOE, 2016). Tables 19-23 and 19-24 present these data. Table 19-23 indicates that electricity and natural gas are the heating sources used by a majority of nonresidential buildings. Of those buildings heated by fuel oil, most are older buildings.

Table 19-24 describes nonresidential building cooling characteristics. About 80% (i.e., $4,461/5,557 \times 100$) of nonresidential buildings have air conditioning, but this varies regionally from 14% in the Northeast to 40% in the South. Nationwide, 79% (i.e., $4,413/5,557 \times 100$) of nonresidential buildings use electricity for air conditioning. The remaining fraction use natural gas or chilled water.

It should be noted, however, that there are many critical exposure assessment elements not addressed by CBECS. These include a number of elements discussed in more detail in the Residential Building Characteristics Studies section (i.e., Section 19.3). Data to characterize the room volume, products and materials, and foundation type for nonresidential buildings were not available in CBECS.

Another characteristic of nonresidential buildings needed in ventilation and air exchange calculations is ceiling height. Unseen spaces (e.g. above ceiling tiles) complicate the volume and mixing assumptions by creating rather large separate compartments. In the residential section of this chapter, ceiling height was assumed to be 8 feet, a figure often assumed for residential buildings. For nonresidential buildings, EPA has assumed a 20-foot ceiling height for warehouses and enclosed shopping malls and a 12-foot average ceiling height for other structures. These assumptions are based on EPA's professional judgment. Murray (1997) found that the impact of assuming an 8-foot ceiling height for residences was insignificant, but nonresidential ceiling height varies more greatly and may or may not have a significant impact on calculations.

19.5. TRANSPORT RATE STUDIES

19.5.1. Air Exchange Rates

Air exchange is the balanced flow into and out of a building and is composed of three processes: (1) infiltration—air leakage through random cracks, interstices, and other unintentional openings in the

building envelope; (2) natural ventilation—airflows through open windows, doors, and other designed openings in the building envelope; and (3) forced or mechanical ventilation—controlled air movement driven by fans (Breen et al., 2014).

For nearly all indoor exposure scenarios, air exchange is treated as the principal means of diluting indoor concentrations. The air exchange rate is generally expressed in terms of ACH (with units of hours⁻¹). It is defined as the ratio of the airflow (m³ hours⁻¹) to the volume (m³). Thus, ACH and building size and volume are negatively correlated. Air exchange rates can affect the dynamic and the steady state behavior of indoor air pollutants (Breen et al., 2014).

Air exchange rates are influenced by many factors including building characteristics, type of ventilation system affecting air flow patterns (includes natural and mechanical), temperature differentials between rooms and floors and between indoors and outdoors, seasonality, occupant behavior (e.g., walking from room to room, opening of windows) and measurement techniques (Lee et al., 2016; Wu and Lin, 2015; Breen et al., 2014). Higher air exchange rates have been observed in the summer and during occupied daytime periods (Bekö et al., 2016; Lee et al., 2016; Wu and Lin, 2015; Breen et al., 2014; Kearney et al 2014; Zhao and Zeng, 2009).

The primary method for measuring air exchange rates in a building consist of releasing a nonreactive gas tracer into the building and allowing it to mix with the indoor air. The tracer gas can be injected into the building using an emitter device (e.g., SF₆) or released from the exhaled breath of building occupants in the form of CO₂. These tracer concentrations are monitored to estimate the air exchange rates. The gas tracer methods are based on a mass balance approach assuming that the gas tracer is well mixed, the tracer concentration outdoor is zero, and accounting for air leakage (Breen et al., 2014).

No measurement surveys have been conducted to directly evaluate the range and distribution of building air exchange rates. In addition, there is almost no information on the use of natural ventilation (e.g., how much or often windows are kept open). Although a significant number of air exchange measurements have been carried out over the years, there has been a diversity of protocols and study objectives. Since the early 1980s, however, an inexpensive PFT technique has been used to measure time-averaged air exchange and interzonal airflows in thousands of occupied residences using essentially similar protocols (Dietz et al., 1986). The PFT technique utilizes miniature permeation tubes as tracer emitters and passive samplers to collect the tracers. Sampling periods

(e.g., days, weeks, months) vary depending on the study design. The passive samplers are returned to the laboratory for analysis by gas chromatography. These measurement results have been compiled to allow various researchers to access the data (Versar, 1989).

19.5.1.1. Key Study of Residential Air Exchange Rates

19.5.1.1.1. Koontz and Rector (1995)—Estimation of distributions for residential air exchange rates

In analyzing the composite data from various projects (2,971 measurements), Koontz and Rector (1995) assigned weights to the results from each state to compensate for the geographic imbalance in locations where PFT measurements were taken. The results were weighted in such a way that the resultant number of cases would represent each state in proportion to its share of occupied housing units, as determined from the 1990 U.S. Census of Population and Housing.

Table 19-25 shows summary statistics from the Koontz and Rector (1995) analysis, for the country as a whole and by census regions. Based on the statistics for all regions combined, the authors suggested that a 10th percentile value of 0.18 ACH would be appropriate as a conservative estimator for air exchange in residential settings, and that the 50th percentile value of 0.45 ACH would be appropriate as a typical air exchange rate. In applying conservative or typical values of air exchange rates, it is important to realize the limitations of the underlying database. Although the estimates are based on thousands of measurements, the residences represented in the database are not a random sample of the U.S. housing stock. Also, the sample population is not balanced in terms of geography or time of year, although statistical techniques were applied to compensate for some of these imbalances. In addition, PFT measurements of air exchange rates assume uniform mixing of the tracer within the building. This is not always so easily achieved. Furthermore, the degree of mixing can vary from day to day and house to house because of the nature of the factors controlling mixing (e.g., convective air monitoring driven by weather, and type and operation of the heating system). The relative placement of the PFT source and the sampler can also cause variability and uncertainty. It should be noted that sampling is typically done in a single location in a house that may not represent the average from that house. In addition, very high and very low values of air exchange rates based on PFT measurements have greater uncertainties than those in the middle of the

distribution. Despite such limitations, the estimates in Table 19-25 are believed to represent the best available information on the distribution of air exchange rates across U.S. residences throughout the year.

19.5.1.1.2. Persily et al. (2010)—Modeled infiltration rate distributions for U.S. housing

Persily et al. (2010) generated frequency distributions of residential infiltration rates using CONTAM, a multizone airflow model. A collection of 209 residences was selected to be representative of 80% of the U.S. housing stock. The residences were taken from a database resulting from two residential housing surveys: the U.S. Department of Energy Residential Energy Consumption Survey (RECS) and the U.S. Census Bureau American Housing Survey (AHS). Together, these data sets included over 60,000 U.S. residences. The RECS 1997 was conducted between mid-April to the middle of June 1997 (U.S. DOE, 1997). The residences were grouped into four categories: detached, attached, manufactured homes, and apartments, and include key characteristics such as age, floor area, number of floors, foundation type, and garage. Representations of these residences were created in the airflow model CONTAM, and were used in this study to provide distributions for infiltration rates. The simulations were conducted for 19 cities representing U.S. climates and accounted for the impacts of ventilation system operation on infiltration rates.

Distributions of air change rates for various house categories are presented in Table 19-26. The 10th and 50th percentiles national average air change rate for single family homes were 0.16 and 0.44 ACH, respectively. For all house categories, the 50th percentile air change rate ranged from 0.09 to 0.58 ACH. In general, houses built after 1970 are tighter and show lower air exchange rates than those built before 1970.

The advantages of this study are that it is based on a relatively large number of homes and that the residences are representative of homes across the United States. However, the results of the study are based on modeling and the data used to generate the simulations were collected in 1997.

19.5.1.2. Relevant Studies of Residential Air Exchange Rates

19.5.1.2.1. Nazaroff et al. (1988)—Radon entry via potable water

Nazaroff et al. (1988) aggregated the data from two studies conducted earlier using tracer-gas decay.

At the time these studies were conducted, they were the largest U.S. studies to include air exchange measurements. The first (Grot and Clark, 1981) was conducted in 266 dwellings occupied by low-income families in 14 different cities. The geometric mean \pm standard deviation for the air exchange measurements in these homes, with a median house age of 45 years, was 0.90 ± 2.13 ACH. The second study (Grimsrud et al., 1983) involved 312 newer residences, with a median age of less than 10 years. Most of the houses were located in Washington, California, Colorado, New York and Ontario, Canada. Based on measurements taken during the heating season, the geometric mean \pm standard deviation for these homes was 0.53 ± 1.71 ACH. Based on an aggregation of the two distributions with proportional weighting by the respective number of houses studied, Nazaroff et al. (1988) developed an overall distribution with a geometric mean of 0.68 ACH and a geometric standard deviation of 2.01.

The limitation of this study is that houses did not represent all climatic regions of the United States and the number of houses included in the studies was small.

19.5.1.2.2. Versar (1989)—Database of PFT ventilation measurements

The residences included in the PFT database do not constitute a random sample across the United States. They represent a compilation of homes visited in the course of about 100 separate field-research projects by various organizations, some of which involved random sampling, and some of which involved judgmental or fortuitous sampling. Table 19-27 summarizes the larger projects in the PFT database, in terms of the number of measurements (samples), states where samples were taken, months when samples were taken, and summary statistics for their respective distributions of measured air exchange rates. For selected projects (Lawrence Berkeley Laboratory, Research Triangle Institute, Southern California—SOCAL), multiple measurements were taken for the same house, usually during different seasons. A large majority of the measurements are from the SOCAL project that was conducted in Southern California. The means of the respective studies generally range from 0.2 to 1.0 ACH, with the exception of two California projects—RTI2 and SOCAL2. Both projects involved measurements in Southern California during a time of year (July) when windows would likely be opened by many occupants.

The limitation of this study is that the PFT database did not base its measurements on a sample that was statistically representative of the national

housing stock. PFT has been found to underpredict seasonal average air exchange by 15 to 35% (Sherman, 1989). Using PFT to determine air exchange can produce significant errors when conditions in the measurement scene greatly deviate from idealizations calling for constant, well-mixed conditions.

19.5.1.2.3. Murray and Burmaster (1995)—Residential air exchange rates in the United States: empirical and estimated parametric distributions by season and climatic region

Murray and Burmaster (1995) analyzed the PFT database using 2,844 measurements (essentially the same cases as analyzed by Koontz and Rector (1995), but without the compensating weights). These authors summarized distributions for subsets of the data defined by climate region and season. The months of December, January, and February were defined as winter; March, April, and May were defined as spring; and so on. Table 19-28 summarizes the results of Murray and Burmaster (1995). Neglecting the summer results in the colder regions, which have only a few observations, the results indicate that the highest air exchange rates occur in the warmest climate region during the summer. As noted earlier, many of the measurements in the warmer climate region were from field studies conducted in Southern California during a time of year (July) when windows would tend to be open in that area. Data for warmer climate region in particular should be used with caution because other areas within this region tend to have very hot summers, and residences use air conditioners, resulting in lower air exchange rates. The lowest rates generally occur in the colder regions during the fall.

19.5.1.2.4. Diamond et al. (1996)—Ventilation and infiltration in high-rise apartment buildings

Diamond et al. (1996) studied air flow in a 13-story apartment building and concluded that “the ventilation to the individual units varies considerably.” With the ventilation system disabled, units at the lower level of the building had adequate ventilation only on days with high temperature differences, while units on higher floors had no ventilation at all. At times, units facing the windward side were over-ventilated. With the mechanical ventilation system operating, they found wide variation in the air flows to individual apartments. Diamond et al. (1996) also conducted a literature review and concluded there were little published data on air exchange in multifamily buildings, and that there was a general problem measuring, modeling, and designing ventilation systems for high-rise multifamily buildings. Air flow

was dependent upon building type, occupants' behavior, unit location, and meteorological conditions.

19.5.1.2.5. Graham et al. (2004)—Contribution of vehicle emissions from an attached garage to residential indoor air pollution levels

There have been several studies of vehicle emission seepage into homes from attached garages, which examined a single home. Graham et al. (2004) conducted a study of vehicle emission seepage of 16 homes with attached garages. On average, 11% of total house leakage was attributed to the house/garage interface (equivalent to an opening of 124 cm²), but this varied from 0.6 to 29.6%. The amount of in-house chemical concentrations attributed to vehicle emissions from the garage varied widely between homes from 9 to 85%. Greater leakage tended to occur in houses where the garage attached to the house on more than one side. The home's age was not an important factor. Whether the engine was warm or cold when it was started was important because cold-start emissions are dominated by the by-products of incomplete combustion. Cold-start tail pipe emissions were 32 times greater for carbon monoxide (CO), 10 times greater for nitrogen oxide (NO_x), and 18 times greater for total hydrocarbon emissions than hot-start tailpipe emissions.

19.5.1.2.6. Price et al. (2006)—Indoor-outdoor air leakage of apartments and commercial buildings

Price et al. (2006) compiled air exchange rate data from 14 different studies on apartment buildings in the United States and Canada. The authors found that indoor-outdoor air exchange rates seem to be twice as high for apartments as for single-family houses. The observed apartment air exchange rates ranged from 0.5 to 2 ACH.

19.5.1.2.7. Breen et al. (2010)—Residential air exchange rates from questionnaires and meteorology: model evaluation in central North Carolina

Breen et al. (2010) conducted a study comparing air exchange rate predictions from two mechanistic models with measurements from 31 detached homes in central North Carolina. Air monitoring was performed for 7 consecutive days in each of four consecutive seasons from summer 2000 to spring 2001. The study included two cohorts. The Raleigh cohort consisted of low to moderate socioeconomic status neighborhoods and the Chapel Hill cohort include moderate socioeconomic status

neighborhoods (Breen et al., 2010). Daily 24-hour air exchange rates were measured using the PFT method. Distributions of air exchange rate for each season and number of days that windows were opened are presented in Table 19-29. It is important to note that information about amount of time that windows were open during the day is lacking.

19.5.1.2.8. Yamamoto et al. (2010)—Residential air exchange rates in three U.S. metropolitan areas: results from the relationship among indoor, outdoor, and personal air study 1999—2001

Between 1999 and 2001, Yamamoto et al. (2010) conducted approximately 500 indoor-outdoor air exchange rate calculations based on residences in metropolitan Elizabeth, NJ; Houston, TX; and Los Angeles, CA. The median air exchange rate across these urban areas was 0.71 ACH; 0.87 in California, 0.88 in New Jersey, and 0.47 in Texas. In Texas, the measured air exchange rates were lower in the summer cooling season (median = 0.37 ACH) than in the winter heating season (median = 0.63 ACH), likely because of the reported use of room air conditioners. The measured air exchange rates in California were higher in summer (median = 1.13 ACH) than in winter (median = 0.61 ACH) because summers in Los Angeles County are less humid than New Jersey or Texas, and residents are more likely to utilize natural ventilation through open windows and screened doors. In New Jersey, air exchange rates in the heating and cooling seasons were similar.

19.5.1.3. Key Study of Nonresidential Air Exchange Rates

19.5.1.3.1. Turk et al. (1987)—Commercial building ventilation rates and particle concentrations

Few air exchange rates for commercial buildings are provided in the literature. Turk et al. (1987) conducted indoor air quality measurements, including air exchange rates, in 38 commercial buildings. The buildings ranged in age from 0.5 to 90 years old. One test was conducted in 36 buildings, and two tests were conducted in 2 buildings. Each building was monitored for 10 working days over a 2-week period yielding a minimum sampling time of 75 hours per building. Researchers found an average ventilation measurement of 1.5 ACH, which ranged from 0.3 to 4.1 ACH with a standard deviation of 0.87. Table 19-30 presents the results by building type.

19.5.1.3.2. Bennett et al. (2012)—Ventilation, temperature, and HVAC characteristics in small and medium commercial buildings in California

HVAC system characteristics and ventilation rates of commercial buildings in California were evaluated by Bennett et al. (2012). A total of 37 small and medium commercial buildings (SMCBs) were selected for study and were classified into small (24 buildings, 90–1,100 m²), medium (7 buildings, 1,100–2,300 m²), and medium/large (6 buildings, 2,300–4,600 m²). The majority of the SMCBs were selected to be representative of retail establishments, offices and restaurants, the most frequent building types in California. Other building types, selected for their potential for indoor pollutant sources, included beauty salons, dental offices, gas stations and gyms. For each building, the heating, ventilating, and air conditioning (HVAC) systems were inspected and measurements of air exchange and indoor environmental quality parameters, such as CO₂ levels, temperature and relative humidity were taken. In addition, whole building ventilation rates were determined using a tracer decay method.

Ventilation measurements for the buildings are presented in Table 19-31. The mean air exchange rate was 1.6 ± 1.7 exchanges per hour, and was similar between buildings with or without outdoor air provided.

This study provides useful information on the HVAC system characteristics and ventilation rates of SMCBs. However, the sample size was relatively small and all of the SMCBs were located in California which may not be representative of SMCBs located in other areas of the United States.

19.5.2. Indoor Air Models

Achieving adequate indoor air quality in a nonresidential building can be challenging. There are many factors that affect indoor air quality in buildings (e.g., building materials, building configuration, outdoor environment, ventilation systems, operation and maintenance, occupants and their activities). Indoor air models are typically used to study, identify, and solve problems involving indoor air quality in buildings, as well as to assess efficiency of energy use. The emphasis of most models is on the physical processes, but for some chemical reactions indoor which may be an important, but variable sink. Models generally assume a known and constant rate of reaction.

Indoor air quality models generally are not software products that can be purchased as “off-the-shelf” items. Most existing software models are research tools that have been developed for specific

purposes and are being continuously refined by researchers. Leading examples of indoor air models implemented as software products are as follows:

- CONTAM 3.2—CONTAM was developed at the National Institute of Standards and Technology (NIST) with support from EPA and the U.S. DOE. (Dols and Polidoro, 2016; Wang et al., 2010; Axley, 1988). CONTAM has been used by others to study the effects of model parameters (e.g., wind speed, presence of natural and mechanical ventilation) and the presence of an attached garage on the infiltration of contaminants indoors (Nirvan et al., 2012).
- IAQX—The Indoor Air Quality and Inhalation Exposure model is a Windows-based simulation software package developed by EPA (Guo, 2000).
- CPIEM 2.0—The California Population Indoor Exposure Model was developed for the California Air Resources Board (Rosenbaum et al., 2002).
- TEM—The Total Exposure Model was developed with support from EPA and the U.S. Air Force (Wilkes, 1998; Wilkes and Nuckols, 2000).
- RISK—RISK was developed by the Indoor Environment Management Branch of the EPA National Risk Management Research Laboratory (Sparks, 1997).
- TRIM—The Total Risk Integrated Methodology is an ongoing modeling project of EPA’s Office of Air Quality Planning and Standards (Efroymson and Murphy, 2001; Palma et al., 1999).
- TOXLT/TOXST—The Toxic Modeling System Long-Term was developed along with the release of the new version of the EPA’s Industrial Source Complex Dispersion Models (U.S. EPA, 1995).
- MIAQ—The Multi-Chamber Indoor Air Quality Model was developed for the California Institute of Technology and Lawrence Berkeley National Laboratory. Documentation last updated in 2002. (Nazaroff and Cass, 1986; Nazaroff and Cass, 1989a).
- MCCEM 1.2—the Multi-Chamber Consumer Exposure Model was developed for EPA Office of Pollution Prevention and Toxics (EPA/OPPT) (GEOMET, 1989; Koontz and Nagda, 1991).
- ART—Advanced Regulation, Evaluation, Authorization and restriction of Chemicals

(REACH) Tool was designed to model inhalation exposures in the occupational setting for a defined group of workers sharing specific operational conditions (Tielemans et al., 2011, 2008; Cherrie et al., 2011)

Price (2001) evaluated the use of many of the above products (TOXLT/TOXST, MCCEM, IAQX, CONTAM, CPIEM, TEM, TRIM, and RISK) in a tiered approach to assessing exposures and risks to children. The information provided is also applicable to adults.

19.5.3. Air Infiltration Models

A variety of mathematical models exist for prediction of air infiltration rates in individual buildings. A number of these models have been reviewed, for example, by Breen et al., (2014), Liddament and Allen (1983), and by Persily and Linteris (1984). Basic principles are concisely summarized in the ASHRAE Handbook of Fundamentals (ASHRAE, 2013). These models have a similar theoretical basis; all address indoor-outdoor pressure differences that are maintained by the actions of wind and stack (temperature difference) effects. The models generally incorporate a network of airflows where nodes representing regions of different pressure are interconnected by leakage paths. Individual models differ in details such as the number of nodes they can treat or the specifics of leakage paths (e.g., individual components such as cracks around doors or windows versus a combination of components such as an entire section of a building). Such models are not easily applied by exposure assessors, however, because the required inputs (e.g., inferred leakage areas, crack lengths) for the model are not easy to gather.

Another approach for estimating air infiltration rates is developing empirical models. Such models generally rely on the collection of infiltration measurements in a specific building under a variety of weather conditions. The relationship between the infiltration rate and weather conditions can then be estimated through regression analysis and is usually stated in the following form:

$$A = a + b |T_i - T_o| + cU^n \quad (\text{Eqn. 19-1})$$

where:

A = air exchange rate (hours⁻¹),
 T_i = indoor temperature (°C),
 T_o = outdoor temperature (°C),
 U = windspeed (m/second),
 n is an exponent with a value typically between 1 and 2, and
 a , b and c are parameters to be estimated.

Relatively good predictive accuracy usually can be obtained for individual buildings through this approach. However, exposure assessors often do not have the information resources required to develop parameter estimates for making such predictions.

A reasonable compromise between the theoretical and empirical approaches has been developed in the model specified by Dietz et al. (1986). The model, drawn from correlation analysis of environmental measurements and air infiltration data, is formulated as follows:

$$A = L \left(0.006 \Delta T \frac{0.03}{C} U^{1.5} \right) \quad (\text{Eqn. 19-2})$$

where:

A = average ACH or infiltration rate, hours⁻¹,
 L = generalized house leakiness factor ($1 < L < 5$),
 C = terrain sheltering factor ($1 < C < 10$),
 ΔT = indoor-outdoor temperature difference (°C), and
 U = windspeed (m/second).

The value of L is greater as house leakiness increases, and the value of C is greater as terrain sheltering (reflects shielding of nearby wind barrier) increases. Although the above model has not been extensively validated, it has intuitive appeal, and it is possible for the user to develop reasonable estimates for L and C with limited guidance. Historical data from various U.S. airports are available for estimation of the temperature and windspeed parameters. As an example application, consider a house that has central values of 3 and 5 for L and C , respectively. Under conditions where the indoor temperature is 20°C (68°F), the outdoor temperature is 0°C (32°F), and the windspeed is 5 m/second, the predicted infiltration rate for that house would be

3 $(0.006 \times 20 + 0.03/5 \times 51.5)$, or 0.56 ACH. This prediction applies under the condition that exterior doors and windows are closed and does not include the contributions, if any, from mechanical systems (see Section 19.3.3.3). Occupant behavior, such as opening windows, can, of course, overwhelm the idealized effects of temperature and wind speed.

Chan et al. (2005) analyzed the U.S. Residential Air Leakage database at Lawrence Berkley National Laboratory (LBNL) containing approximately 70,000 air leakage measurements from 30 states (predominantly Ohio, Alaska, and Wisconsin). They present the following equation for estimating ACH:

$$ACH = 48 \left(\frac{2.5}{H} \right)^{0.3} \frac{NL}{HF} [h^{-1}] \quad (\text{Eqn. 19-3})$$

where:

ACH = air changes per hour,
 H = building height (meters),
 NL = normalized leakage (unitless),
 F = scaling factor (unitless), and
 h = hours.

Chan et al. (2005) found that “older and smaller homes are more likely to have higher normalized leakage areas than newer and larger ones.” Table 19-32 summarizes the normalized leakage distributions in the United States.

It should be noted that newer homes were generally built tighter until about 1997 when the construction trend leveled off. Sherman and Matson (2002) also examined LBNL’s U.S. Residential Air Leakage database and found that average normalized leakage for 22,000 houses already in the database was 1.18 NL (total leakage cm^2 normalized for dwelling size m^2), but leakage among the 8,300 newer homes averaged 0.30 NL .

19.5.4. Vapor Intrusion

Vapor intrusion is the process by which contaminants present in the subsurface (both soil and groundwater) migrate through the soil via diffusion and advection and can enter building structures through the foundation cracks (U.S. EPA 2015, 2012; Murphy and Chan, 2011; Yao et al., 2011). In 1998, concerns about subsurface contamination of soil or ground water impacting indoor air quality led the EPA to develop a series of models for estimating health risks from subsurface vapor intrusion into buildings

based on the analytical solutions of Johnson and Ettinger (1991). Models describing the vapor entry into buildings generally consist of two main parts. One part describes the vapor transport in the soil and the other its entry into the building (Yao and Suuberg, 2013). Models can vary from simple 1-dimensional screening tools to more complex 3-dimensional models requiring numerical solutions (Yao and Suuberg, 2013). Since 1991, the models have been revised, and new models have been added. The 3-phase soil contamination models theoretically partition the contamination into three discrete phases: (1) in solution with water, (2) sorbed to the soil organic carbon, and (3) in vapor phase within the air-filled pores of the soil. Two new models have been added, allowing the user to estimate vapor intrusion into buildings from measured soil gas data (U.S. EPA 2000a). When Non-Aqueous Phase Liquid (NAPL) is present in soils, the contamination includes a fourth or residual phase. In such cases, the new NAPL models can be used to estimate the rate of vapor intrusion into buildings and the associated health risks. The new NAPL models use a numerical approach for simultaneously solving the time-averaged soil and building vapor concentration for each of up to 10 soil contaminants (U.S. EPA 2000a). This involves a series of iterative calculations for each contaminant. A spreadsheet with these models is available online from EPA at <https://www.epa.gov/vaporintrusion/epa-spreadsheet-modeling-subsurface-vapor-intrusion>. Technical information and resources pertaining to vapor intrusion can be found in <https://www.epa.gov/vaporintrusion/vapor-intrusion-resources>.

Although mathematical models such as the Johnson and Ettinger (1991) have been widely used, vapor intrusion modeling has been the focus of more recent studies (Yao and Suuberg, 2013). Other analytical approximations have been applied to estimate contaminant subsurface concentrations and study the effects of foundation features and source location on vapor intrusion (Yao et al., 2012, Yao et al., 2011). Other researchers have developed a systematic approach to model steady state advective and diffusive fluxes between multimedia compartments including ground water, soil, and air with applications to vapor intrusion calculations (Murphy and Chan, 2011). They determined that the presence of a basement significantly reduces first floor exposures. In addition, they concluded that the resistance associated with diffusion in ground water and water table fluctuations cannot be neglected (Murphy and Chan, 2011.) In addition to foundation characteristics, Yao and Suuberg (2013) observed that biodegradation plays a significant role in subsurface

concentration attenuation. However, other processes, like reaction mechanisms and kinetics, are not well understood. The lack of formal vapor intrusion model validation continues to be a challenge (Yao and Suuberg, 2013).

19.5.5. Deposition and Filtration

Deposition refers to the removal of airborne substances to available surfaces that occurs as a result of gravitational settling and diffusion, as well as electrophoresis and thermophoresis. Filtration is driven by similar processes, but is confined to material through which air passes. Filtration is usually a matter of design, whereas deposition is a matter of fact.

Outdoor particles can penetrate (infiltrate) building structures and become a source of indoor particle exposure (Gao and Zhang et al., 2009). Infiltration factors are affected by numerous elements including: air exchange rates, forced air heating, exhaust fan operation, air conditioning use, the use of filtration devices, meteorological parameters such as wind speed, indoor-outdoor temperature differentials, particle size, and composition of particulate matter (e.g., volatile chemicals) (Kearney et al., 2014). Air exchange rates can have a significant effect on particle number concentrations indoor under stable outdoor particle number concentrations. Generally, a higher ACH results in lower particulate number concentrations indoors (Guo et al., 2008). Models have been developed that help predict indoor concentrations of outdoor particles in residences (El Orch et al., 2014).

Semivolatile organic compounds (SVOC) are also present in indoor air environments. Sources of these compounds include for example: indoor materials, consumer products (e.g., personal care products, household cleaning products), combustion products, environmental tobacco smoke, and intrusion from outdoor air (Singer et al., 2003; Weschler and Nazaroff 2008). The formation of organic films on indoor surfaces have been confirmed by both direct and indirect measurements (Weschler and Nazaroff, 2017). Weschler and Nazaroff (2017) developed a simple model of organic film growth to improve estimates of human exposure to SVOCs.

Gases can also penetrate the building envelope from attached garages. In addition to automobile exhaust, people often store gasoline, oil, paints, lacquers, and yard and garden supplies in garages. Appliances such as furnaces, heaters, hot water heaters, dryers, gasoline-powered appliances, and wood stoves may also impact indoor air quality. Garages can be a source of volatile organic compounds (VOCs) such as benzene, toluene,

ethylbenzene, *m,p*-xylene, and *o*-xylene. Emmerich et al. (2003) conducted a literature review on indoor air quality and the transport of pollutants from attached garages to residential living spaces. The authors found the body of literature on the subject was limited and contained little data with regard to airtightness and geometry of the house-garage interface, and the impact of heating and cooling equipment. They concluded, however, that there is substantial evidence that the transport of contaminants from garages has the potential to negatively impact residences.

19.5.5.1. Deposition

The deposition of particulate matter and reactive gas-phase pollutants to indoor surfaces is often stated in terms of a characteristic deposition velocity (m hour^{-1}) allied to the surface-to-volume ratio ($\text{m}^2 \text{m}^{-3}$) of the building or room interior, forming a first order loss rate (hour^{-1}). Theoretical considerations specific to indoor environments have been summarized in comprehensive reviews by Nazaroff and Cass (1989b) and Nazaroff et al. (1993).

For airborne particles, deposition rates depend on aerosol properties (size, shape, density) as well as room factors (thermal gradients, turbulence, surface geometry). The motions of larger particles are dominated by gravitational settling; the motions of smaller particles are subject to convection and diffusion. Consequently, larger particles tend to accumulate more rapidly on floors and up-facing surfaces while smaller particles may accumulate on surfaces facing in any direction. Figure 19-3 illustrates the general trend for particle deposition across the size range of general concern for inhalation exposure ($<10 \mu\text{m}$). Nano-particles have been demonstrated to have higher deposition rates and lower penetration efficiencies (Guo et al., 2008). Penetration refers to the infiltration of particles in the air that passes through the building shell (Chen and Zhao, 2011) (See also Section 19.5.7). The current thought is that theoretical calculations of deposition rates are likely to provide unsatisfactory results due to knowledge gaps relating to near-surface air motions and other sources of inhomogeneity (Nazaroff et al., 1993).

19.5.5.1.1. Thatcher and Layton (1995)—Deposition, resuspension, and penetration of particles within a residence

Thatcher and Layton (1995) evaluated removal rates for indoor particles in four size ranges (1–5, 5–10, 10–25, and $>25 \mu\text{m}$) in a study of one house occupied by a family of four. Table 19-33 lists these values. In a subsequent evaluation of data collected in

100 Dutch residences, Layton and Thatcher (1995) estimated settling velocities of 2.7 m hour^{-1} for lead-bearing particles captured in total suspended particulate matter samples.

19.5.5.1.2. Wallace (1996)—Indoor particles: a review

In a major review of indoor particles, Wallace (1996) cited overall particle deposition per hour (hour^{-1}) for respirable ($\text{PM}_{2.5}$), inhalable (PM_{10}), and coarse (difference between PM_{10} and $\text{PM}_{2.5}$) size fractions determined from EPA's Particle Total Exposure Assessment Methodological Study (PTEAM) study. These values, listed in Table 19-34, were derived from measurements conducted in nearly 200 residences.

19.5.5.1.3. Thatcher et al. (2002)—Effects of room furnishings and air speed on particle deposition rates indoors

Thatcher et al. (2002) measured deposition loss rate coefficients for particles of different median diameters (0.55 to 8.66 μm) with fans off and on at various airspeeds in three types of experimental rooms: (1) bare (unfurnished with metal floor), (2) carpeted and unfurnished, and (3) fully furnished. Table 19-35 summarizes the results.

19.5.5.1.4. He et al. (2005)—Particle deposition rates in residential houses

He et al. (2005) investigated particle deposition rates for particles ranging in size from 0.015 to 6 μm . The lowest deposition rates were found for particles between 0.2 and 0.3 μm for both minimum (air exchange rate: $0.61 \pm 0.45 \text{ hour}^{-1}$) and normal (air exchange rate: $3.00 \pm 1.23 \text{ hour}^{-1}$) conditions. Thus, air exchange rate was an important factor affecting deposition rates for particles between 0.08 and 1.0 μm , but not for particles smaller than 0.08 μm or larger than 1.0 μm .

19.5.5.2. Filtration

A variety of air cleaning techniques have been applied to residential settings. EPA (2009) summarizes available information on residential air cleaners. Basic principles related to residential-scale air cleaning technologies have also been summarized in conjunction with reporting early test results (Offerman et al., 1984). General engineering principles are summarized in ASHRAE (2016). In addition to fibrous filters integrated into central heating and air conditioning systems, extended surface filters and High Efficiency Particle Arrest filters, as

well as electrostatic systems, are available to increase removal efficiency. Free-standing air cleaners (portable and/or console) are also being used. Shaughnessy and Sextro (2007) discuss the testing process to evaluate the efficacy of portable air cleaners. Product-by-product test results reported by Hanley et al. (1994); Shaughnessy et al. (1994); and Offerman et al. (1984) exhibit considerable variability across systems, ranging from ineffectual ($<1\%$ efficiency) to nearly complete removal.

19.5.6. Interzonal Airflows

Exposure assessments for indoor air pollutants generally assume a well-mixed environment. However, pollutant concentrations vary with distance from the source, ventilation rate, and relative height of the source (Acevedo-Bolton et al., 2012).

Residential structures consist of a number of rooms that may be connected horizontally, vertically, or both horizontally and vertically. Before considering residential structures as a detailed network of rooms, it is convenient to divide them into one or more zones. At a minimum, each floor is typically defined as a separate zone. For indoor air exposure assessments, further divisions are sometimes made within a floor, depending on (1) locations of specific contaminant sources and (2) the presumed degree of air communication among areas with and without sources.

Defining the airflow balance for a multiple-zone exposure scenario rapidly increases the information requirements as rooms or zones are added. As shown in Figure 19-4, a single-zone system (considering the entire building as a single well-mixed volume) requires only two airflows to define air exchange. Further, because air exchange is balanced flow (air does not “pile up” in the building, nor is a vacuum formed), only one number (the air exchange rate) is needed. With two zones, 6 airflows are needed to accommodate interzonal airflows plus air exchange; with three zones, 12 airflows are required. In some cases, the complexity can be reduced using judicious (if not convenient) assumptions. Interzonal airflows connecting nonadjacent rooms can be set to zero, for example, if flow pathways do not exist. Symmetry also can be applied to the system by assuming that each flow pair is balanced.

Axley (2007) discusses the history and theory of multizonal airflow models. Examples of interzonal airflow models include CONTAM (developed by NIST) and COMIS (Haas et al., 2002; Feustel, 1999; Feustel and Raynor-Hoosen, 1990).

19.5.7. House Dust and Soil Loadings

House dust is a complex mixture of biologically derived material (animal dander, fungal spores, etc.), particulate matter deposited from the indoor aerosol, and soil particles brought in by foot traffic. House dust may contain VOCs (Wolkoff and Wilkins, 1994; Hirvonen et al., 1995), pesticides from imported soil particles as well as from direct applications indoors (Roberts et al., 1991), and trace metals derived from outdoor sources (Layton and Thatcher, 1995). The indoor abundance of house dust depends on the interplay of deposition from the airborne state, resuspension due to various activities, direct accumulation, and infiltration.

In the absence of indoor sources, indoor concentrations of particulate matter are significantly lower than outdoor levels. For some time, this observation supported the idea that a significant fraction of the outdoor aerosol is filtered out by the building envelope. The ratios of indoor to outdoor particle concentrations vary depending on factors such as: the difference in size-dependent indoor particle emission rates, the geometry of the cracks in building envelopes, and the air exchange rates (Chen and Zhao, 2011).

It should be noted that carpet dust loadings may be higher than previously believed. This is important because embedded dust is a reservoir for organic compounds. Fortune et al. (2000) compared the mass of dust in carpets removed using conventional vacuuming to that removed by vacuuming with a beater-bar to remove deeply embedded dust. The amount removed was 10 times that removed by conventional vacuuming.

19.5.7.1. *Roberts et al. (1991)—Development and Field Testing of a High-Volume Sampler for Pesticides and Toxics in Dust*

Dust loadings, reported by Roberts et al. (1991), were measured in conjunction with the Nonoccupational Pesticide Exposure Study (NOPES). In this study, house dust was sampled from a representative grid using a specially constructed high-volume surface sampler. The surface sampler collection efficiency was verified in conformance with ASTM F608 (ASTM, 1989). Table 19-36 summarizes data collected from carpeted areas in volunteer households in Florida encountered during the course of NOPES. Seven of the nine sites were single-family detached homes, and two were mobile homes. The authors noted that the two houses exhibiting the highest dust loadings were only those homes where a vacuum cleaner was not used for housekeeping.

19.5.7.2. *Thatcher and Layton (1995)—Deposition, Resuspension, and Penetration of Particles within a Residence*

Relatively few studies have been conducted at the level of detail needed to clarify the dynamics of indoor aerosols. One intensive study of a California residence (Thatcher and Layton, 1995), however, provides instructive results. Using a model-based analysis for data collected under controlled circumstances, the investigators verified penetration of the outdoor aerosol and estimated rates for particle deposition and resuspension (see Table 19-37). The investigators stressed that normal household activities are a significant source of airborne particles larger than 5 μm . During the study, they observed that just walking into and out of a room could momentarily double the concentration. The airborne abundance of submicrometer particles, on the other hand, was unaffected by either cleaning or walking. They also concluded that large particles (over 25 μm) settle eight times faster than small particles (1–5 μm).

Mass loading of floor surfaces (see Table 19-38) was measured in the study of Thatcher and Layton (1995) by thoroughly cleaning the house and sampling accumulated dust, after 1 week of normal habitation and no vacuuming. The methodology, validated under ASTM F608 (ASTM, 1989), showed fine dust recovery efficiencies of 50% with new carpet and 72% for linoleum. Tracked areas showed consistently higher accumulations than untracked areas, confirming the importance of tracked-in material. Differences between tracked areas upstairs and downstairs show that tracked-in material is not readily transported upstairs. The consistency of untracked carpeted areas throughout the house, suggests that, in the absence of tracking, particle transport processes are similar on both floors.

19.6. CHARACTERIZING INDOOR SOURCES

Product- and chemical-specific mechanisms for indoor sources can be described using simple emission factors to represent instantaneous releases, as well as constant releases over defined time periods; more complex formulations may be required for time-varying sources. Guidance documents for characterizing indoor sources within the context of the exposure assessment process are limited (see, for example, Jennings et al., 1987b; Wolkoff, 1995). Fairly extensive guidance exists in the technical literature, however, provided that the exposure assessor has the means to define (or estimate) key mechanisms and chemical-specific parameters. Basic

concepts are summarized below for the broad source categories that relate to airborne contaminants, waterborne contaminants, and for soil/house dust indoor sources.

19.6.1. Source Descriptions for Airborne Contaminants

Table 19-39 summarizes simplified indoor source descriptions for airborne chemicals for direct emission sources (e.g., combustion, pressurized propellant products), as well as emanation sources (e.g., evaporation from “wet” films, diffusion from porous media), and transport-related sources (e.g., infiltration of outdoor air contaminants, soil gas entry).

Direct-emission sources can be approximated using simple formulas that relate pollutant mass released to characteristic process rates. Combustion sources, for example, may be stated in terms of an emission factor, fuel content (or heating value), and fuel consumption (or carrier delivery) rate. Emission factors for combustion products of general concern (e.g., CO, NO_x) have been measured for a number of combustion appliances using room-sized chambers (see, for example, Relwani et al., 1986). Other direct-emission sources would include volatiles released from water use and from pressurized consumer products. Resuspension of house dust (see Section 19.5.5.1) would take on a similar form by combining an activity-specific rate constant with an applicable dust mass.

Diffusion-limited sources (e.g., carpet backing, furniture, flooring, dried paint) represent probably the greatest challenge in source characterization for indoor air quality. Vapor-phase organics dominate this group, offering great complexity because (1) there is a fairly long list of chemicals that could be of concern, (2) ubiquitous consumer products, building materials, coatings, and furnishings contain varying amounts of different chemicals, (3) source dynamics may include nonlinear mechanisms, and (4) for many of the chemicals, emitting as well as nonemitting materials evident in realistic settings may promote reversible and irreversible sink effects. Very detailed descriptions for diffusion-limited sources can be constructed to link specific properties of the chemical, the source material, and the receiving environment to calculate expected behavior (see, for example, Schwoppe et al., 1992; Cussler, 1984). Validation to actual circumstances, however, suffers practical shortfalls because many parameters simply cannot be measured directly.

The exponential formulation listed in Table 19-39 was derived based on a series of papers generated

during the development of chamber testing methodology by EPA (Dunn, 1987; Dunn and Tichenor, 1988; Dunn and Chen, 1993). This framework represents an empirical alternative that works best when the results of chamber tests are available. Estimates for the initial emission rate (E_0) and decay factor (k_s) can be developed for hypothetical sources from information on pollutant mass available for release (M) and supporting assumptions.

Assuming that a critical time period (t_c) coincides with reduction of the emission rate to a critical level (E_c) or with the release of a critical fraction of the total mass (M_c), the decay factor can be estimated by solving either of these relationships:

$$\frac{E_c}{E_0} = e^{-k_s t_c} \quad (\text{Eqn. 19-4})$$

where:

E_c = emission rate to a critical level ($\mu\text{g hour}^{-1}$),
 E_0 = initial emission rate ($\mu\text{g hour}^{-1}$),
 k_s = decay factor ($\mu\text{g hour}^{-1}$), and
 t_c = critical time period (hours),

or

$$\frac{M_c}{M} = 1 - e^{-k_s t_c} \quad (\text{Eqn. 19-5})$$

where:

M_c = critical mass (μg), and
 M = total mass (μg).

The critical time period can be derived from product-specific considerations (e.g., equating drying time for paint to 90% emissions reduction). Given such an estimate for k_s , the initial emission rate can be estimated by integrating the emission formula to infinite time under the assumption that all chemical mass is released:

$$M = \int_0^{\infty} E_0 e^{-k_s t} dt = \frac{E_0}{k_s} \quad (\text{Eqn. 19-6})$$

The basis for the exponential source algorithm has also been extended to the description of more complex diffusion-limited sources. With these sources, diffusive or evaporative transport at the interface may be much more rapid than diffusive transport from within the source material, so that the abundance at the source/air interface becomes depleted, limiting the transfer rate to the air. Such effects can prevail with skin formation in “wet” sources like stains and paints (see, for example, Chang and Guo, 1992). Similar emission profiles have been observed with the emanation of formaldehyde from particleboard with “rapid” decline as formaldehyde evaporates from surface sites of the particleboard over the first few weeks. It is then followed by a much slower decline over ensuing years as formaldehyde diffuses from within the matrix to reach the surface (see, for example, Zinn et al., 1990).

Transport-based sources bring contaminated air from other areas into the airspace of concern. Examples include infiltration of outdoor contaminants, and soil gas entry. Soil gas entry is a particularly complex phenomenon and is frequently treated as a separate modeling issue (Provoost et al., 2010; Little et al., 1992; Sextro, 1994). Room-to-room migration of indoor contaminants would also fall under this category, but this concept is best considered using multizone models.

19.6.2. Source Descriptions for Waterborne Contaminants

Residential water supplies may be a route for exposure to chemicals through ingestion, dermal contact, or inhalation. These chemicals may appear in the form of contaminants (e.g., trichloroethylene) as well as naturally occurring by-products of water system history (e.g., chloroform, radon). Among indoor water uses, showering, bathing, and hand-washing of dishes or clothes provide the primary opportunities for dermal exposure. The escape of volatile chemicals to the gas phase associates water use with inhalation exposure. The exposure potential for a given chemical will depend on the source of water, the types and extents of water uses, and the extent of volatilization of specific chemicals. Primary types of residential water use include showering/bathing, toilet use, clothes washing, dishwashing, and faucet use (e.g., for drinking, cooking, general cleaning, or washing hands). Information about household water use has been investigated by the Water Research Foundation and published in the Residential End Use of Water (REU) (DeOreo et al., 2016). The survey collected data from 2010 through 2013 from randomly selected

single-family houses in the United States and Canada. The average per capita indoor water use was 58.6 gal/day. Figure 19-5 shows the relative percentage of indoor per capita water use across all uses. Toilet flushing was the largest indoor water use in gallons per capita per day (14.2 gpcd, 24%). Other relevant information on activity patterns (e.g., time showering, time indoors, etc.) can be found in Chapter 16 of the *Exposure Factors Handbook* (U.S. EPA 2011).

Upper-bounding estimates of chemical release rates from water use can be formulated as simple emission factors by combining the concentration in the feed water (g m^{-3}) with the flow rate for the water use ($\text{m}^3 \text{hour}^{-1}$), and assuming that the chemical escapes to the gas phase. For some chemicals, however, not all of the chemical escapes in realistic situations due to diffusion-limited transport and solubility factors. For inhalation exposure estimates, this may not pose a problem because the bounding estimate would overestimate emissions by no more than approximately a factor of two. For multiple exposure pathways, the chemical mass remaining in the water may be of importance. Refined estimates of volatile emissions are usually considered under two-resistance theory to accommodate mass transport aspects of the water-air system (see, for example, U.S. EPA, 2000b; Howard-Reed et al., 1999; Moya et al., 1999; Little, 1992; Andelman, 1990; McKone, 1987). More detailed descriptions of models used to estimate emissions from indoor water sources including showers, bathtubs, dishwashers, and washing machines are included in EPA, (2000b). Release rates (S) are formulated as

$$S = K_m F_w \left[C_w - \frac{C_a}{H} \right] \quad (\text{Eqn. 19-7})$$

where:

- S = chemical release rate (g hour^{-1}),
- K_m = dimensionless mass-transfer coefficient,
- F_w = water flow rate ($\text{m}^3 \text{hour}^{-1}$),
- C_w = concentration in feed water (g m^{-3}),
- C_a = concentration in air (g m^{-3}), and
- H = dimensionless Henry's Law constant.

Because the emission rate is dependent on the air concentration, recursive techniques are required. The mass-transfer coefficient is a function of water use

characteristics (e.g., water droplet size spectrum, fall distance, water film) and chemical properties (diffusion in gas and liquid phases). Estimates of practical value are based on empirical tests to incorporate system characteristics into a single parameter (see, for example, Giardino et al., 1990). Once characteristics of one chemical-water use system are known (reference chemical, subscript *r*), the mass-transfer coefficient for another chemical (index chemical, subscript *i*) delivered by the same system can be estimated using formulations identified in the review by Little (1992):

$$\frac{1}{K} \left(\frac{D_{Li}}{D_{Lr}} \right)^{1/2} = \frac{1}{K_{Lr}} \\ = \frac{1}{K_{Gr}} - \frac{1}{H} \left(\frac{D_{Gr}}{D_{Gi}} \right)^{2/3} \left(\frac{D_{Li}}{D_{Lr}} \right)^{1/2} \quad (\text{Eqn. 19-8})$$

where:

D_L = liquid diffusivity ($\text{m}^2 \text{ second}^{-1}$),
 D_G = gas diffusivity ($\text{m}^2 \text{ second}^{-1}$),
 KL = liquid-phase mass-transfer coefficient,
 KG = gas-phase mass transfer coefficient, and
 H = dimensionless Henry's Law constant.

19.6.3. Soil and House Dust Sources

The rate process descriptions compiled for soil and house dust provide inputs for estimating indoor emission rates:

$$S_d = M_d R_d A_f \quad (\text{Eqn. 19-9})$$

where:

S_d = dust emission (g hour^{-1}),
 M_d = dust mass loading (g m^{-2}),
 R_d = resuspension rates (hour^{-1}), and
 A_f = floor area (m^2).

Because house dust is a complex mixture, transfer of particle-bound constituents to the gas phase may be of concern for some exposure assessments. For

emission estimates, one would then need to consider particle mass residing in each reservoir (dust deposit, airborne).

19.7. ADVANCED CONCEPTS

19.7.1. Uniform Mixing Assumption

Many exposure measurements are predicated on the assumption of uniform mixing within a room or zone of a house. Mage and Ott (1994) offer an extensive review of the history of use and misuse of the concept. Experimental work by Baughman et al. (1994) and Drescher et al. (1995) indicates that, for an instantaneous release from a point source in a room, fairly complete mixing is achieved within 10 minutes when convective flow is induced by solar radiation. Another study by Gadgil et al. (2003) showed that mixing time depended on the room airflow the source location. However, up to 100 minutes may be required for complete mixing under quiescent (nearly isothermal) conditions. While these experiments were conducted at extremely low air exchange rates ($<0.1 \text{ ACH}$), based on the results, attention is focused on mixing within a room.

The situation changes if a human invokes a point source for a longer period and remains in the immediate vicinity of that source. Personal exposure in the near vicinity of a source can be much higher than the well-mixed assumption would suggest. A series of experiments conducted by GEOMET (1989) for the EPA involved controlled point-source releases of carbon monoxide tracer (CO), each for 30 minutes. Breathing-zone measurements located within 0.4 m of the release point were 10 times higher than for other locations in the room during early stages of mixing and transport.

Similar investigations by Acevedo-Bolton et al. (2012) studied the proximity of source effects in two naturally ventilated homes in Northern California. They found high variability of CO concentrations measured within 1 m from the source with 5 minute averages varying more than 100 fold. Other research conducted by Furtaw et al. (1996) involved a series of experiments in a controlled-environment, room-sized chamber. Furtaw et al. (1996) studied spatial concentration gradients around a continuous point source simulated by sulfur hexafluoride (SF_6) tracer with a human moving about the room. Average breathing-zone concentrations when the subject was near the source exceeded those several meters away by a factor that varied inversely with the ventilation intensity in the room. At typical room ventilation rates, the ratio of source-proximate to slightly-removed concentration was on the order of 2:1.

19.7.2. Reversible Sinks

The sorption of SVOCs onto indoor surfaces are referred to as the “sink effect.” Different building materials sorb different compounds based on polarity, indoor humidity, and temperature (Won et al., 2001). Surface roughness also plays a role in the absorption of chemicals onto surfaces (Wu et al., 2017). The subsequent re-emission of these compounds into indoor air is referred to as a “reversible sink.” The reversible sink effect can significantly affect the fate and transport of indoor SVOCs (Wu et al., 2017). For some chemicals, the actions of reversible sinks are of concern. For an initially “clean” condition in the sink material, sorption effects can greatly deplete indoor concentrations. However, once enough of the chemical has been adsorbed, the diffusion gradient will reverse, allowing the chemical to escape. For persistent indoor sources, such effects can serve to reduce indoor levels initially, but once the system equilibrates, the net effect on the average concentration of the reversible sink is negligible. Over suitably short time frames, this can also affect integrated exposure. For indoor sources whose emission profile declines with time (or ends abruptly), reversible sinks can serve to extend the emissions period as the chemical desorbs long after direct emissions are finished. Reversible sink effects have been observed for a number of chemicals in the presence of carpeting, wall coverings, and other materials commonly found in residential environments. As an example, in the case of environmental tobacco smoke, clothing and human skin have been found to serve as a reversible sink. The lingering residues of tobacco products are referred to as third-hand smoke (Sleiman et al., 2010).

Interactive sinks (and models of the processes) are of special importance; while sink effects can greatly reduce indoor air concentrations, re-emission at lower rates over longer time periods could greatly extend the exposure period of concern. For completely reversible sinks, the extended time could bring the cumulative exposure to levels approaching the sink-free case. Publications (Axley and Lorenzetti, 1993; Tichenor et al., 1991) show that first principles provide useful guidance in postulating models and setting assumptions for reversible-irreversible sink models. Sorption/desorption can be described in terms of Langmuir (monolayer) as well as Brunauer-Emmet-Teller (BET, multilayer) adsorption.

Table 19-6. Average Estimated Volumes of U.S. Residences, by Housing Type, Census Region, and Urbanicity		
	Volume (m³) ^a	% of Total
Housing Type		
Single-family detached	562	63.3
Single-family attached	401	5.9
Apartments in 2–4 unit buildings	249	7.9
Apartments in 5 or more unit buildings	192	16.8
Mobile homes	246	6.1
Census Region		
Northeast	480	18.3
Midwest	515	22.8
South	423	37.1
West	387	21.8
Urban and Rural ^b		
Urban	421	77.6
Rural	536	22.4
All housing types	446	NA
^a	Volumes calculated from floor areas assuming a ceiling height of 8 feet. Includes all basements, finished or conditioned (heated or cooled) areas of attics, and conditioned garage space that is attached to the home. Unconditioned and unfinished areas in attics and attached garages are excluded.	
^b	Housing units are classified as urban or rural using definitions created by the U.S. census bureau.	
Source: U.S. DOE (2013).		

Table 19-7. Average Volume of Single Family, Multifamily and Mobile Homes by Type^a						
Number of Stories or Levels in Housing Unit	Single Family		Multifamily		Mobile Homes	
	Volume (m ³)	% of Total	Volume (m ³)	% of Total	Volume (m ³)	% of Total
1 story	438	58.8	199	90.8	NA	NA
2 stories	705	37.7	321	8.5	NA	NA
3 or more stories	777	2.0	494	0.7	NA	NA
Split level	635	1.5	NA	NA	NA	NA
Census region						
Northeast	644	16.2	224	27.0	233	7.2
Midwest	616	24.5	217	19.9	247	15.9
South	506	37.8	209	29.9	256	56.5
West	476	21.5	191	23.1	225	20.3
Urbanicity ^b						
Urban	531	73.4	210	95.7	227	50
Rural	598	26.6	225	4.3	266	50
^a Volumes calculated from floor areas assuming a ceiling height of 8 feet. Includes all basements, finished or conditioned (heated or cooled) areas of attics, and conditioned garage space that is attached to the home. Unconditioned and unfinished areas in attics and attached garages are excluded. ^b Housing units are classified as urban or rural using definitions created by the U.S. Census Bureau.

	All Divisions	43.5
^a	Housing characteristics data were collected between August 2015 and April 2016.	
^b	Housing units are classified using criteria created by the U.S. Census Bureau based on 2010 Census data. Urbanized areas are densely settled groupings of blocks or tracts with 50,000 or more people, while urban clusters have at least 2,500 but less than 50,000 people. All other areas are rural.	
^c	Total United States includes all primary occupied housing units in the 50 states and the District of Columbia. Vacant housing units, seasonal units, second homes, military houses, and group quarters are excluded. Includes single family detached and attached homes.	
Q	= Data withheld either because the Relative Standard Error (RSE) was greater than 50% or fewer than 10 households were sampled.

GLOSSARY OF TERMS

Absorbed dose—The amount of an agent that enters a target by crossing an exposure surface that acts as an absorption barrier. See also *Absorption barrier, Dose, and Internal dose*.

Absorption barrier—Any exposure surface that may retard the rate of penetration of an agent into a target. Examples include the skin, respiratory tract lining, and gastrointestinal tract wall.

Activity pattern data—Information on human activities used in exposure assessments. These may include a description of the activity, frequency of activity, duration spent performing the activity, and the microenvironment in which the activity occurs.

Acute exposure—A single exposure to a toxic substance which may result in severe biological harm or death. Acute exposures are usually characterized as lasting no longer than a day, as compared to longer, continuing exposure over a period of time.

Adherence factor—The amount of a material (e.g., soil) that adheres to the skin per unit of surface area.

Activity pattern (time use) data—Information on activities in which various individuals engage, length of time spent performing various activities, locations in which individuals spend time and length of time spent by individuals within those various environments.

Age dependent adjustment factor (ADAF)—In cases where age-related differences in toxicity occur, differences in both toxicity and exposure need to be integrated across all relevant age intervals, by the use of age dependent potency adjustment factors (ADAFs). This is a departure from the way cancer risks have historically been calculated based upon the premise that risk is proportional to the daily average of the long-term adult dose.

Agent—Refers to a chemical, biological, or physical entity that contacts a *target*.

Aggregate exposure—The combined exposure of an individual (or defined population) to a specific agent or stressor via relevant routes, pathways, and sources. Total exposure can include exposure through multiple routes (e.g., dermal, inhalation, and ingestion).

Agricultural commodity—Used by U.S. EPA to mean plant (or animal) parts consumed by humans as food. When such items are raw or unprocessed, they are referred to as "raw agricultural commodities."

Air exchange rate—Rate of air leakage through windows, doorways, intakes and exhausts, and "adventitious openings" (i.e., cracks and seams) that combine to form the leakage configuration of the building envelope plus natural and mechanical ventilation.

All water sources—Includes water from all supply sources such as community water supply (i.e., tap water), bottled water, etc.

Analytical uncertainty propagation—Examining how uncertainty in individual parameters affects the overall uncertainty of the exposure assessment.

Anthropometric—The study of human body measurements for use in anthropological classification and comparison.

As-consumed intake—Intake rate based on the weight of the food in the form that it is consumed (e.g., cooked or prepared).

Assessment—A determination or appraisal of possible consequences resulting from an analysis of data.

Average Daily Dose (ADD)—The mean amount of an agent to which a person is exposed on a daily basis, often averaged over a long period of time. U.S. EPA is transitioning from average daily dose methodologies to more refined aggregate and cumulative approaches for estimating exposure across each lifestage. See also *Lifetime average daily dose (LADD)* and *Time-averaged exposure*.

Bayesian Analysis—Bayesian analysis is a method of statistical inference in which the knowledge of prior events is used to predict future events. Bayes' Theorem is a means of quantifying uncertainty.

Benchmark Dose or Concentration—An exposure due to a dose or concentration of a substance associated with a specified low incidence of risk, generally in the range of 1% to 10%, of a health effect; or the dose or concentration associated with a specified measure or change of a biological effect.

Best Tracer Method (BTM)—Method for estimating soil ingestion that allows for the selection of the most recoverable tracer for a particular subject or group of subjects. Selection of the best tracer is made on the basis of the food/soil (F/S) ratio.

Bioaccumulate—The increase in concentration in living organisms as they take in contaminated air, water, or food because the substances are very slowly metabolized or excreted.

Bias—A systematic error inherent in a method or caused by some feature of the measurement system.

Bioavailability—The rate and extent to which an agent can be absorbed by an organism and is available for metabolism or interaction with biologically significant receptors. Bioavailability involves both release from a medium (if present) and absorption by an organism.

Bioconcentrate—The accumulation of a chemical in tissues of a fish or other organism to levels greater than in the surrounding medium.

Biokinetic model comparison—A methodology that compares direct measurements of a biomarker such as blood or urine levels of a toxicant with predictions from a biokinetic model.

Biological marker or biomarker—An indicator of changes or events in biological systems. Biological markers of exposure are cellular, biochemical, analytical, or molecular measures that are obtained from biological media such as tissues, cells, or fluids and are indicative of exposure to an agent. Biomarkers of effect are quantifiable changes, indicating exposure to a compound, while biomarkers of susceptibility are characteristics that make an individual susceptible to the effects of an exposure.

Biomarker model comparison—A methodology that compares results from a biokinetic exposure model to biomarker measurements children blood. The method is used to confirm assumptions about ingested soil and dust quantities in this handbook.

Basal Metabolic Rate (BMR)—Minimum level of energy required to maintain normal body functions.

Body Mass Index (BMI)—The ratio of weight and height squared.

Bootstrap—A statistical method of resampling data use to estimate variance and bias of an estimator and provide confidence intervals for parameters.

Bounding estimate—An estimate of exposure, dose, or risk that is higher or lower than that incurred by the person with the highest or lowest exposure, dose, or risk in the population being assessed. Bounding estimates are useful in developing statements that exposures, doses, or risks are "not greater than" or "less than" the estimated value, because assumptions are used which define the likely bounding conditions.

Central tendency exposure—A measure of the middle or the center of an exposure distribution. The mean is the most commonly used measure of central tendency.

Chronic exposure—Repeated exposure by the oral, dermal, or inhalation route for more than approximately 10% of the life span in humans (more than approximately 90 days to 2 years in typically used laboratory animal species).

Chronic intake—The long term period over which a substance crosses the outer boundary of an organism without passing an absorption barrier.

Classical statistical methods—Estimating the population exposure distribution directly, based on measured values from a representative sample.

Coating—Method used to measure skin surface area, in which either the whole body or specific body regions are coated with a substance of known density and thickness.

Community water—Includes tap water ingested from community or municipal water supply.

Comparability—The ability to describe likenesses and differences in the quality and relevance of two or more data sets.

Concentration—Amount of a material or agent dissolved or contained in unit quantity in a given medium or system.

Confidence intervals—An estimated range of values with a given probability of including the population parameter of interest. The range of values is usually based on the results of a sample that estimated the mean and the sampling error or standard error.

Consumer-only intake rate—The average quantity of food consumed per person in a population composed only of individuals who ate the food item of interest during a specified period.

Contact boundary—The surface on a *target* where an *agent* is present. Examples of outer exposure surfaces include the exterior of an eyeball, the skin surface, and a conceptual surface over the nose and open mouth. Examples of inner exposure surfaces include the gastrointestinal tract, the respiratory tract, and the urinary tract lining. As an exposure surface gets smaller, the limit is an *exposure point*. It is also referred to as an *exposure surface*.

Contaminant concentration—Contaminant concentration is the concentration of the contaminant in the medium (air, food, soil, etc.) contacting the body and has units of mass/volume or mass/mass.

Creel study—A study in which fishermen are interviewed while fishing.

Cumulative exposure—Exposure via mixtures of contaminants both indoors and outdoors. Exposure may also occur through more than one pathway. New directions in risk assessments in U.S. EPA put more emphasis on total exposures via multiple pathways.

Deposition—The removal of airborne substances to available surfaces that occurs as a result of gravitational settling and diffusion, as well as electrophoresis and thermophoresis.

Dermal absorption—A route of exposure by which substances can enter the body through the skin.

Dermal adherence—The loading of a substance onto the outer surface of the skin.

Diary study—Survey in which individuals are asked to record food intake, activities, or other factors in a diary which is later used to evaluate exposure factors associated with specific populations.

Direct water ingestion—Consumption of plain water as a beverage. It does not include water used for preparing beverages such as coffee or tea.

Distribution—A set of values derived from a specific population or set of measurements that represents the range and array of data for the factor being studied.

Doers—Survey respondents who report participating in a specified activity.

Dose—The amount of an agent that enters a target after crossing an exposure surface. If the exposure surface is an absorption barrier, the dose is an *absorbed dose*. If the exposure surface is not an absorption barrier, the dose is an *intake dose*.

Dose rate—Dose per unit time.

Dose-response assessment—Analysis of the relationship between the total amount of an agent administered to, taken up by, or absorbed by an organism, system, or target population and the changes developed in that organism, system, or target population in reaction to that agent, and inferences derived from such an analysis with respect to the entire population. Dose-response assessment is the second of four steps in risk assessment.

Dose-response curve—Graphical presentation of a dose-response relationship.

Dose-response relationship—The resulting biological responses in an organ or organism expressed as a function of a series of doses.

Dressed weight—The portion of the harvest brought into kitchens for use, including bones for particular species.

Drinking water—All fluids consumed by individuals to satisfy body needs for internal water.

Dry-weight intake rates—Intake rates that are based on the weight of the food consumed after the moisture content has been removed.

Dust Ingestion—Consumption of dust that results from various behaviors including, but not limited to, mouthing objects or hands, eating dropped food, consuming dust directly, or inhaling dust that passes from the respiratory system into the gastrointestinal tract.

Effect—Change in the state or dynamics of an organism, system, or (sub) population caused by exposure to an agent.

Employer tenure—The length of time a worker has been with the same employer.

Energy expenditures—The amount of energy expended by an individual during activities.

Exclusively breast fed—Infants whose sole source of milk comes from human milk with no other milk substitutes.

Exposed foods—Foods grown above ground.

Exposure—Contact between an agent and a target.

Exposure assessment—The process of estimating or measuring the magnitude, frequency, and duration of exposure to an agent, along with the number and characteristics of the population exposed.

Exposure concentration—The concentration of a chemical in its transport or carrier medium at the point of contact.

Exposure duration—Length of time over which contact with the contaminant lasts.

Exposure event—The occurrence of continuous contact between an agent and a target.

Exposure factor—Factors related to human behavior and characteristics that help determine an individual's exposure to an agent.

Exposure frequency—The number of exposure events in an exposure duration.

Exposure loading—The exposure mass divided by the exposure surface area. For example, a dermal exposure measurement based on a skin wipe sample, expressed as a mass of residue per skin surface area, is an exposure loading.

Exposure pathway—The physical course a chemical takes from the source to the organism exposed.

Exposure route—The way a chemical pollutant enters an organism after contact, e.g., by ingestion, inhalation, or dermal absorption.

Exposure scenario—A set of facts, assumptions, and interferences about how exposure takes place that aids the exposure assessor in evaluating estimating, or quantifying exposures.

Exposure surface—See contact boundary.

Fate—Pattern of distribution of an agent, its derivatives, or metabolites in an organism, system, compartment, or population of concern as a result of transport, partitioning, transformation, or degradation.

Foremilk—Milk produced at the beginning of breastfeeding.

General population—The total of individuals inhabiting an area or making up a whole group.

Geographic information system (GIS)—GIS is a system of hardware and software that captures, stores, analyzes, manages, and presents geographic data.

Geometric mean—The n^{th} root of the product of n values.

Geophagy—A form of soil ingestion involving the intentional ingestion of earths, usually associated with cultural practices.

Hazard—Inherent property of an agent or situation having the potential to cause adverse effects when an organism, system, or population is exposed to that agent.

Hazard assessment—A process designed to determine the possible adverse effects of an agent or situation to which an organism, system, or target population could be exposed. The process typically includes hazard identification, dose-response evaluation and hazard characterization. The process focuses on the hazard, in contrast to risk assessment, where exposure assessment is a distinct additional step.

High-end exposure—An estimate of individual exposure or dose for those persons at the upper end of an exposure or dose distribution, conceptually above the 90th percentile, but not higher than the individual in the population who has the highest exposure or dose. See also Bounding estimate.

Hindmilk—Milk produced at the end of the breastfeeding.

Home-produced foods—Fruits and vegetables produced by home gardeners, meat and dairy products derived from consumer-raised livestock, game meat, and home caught fish.

Human Equivalent Concentration or Dose—The human concentration (for inhalation exposure) or dose (for other routes of exposure) of an agent that is believed to induce the same magnitude of toxic effect as the experimental animal species concentration or dose. This adjustment may incorporate toxicokinetic information on the particular agent, if available, or use a default procedure, such as assuming that daily oral doses experienced for a lifetime are proportional to body weight raised to the 0.75 power.

Indirect water ingestion—Includes water added during food preparation, but not water intrinsic to purchased foods. Indirect water includes for example, water used to prepare baby formulas, cake mix, and concentrated orange juice.

Indoor settled dust—Particles in building interiors that have settled onto objects, surfaces, floors, and carpeting. These particles may include soil particles that have been tracked into the indoor environment from outdoors.

Infiltration—Air leakage through random cracks, interstices, and other unintentional openings in the building envelope.

Inhalation dosimetry—Process of measuring or estimating inhaled dose.

Inhalation unit risk—The upper-bound excess lifetime cancer risk estimated to result from continuous exposure to an agent at a concentration of $1 \mu\text{g}/\text{m}^3$ in air for a lifetime.

Inhaled dose—The amount of an inhaled substance that is available for interaction with metabolic processes or biologically significant receptors after crossing the outer boundary of an organism.

Insensible water loss—Evaporative water losses that occur during breastfeeding. Corrections are made to account for insensible water loss when estimating breast milk intake using the test weighing method.

Intake—The process by which a substance crosses the outer boundary of an organism without passing an absorption barrier (e.g., through ingestion or inhalation).

Intake dose—The amount of an agent that enters a target by crossing an exposure surface that does not act as an absorption barrier. See also *Absorption barrier* and *Dose*.

Intake rate—Rate of inhalation, ingestion, and dermal contact depending on the route of exposure. For ingestion, the intake rate is simply the amount of food containing the contaminant of interest that an individual ingests during some specific time period (units of mass/time). For inhalation, the intake rate is the rate at which contaminated air is inhaled. Factors that affect dermal exposure are the amount of material that comes into contact with the skin, and the rate at which the contaminant is absorbed.

Inter-individual variability—Variations between individuals in terms of human characteristics such as age or body weight, or behaviors such as location, activity patterns, and ingestion rates.

Internal dose—The amount of an agent that enters a target by crossing an exposure surface that acts as an absorption barrier. Synonymous with absorbed dose. See also *Absorption barrier* and *Dose*.

Interzonal air flows—Transport of air through doorways, ductwork, and service chaseways that interconnect rooms or zones within a building.

Intra-individual variability—Fluctuations in an individual's physiologic (e.g., body weight), or behavioral characteristics (e.g., ingestion rates or activity patterns).

Key study—A study that is the most up-to-date and scientifically sound for deriving recommendations for exposure factors. Alternatively, studies may be classified as “relevant” and not “key” for one or more of the following: (1) they provide supporting data (e.g., older studies on food intake that may be useful for trend analysis); (2) they provide information related to the factor of interest (e.g., data on prevalence of breast feeding); or (3) the study design or approach makes the data less applicable for exposure assessment purposes (e.g., studies with small sample size, studies not conducted in the United States). As new data or analyses are published, “key” studies may be moved to the “relevant” category because they are replaced by more up-to-date data or an analysis of improved quality.

Lead isotope ratio methodology—A method that measures different lead isotopes in children's blood and/or urine, food, water, and house dust and compares the ratio of these isotopes to infer sources of lead exposure that may include dust or other environmental exposures.

Life expectancy—The length of an individual's life.

Lifestage—A distinguishable time frame in an individual's life characterized by unique and relatively stable behavioral and/or physiological characteristics that are associated with development and growth.

Lifetime Average Daily Dose (LADD)—Dose rate averaged over a lifetime. The LADD is used for compounds with carcinogenic or chronic effects. The LADD is usually expressed in terms of mg/kg-day or other mass/mass-time units. Often used in carcinogen risk assessments that employ linear low-dose extrapolation methods. See also *Average daily dose* and *Time-averaged exposure*.

Limiting Tracer Method (LTM)—Method for evaluating soil ingestion that assumes that the maximum amount of soil ingested corresponds with the lowest estimate from various tracer elements.

Local circulation—Convective and advective air circulation and mixing within a room or within a zone.

Long-term exposure—Repeated exposure for more than 30 days, up to approximately 10% of the life span in humans (more than 30 days).

Lowest-Observed-Adverse-Effect Level (LOAEL)—The lowest exposure level at which there are biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control group.

Margin of safety—For some experts, margin of safety has the same meaning as margin of exposure, while for others, margin of safety means the margin between the reference dose and the actual exposure.

Mass-balance/tracer techniques—Method for evaluating soil intake that accounts for both inputs and outputs of tracer elements. Tracers in soil, food, medicine and other ingested items as well as in feces and urine are accounted for.

Mean value—Simple or arithmetic average of a range of values, computed by dividing the total of all values by the number of values.

Measurement error—A systematic error arising from inaccurate measurement (or classification) of subjects on the study variables.

Measurement end-point—Measurable (ecological) characteristic that is related to the valued characteristic chosen as an assessment point.

Mechanical ventilation—Controlled air movement driven by fans. Also referred to as forced ventilation.

Median value—The value in a measurement data set such that half the measured values are greater and half are less.

Metabolic Equivalent of Work (MET)—A dimensionless energy expenditure metric used to represent an activity level.

Microenvironment—Surroundings that can be treated as homogeneous or well characterized in the concentrations of an agent (e.g., home, office, automobile, kitchen, store).

Mode of action—Defined as a sequence of key events and processes, starting with interaction of an agent with a cell, proceeding through operational and anatomical changes, and resulting in cancer formation.

Model uncertainty—Uncertainty regarding gaps in scientific theory required to make predictions on the basis of causal inferences.

Moisture content—The portion of foods made up by water. The percent water is needed for converting food intake rates and residue concentrations between whole-weight and dry-weight values.

Monte Carlo technique—A repeated random sampling from the distribution of values for each of the parameters in a generic (exposure or dose) equation to derive an estimate of the distribution of (exposures or doses in) the population.

Mouthing behavior—Activities in which objects, including fingers, are touched by the mouth or put into the mouth except for eating and drinking, and includes licking, sucking, chewing, and biting.

Natural ventilation—Airflow through open windows, doors, and other designed openings in the building envelope.

Non-dietary ingestion—Ingestion of non-food substances, typically resulting from the mouthing of hands and objects.

No-Observed-Adverse-Effect-Level (NOAEL)—The highest exposure level at which there are no biologically significant increases in the frequency or severity of adverse effect between the exposed population and its appropriate control; some effects may be produced at this level, but they are not considered adverse or precursors of adverse effects.

Occupational mobility—An indicator of the frequency at which workers change from one occupation to another.

Occupational tenure—The cumulative number of years a person worked in his or her current occupation, regardless of number of employers, interruptions in employment, or time spent in other occupations.

Outdoor settled dust—Particles that have settled onto outdoor objects and surfaces due to either wet or dry deposition.

Oxygen consumption (VO₂)—The rate at which oxygen is used by tissues.

Parameter uncertainty—Uncertainty regarding some parameter.

Partially breast fed—Infants whose source of milk comes from both human milk and other milk substitutes.

Pathway—The physical course a chemical or pollutant takes from the source to the organism exposed.

Physiologically-based pharmacokinetic (PBPK) modeling—PBPK modeling is an approach for predicting the absorption, distribution, metabolism and excretion of a compound in humans.

Per capita intake rate—The average quantity of food consumed per person in a population composed of both individuals who ate the food during a specified time period and those that did not.

Pica—Pica behavior is the repeated eating of non-nutritive substances, whereas soil-pica is a form of soil ingestion that is characterized by the recurrent ingestion of unusually high amounts of soil (i.e., on the order of 1,000–5,000 milligrams per day or more).

Plain tap water—Excludes tap water consumed in the form of juices and other beverages containing tap water.

Population mobility—An indicator of the frequency at which individuals move from one residential location to another.

Population risk descriptor—An assessment of the extent of harm to the population being addressed. It can be either an estimate of the number of cases of a particular effect that might occur in a population (or population segment), or a description of what fraction of the population receives exposures, doses, or risks greater than a specified value.

Potential dose—The amount of a chemical contained in material ingested, air breathed, or bulk material applied to the skin.

Poverty/income ratio—Ratio of reported family income to federal poverty level.

Precision—A measure of the reproducibility of a measured value under a given set of circumstances.

Preparation losses—Net cooking losses, which include dripping and volatile losses, post cooking losses, which involve losses from cutting, bones, excess fat, scraps and juices, and other preparation losses which include losses from paring or coring.

Primary data/analysis—Information gathered from observations or measurements of a phenomena or the surveying of respondents.

Probabilistic uncertainty analysis—Technique that assigns a probability density function to each input parameter, then randomly selects values from each of the distributions and inserts them into the exposure equation. Repeated calculations produce a distribution of predicted values, reflecting the combined impact of variability in each input to the calculation. Monte Carlo is a common type of probabilistic Uncertainty analysis.

Protected products—Foods that have an outer protective coating that is typically removed before consumption.

Questionnaire/survey response—A “question and answer” data collection methodology conducted via in-person interview, mailed questionnaire, or questions administered in a test format in a school setting.

Random samples—Samples selected from a statistical population such that each sample has an equal probability of being selected.

Range—The difference between the largest and smallest values in a measurement data set.

Ready-to-feed—Infant and baby products (formula, juices, beverages, baby food), and table foods that do not need to have water added to them prior to feeding.

Real-time hand recording—Method by which trained observers manually record information on children’s behavior.

Reasonable maximum exposure—A semiquantitative term referring to the lower portion of the high end of the exposure, dose, or risk distribution. As a semiquantitative term, it should refer to a range that can conceptually be described as above the 90th percentile in the distribution, but below the 98th percentile.

Recreational/sport fishermen—Individuals who catch fish as part of a sporting or recreational activity and not for the purpose of providing a primary source of food for themselves or for their families.

Reference Concentration (RfC)—An estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive target groups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. It can be derived from a NOAEL, LOAEL, or benchmark concentration, with uncertainty factors generally applied to reflect limitations of the data used. Generally used in U.S. EPA's noncancer health assessments. Durations include acute, short-term, subchronic, and chronic.

Reference Dose (RfD)—An estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive target groups) that is likely to be without an appreciable risk of deleterious noncancer effects during a lifetime. It can be derived from a NOAEL, LOAEL, or benchmark dose, with uncertainty factors generally applied to reflect limitations of the data used. Generally used in U.S. EPA's noncancer health assessments. Durations include acute, short-term, subchronic, and chronic.

Relevant study—Studies that are applicable or pertinent, but not necessarily the most important to derive exposure factors. See also Key study.

Representativeness—The degree to which a sample is, or samples are, characteristic of the whole medium, exposure, or dose for which the samples are being used to make inferences.

Residential occupancy period—The time between a person moving into a residence and the time the person moves out or dies.

Residential volume—The volume (m³) of the structure in which an individual resides and may be exposed to airborne contaminants.

Risk—The probability of an adverse effect in an organism, system, or population caused under specified circumstances by exposure to an agent.

Risk assessment—A process intended to calculate or estimate the risk to a given target organism, system, or population, including the identification of attendant uncertainties, following exposure to a particular agent, taking into account the inherent characteristics of the agent of concern as well as the characteristics of the specific target system. The risk assessment process includes four steps: hazard identification, hazard characterization (related term: Dose-response assessment), exposure assessment, and risk characterization. It is the first component in a risk analysis process.

Risk characterization—The qualitative and, wherever possible, quantitative determination, including attendant uncertainties, of the probability of occurrence of known and potential adverse effects of an agent in a given organism, system, or population, under defined exposure conditions. Risk characterization is the fourth step in the risk assessment process.

Risk communication—Interactive exchange of information about (health or environmental) risks among risk assessors, managers, news media, interested groups, and the general public.

Route—The way a chemical or pollutant enters an organism after contact, e.g., by ingestion, inhalation, or dermal absorption.

Sample—A small part of something designed to show the nature or quality of the whole. Exposure-related measurements are usually samples of environmental or ambient media, exposures of a small portion of a population for a short time, or biological samples, all for the purpose of inferring the nature and quality of parameters important to evaluating exposure.

Scenario uncertainty—Uncertainty regarding missing or incomplete information needed to fully define exposure and dose.

Screening-level assessment—An exposure assessment that examines exposures that would fall on or beyond the high end of the expected exposure distribution.

Secondary data/analysis—The reanalysis of data collected by other individuals or group; an analysis of data for purposes other than those for which the data were originally collected.

Sensitivity analysis—Process of changing one variable while leaving the others constant to determine its effect on the output. This procedure fixes each uncertain quantity at its credible lower and upper bounds (holding all others at their nominal values, such as medians) and computes the results of each combination of values. The results help to identify the variables that have the greatest effect on exposure estimates and help focus further information-gathering efforts.

Serving sizes—The quantities of individual foods consumed per eating occasion. These estimates may be useful for assessing acute exposures.

Short-term exposure—Repeated exposure for more than 24 hours, up to 30 days.

Slope Factor—An upper bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per mg/kg-day, is generally reserved for use in the low-dose region of the dose-response relationship, that is, for exposures corresponding to risks less than 1 in 100.

Soil—Particles of unconsolidated mineral and/or organic matter from the earth's surface that are located outdoors, or are used indoors to support plant growth.

Soil adherence—The quantity of soil that adheres to the skin and from which chemical contaminants are available for uptake at the skin surface.

Soil ingestion—The intentional or unintentional consumption of soil, resulting from various behaviors including, but not limited to, mouthing, contacting dirty hands, eating dropped food, or consuming soil directly. Soil-pica is a form of soil ingestion that is characterized by the recurrent ingestion of unusually high amounts of soil (i.e., on the order of 1,000–5,000 milligrams per day or more). Geophagy is also a form of soil ingestion defined as the intentional ingestion of earths and is usually associated with cultural practices.

Spatial variability—Variability across location, whether long- or short-term.

Subchronic exposure—Repeated exposure by the oral, dermal, or inhalation route for more than 30 days, up to approximately 10% of the life span in humans (more than 30 days up to approximately 90 days in typically used laboratory animal species).

Subsistence fishermen—Individuals who consume fresh caught fish as a major source of food.

Surface area—Coating, triangulation, and surface integration are direct measurement techniques that have been used to measure total body surface area and the surface area of specific body parts. Consideration has been given for differences due to age, gender, and race. Surface integration is performed by using a planimeter and adding the areas.

Surface integration—Method used to measure skin surface area in which a planimeter is used to measure areas of the skin, and the areas of various surfaces are summed.

Survey response methodology—Responses to survey questions are analyzed. This methodology includes questions asked of children directly, or their care givers, about behaviors affecting exposures.

Target—refers to any physical, biological, or ecological object exposed to an *agent*.

Tap water from food manufacturing—Water used in industrial production of foods.

Temporal variability—Variability over time, whether long- or short-term.

Threshold—Dose or exposure concentration of an agent below which a stated effect is not observed or expected to occur.

Time-averaged exposure—The time-integrated exposure divided by the exposure duration. An example is the daily average exposure of an individual to carbon monoxide. (Also called timeweighted average exposure.)

Total dietary intake—The sum of all foods in the following food categories: dairy, meats, fish, eggs, grains, vegetables, fruits, and fats. It does not include beverages, sugar, candy, sweets, nuts and nut products.

Total tap water—Water consumed directly from the tap as a beverage or used in the preparation of foods and beverages (i.e., coffee, tea, frozen juices, soups, etc.).

Total fluid intake—Consumption of all types of fluids including tapwater, milk, soft drinks, alcoholic beverages, and water intrinsic to purchased foods.

Total water—Water from tap water and non tap water sources including water contained in food.

Toxicodynamics—The physiological mechanisms by which toxins are absorbed, distributed, metabolized and excreted

Toxicokinetics—The passage through the body of a toxic agent or its metabolites, usually in an action similar to that of pharmacokinetics.

Tracer-element studies—Soil ingestion studies that use trace elements found in soil and poorly metabolized in the human gut as indicators of soil intake.

Triangulation—Method used to measure skin surface area in which areas of the body are marked into geometric figures, then their linear dimensions are calculated.

Uncertainty—Uncertainty represents a lack of knowledge about factors affecting exposure or risk and can lead to inaccurate or biased estimates of exposure. The types of uncertainty include: scenario, parameter, and model.

Unit risk—The quantitative estimate in terms of either risk per $\mu\text{g/L}$ drinking water (water unit risk) or risk per $\mu\text{g/m}^3$ air breathed (air unit risk).

Upper percentile—Values in the upper tail (i.e., between 90th and 99.9th percentile) of the distribution of values for a particular exposure factor. Values at the upper end of the distribution of values for a particular set of data.

Uptake—The process by which a substance crosses an absorption barrier and is absorbed into the body.

Usual dietary intakes—Refers to the long-term average daily intake by an individual.

Vapor intrusion—The migration of volatile chemicals from contaminated groundwater or soil into an overlying building.

Variability—Variability arises from true heterogeneity across people, places or time and can affect the precision of exposure estimates and the degree to which they can be generalized. The types of variability include: spatial, temporal, and inter-individual.

Ventilation Rate (VR)—Alternative term for inhalation rate or breathing rate. Usually measured as minute volume, i.e., volume (liters) of air exhaled per minute.

Video transcription—Method by which trained videographers tape a child's activities and subsequently extract data manually with computer software.

Wet-weight intake rates—Intake rates that are based on the wet (or whole) weight of the food consumed. This in contrast to dry-weight intake rates.

Worst case scenario—The maximum possible exposure, when everything that can plausibly happen to maximize exposure happens. The worst case represents a hypothetical individual and an extreme set of conditions that usually will not be observed in an actual population.
