APPENDIX 2. SOURCE TO DEPOSITION 2-1

2.1.	Introduction	2-1
2.2.	Sources of Nitrogen and Sulfur Compounds and Particulate Matter to the Atmosphere	2-5
2.2.1.	National Emissions by Source	2-6
Table 2-1	Emissions of NO _x (nitric oxide + nitrogen dioxide), sulfur dioxide, and ammonia by source category for 2014 (Teragrams ^a N, S/yr).	2-7
2.2.2.	Methods of Estimating Emissions	2-8
Figure 2-1	Modeling system used to compute 2014 Fertilizer Application Emissions.	2-11
Figure 2-2	Process to produce specific location and practice specific daily emission factors for livestock waste.	2-12
2.2.3.	Evaluation and Uncertainty	2-13
2.3.	Atmospheric Chemistry of Nitrogen and Sulfur Species and Particulate Matter (PM)	2-16
2.3.1.	Nitrogen Oxides	2-16
Figure 2-3	Schematic diagram showing pathways for reactive nitrogen species in ambient air.	2-17
Table 2-2	Henry's law coefficients for selected reactive nitrogen species at 25°C in water.	2-18
2.3.2.	Sulfur Oxides	2-20
Figure 2-4	Rate of conversion of sulfur (IV) to sulfur (VI) by different oxidation paths as a function of pH.	2-21
2.3.3.	Acid Neutralization by Ammonia	2-22
2.3.4.	Organic Nitrogen and Sulfur	2-24
2.3.5.	Organic Acids	2-25
2.3.6.	Particulate Matter (PM)	2-26
Figure 2-5	Contributions of organic carbon (OC), elemental carbon (EC), sulfate, nitrate, sea salt, and crustal components to PM _{2.5} at selected sites (A) 2003–2005 (B) 2013–2015.	2-27
2.4.	Concentration and Deposition Measurements	2-28
2.4.1.	Monitoring Networks	2-28
Table 2-3	Summary of monitoring networks used by Schwede and Lear (2014a).	2-30

CONTENTS (Continued)

2.4.2.	NO ₂ , NO _x , and NO _y	2-32
2.4.3.	Ammonia	2-34
2.4.4.	Sulfur Dioxide	2-37
Table 2-4	Sources of uncertainty for individual Ozone Monitoring Instrument measurements in the study of Nowlan et al. (2014).	2-38
2.4.5.	Filter-Based Concentration Measurements	2-38
Figure 2-6	Clean Air Status and Trends Network filter pack.	2-39
Figure 2-7	Comparison between weekly average measurements of sulfur dioxide using the Clean Air Status and Trends Network filter pack and the trace ultraviolet pulsed fluorescence monitor in 2014.	2-41
2.4.6.	Deposition Measurements	2-42
2.5.	Modeling Chemistry, Transport, and Deposition	2-45
2.5.1.	Advances in Chemistry-Transport Model (CTM) Modeling	2-45
2.5.2.	Modeling Deposition	2-47
Figure 2-8	Schematic diagram showing mechanisms for transferring pollutants from the atmosphere to the surface.	2-48
Table 2-5	Average dry deposition velocities (cm/s) for several gases over land surfaces.	2-49
Table 2-6	Deposition velocity (cm/s) for sulfur dioxide averaged over different land use types for summer and winter.	2-49
Figure 2-9	Modeled and measured deposition velocities over grass (left figure) and coniferous forest canopies (right figure) for particles of density 1 gm/cm ³ depositing under similar friction velocity (u^*) ($35 < u^* < 56$ cm/s).	2-51
Figure 2-10	Schematic of the interactions involved in the exchange of nitrogen oxides between the atmosphere and the forest canopy as identified by Min et al. (2014).	2-54
Figure 2-11	Scatterplots showing transference ratios for oxidized nitrogen and sulfur oxides comparing the Community Multiscale Air Quality model to the Comprehensive Air Quality Model with Extensions in (a) and (c) and comparing 2005 to 2014 in (b) and (d).	2-59
2.5.3.	Model Evaluation and Uncertainty	2-60
Table 2-7	Reported comparisons of chemical transport models and observations of nitrogen and sulfur wet deposition	2-61
2.6.	Geographic Distribution of Concentration and Deposition	2-61
2.6.1.	pH and H ⁺ Equivalents	2-64
Figure 2-12	(Left) pH of rainwater, 1989–1991; (Right) pH of rainwater, 2012–2014.	2-65
Figure 2-13	Difference in wet deposition of nitrate, ammonium, and sulfate expressed as hydrogen ion equivalents (eq/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2012 to 2014.	2-66
2.6.2.	Total Nitrogen	2-67
Figure 2-14	Total (wet + dry) deposition of nitrogen (kg N/ha/yr) over the contiguous U.S. 2011–2013.	2-68
Figure 2-15	(A) Percentage of total nitrogen deposition as reduced inorganic nitrogen over the contiguous U.S. 2011–2013. (B) Percentage of total nitrogen deposition as oxidized nitrogen over the contiguous U.S. 2011–2013.	2-69
Figure 2-16	Three-year average percentage of total nitrogen deposition by species (i.e., those species that are not measured in the networks) simulated by the Community Multiscale Air Quality modeling system.	2-70

CONTENTS (Continued)

	Figure 2-17	Wet deposition of ammonium + nitrate (kg N/ha/yr) over the contiguous U.S. in two, 3-year periods, 2012 to 2014 and 1989 to 1991. Also shown are active National Trends Network sites in either period. _____	2-71
2.6.3.	Oxidized Nitrogen _____		2-72
	Figure 2-18	Distribution of annual NO _x emissions in 2001. _____	2-73
	Figure 2-19	Distribution of annual average total oxidized nitrogen species concentrations for 2011 simulated by Community Multiscale Air Quality modeling system. _____	2-74
	Figure 2-20	Seasonal average surface nitrogen dioxide mixing ratios in parts per billion for winter (upper panel) and summer (lower panel) derived by the Ozone Monitoring Instrument/GEOS-Chem model for 2009–2011. The Ozone Monitoring Instrument has an overpass at approximately 1:30 p.m. local standard time. _____	2-75
	Figure 2-21	Three-year average (2011–2013) surface concentrations of nitric acid based on monitoring data obtained at Clear Air Status and Trends Network sites (black dots). _____	2-77
	Figure 2-22	Three-year average (2011–2013) surface concentrations of particulate nitrate based on monitoring data obtained at Clear Air Status and Trends Network sites (black dots). _____	2-78
	Figure 2-23	Total oxidized nitrogen deposition over the contiguous U.S. 2011–2013. _____	2-79
	Figure 2-24	(Left) nitrate wet deposition, 1989–1991; (Right) nitrate wet deposition, 2012–2014. _____	2-80
	Figure 2-25	Difference in wet deposition of nitrate (kg N/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2012 to 2014. The range of positive values is smaller than that for negative values. _____	2-81
2.6.4.	Reduced Nitrogen _____		2-81
	Figure 2-26	Distribution of annual ammonia (NH ₃) emissions by county in 2001. _____	2-83
	Figure 2-27	Average (2012) surface concentration of ammonia obtained by the Ambient Ammonia Monitoring Network at select Clear Air Status and Trends Network sites. Concentrations of ammonia (µg/m ³) can be converted to mixing ratios (parts per billion) to rough approximation at normal temperature and pressure by multiplying by 1.4. _____	2-84
	Figure 2-28	Three-year average (2011–2013) surface concentrations of particulate ammonium (µg/m ³) based on monitoring data obtained at Clear Air Status and Trends Network sites (black dots). _____	2-85
	Figure 2-29	Total reduced inorganic nitrogen deposition over the contiguous U.S. 2011–2013. _____	2-86
	Figure 2-30	(Left) ammonium wet deposition, 1989–1991; (Right) ammonium wet deposition, 2012–2014. _____	2-87
	Figure 2-31	Difference in wet deposition of ammonium (kg N/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2012 to 2014. _____	2-88
2.6.5.	Sulfur Oxides _____		2-88
	Figure 2-32	Distribution of annual sulfur dioxide (SO ₂) emissions by county from the 2014 National Emissions Inventory. _____	2-89
	Figure 2-33	Three-year average (2011–2013) surface concentrations of sulfur dioxide obtained by fusion of monitoring data obtained at Clear Air Status and Trends Network sites (black dots) and Community Multiscale Air Quality model system results. Concentrations (µg/m ³) can be converted to mixing ratios (parts per billion) at normal temperature and pressure) to rough approximation by multiplying by 0.37. _____	2-90

CONTENTS (Continued)

	Figure 2-34	Three-year average (2011–2013) surface concentrations of particulate sulfate based on monitoring data obtained at Clean Air Status and Trends Network sites (black dots). _____	2-91
	Figure 2-35	Total deposition of sulfur (kg S/ha/yr) over the contiguous U.S. 2011–2013. _____	2-92
	Figure 2-36	Percentage of deposition of total sulfur as dry deposition over the contiguous U.S. 2011–2013. _____	2-93
	Figure 2-37	(Left) sulfate wet deposition, 1989–1991; (Right) sulfate wet deposition, 2012–2014. _____	2-94
	Figure 2-38	Difference in wet deposition of sulfate (kg S/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2012 to 2014. The range of positive values is much smaller than for negative values. _____	2-94
2.6.6.	Particulate Matter (PM)	_____	2-95
	Figure 2-39	3-year average concentrations of particulate matter smaller than 2.5 μm diameter ($\text{PM}_{2.5}$) 2013–2015. _____	2-96
	Figure 2-40	National monthly average concentrations of particulate matter smaller than 2.5 μm diameter ($\text{PM}_{2.5}$; top) and sulfate in $\text{PM}_{2.5}$ (bottom) from 2000–2015 (concentrations in $\mu\text{g}/\text{m}^3$). _____	2-97
	Figure 2-41	98th percentile concentrations for $\text{PM}_{10-2.5}$ between 2013–2015. _____	2-98
2.6.7.	Distributions of Dry Deposition of Nitrogen Dioxide and Sulfur Dioxide Derived Using Satellite-Based Measurements and Chemistry Transport Models	_____	2-98
	Figure 2-42	Top panel: modeled deposition velocities for nitrogen dioxide and sulfur dioxide for 2005 to 2007; middle panel: Satellite-model estimates of annual mean dry deposition fluxes of nitrogen dioxide and sulfur dioxide; bottom panel: uncertainties in estimates. _____	2-100
2.6.8.	Background Concentrations and Deposition	_____	2-101

APPENDIX 3. DIRECT PHYTOTOXIC EFFECTS OF GASEOUS OXIDIZED NITROGEN AND SULFUR ON VEGETATION _____ 3-1

3.1.	Introduction _____	3-1
	Figure 3-1 The microarchitecture of a dicot leaf. While details among species vary, the general overview remains the same. Light that drives photosynthesis generally falls upon the upper (adaxial) leaf surface. Carbon dioxide, oxides of sulfur, oxides of nitrogen, and ozone gases generally enter by diffusion through the guard cells (or stomata) on the lower (abaxial) leaf surface, while water vapor exits through the stomata (transpiration). _____	3-3
3.2.	Direct Phytotoxic Effects of Sulfur Dioxide on Vegetation _____	3-3
	Figure 3-2 Map of maximum 3-hour daily max average sulfur dioxide concentration reported at Air Quality System monitoring sites for 2016. _____	3-5
3.3.	Direct Phytotoxic Effects of Nitric Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate _____	3-7
	Figure 3-3 Map of U.S. annual average nitrogen dioxide concentrations for 2013. _____	3-8
3.4.	Direct Phytotoxic Effects of Nitric Acid _____	3-13
3.5.	Summary _____	3-15
	3.5.1. Sulfur Dioxide _____	3-15
	3.5.2. Nitrogen Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate _____	3-16
	3.5.3. Nitric Acid _____	3-16

APPENDIX 4. SOIL BIOGEOCHEMISTRY _____ 4-1

CONTENTS (Continued)

APPENDIX 5. BIOLOGICAL EFFECTS OF TERRESTRIAL ACIDIFICATION _____ 5-1

5.1.	Introduction _____		5-1
	Figure 5-1	Diagram based on Fenn et al. (2006) showing indicators of forest physiological function, growth, and structure that are linked to biogeochemical cycles through processes that control rates of calcium supply. Calcium affects plant physiological processes that influence growth rates and the capacity of plants to resist environmental stresses, such as extremes of temperature, drought, insects, and diseases. Therefore, acidifying deposition, which can deplete soil calcium or interfere with calcium uptake through mobilization of soil aluminum, can affect forest health. _____	5-3

7.2.2.	The Estuary Environment _____	7-78
Figure 7-7	Schematic diagram illustrating sources, transformations, and fate of nitrogen along the estuary-to-ocean continuum. Surface, subsurface, and atmospheric pathways of externally supplied or new nitrogen inputs attributable to anthropogenic activities are shown as internal nitrogen cycling. The combined anthropogenic nitrogen inputs are shown as a thick arrow (upstream), which decreases in thickness downstream as a portion of the nitrogen inputs settles to the bottom sediments and is buried and/or denitrified. Nitrogen (N ₂) fixation is a biologically mediated new nitrogen input. The linkage of anthropogenically enhanced nitrogen inputs to accelerated primary production or eutrophication and its trophic and biogeochemical fate are also shown. _____	7-79

	Figure 10-7 Summary conceptual schematic illustrating the effect of changes in the proportion of NH_4^+ and NO_3^- in the loads of N provided to a natural system. When NH_4^+ is the dominant form, and when waters are warmer, flagellates, cyanobacteria, and chlorophytes among other classes may proliferate, leading to overall productivity dominated by the small size class of algae (e.g., $<5 \mu\text{m}$). In contrast, when NO_3^- is the dominant form provided, especially under cooler water conditions, diatoms more likely dominate, and their overall production will be more likely dominated by cells of a larger size class (e.g., $>5 \mu\text{m}$). Moreover, chlorophyll a yield and total production may be higher than under the NH_4^+ enrichment condition. _____	10-43

	Table 12-4 New studies on the biology of sulfate-reducing prokaryotes. ____	12-28
	Figure 12-7 The effect of different environmental factors on the relationship between sulfate and mercury methylation. Methylmercury (MeHg) accumulation is minimal at low and high sulfate concentrations, with an optimum near 100 μ M sulfate (blue line). High dissolved organic matter (DOM) will increase the magnitude of MeHg production across the range of sulfate concentrations (red line). Sulfide produced by methylators will inhibit further methylation if it accumulates in the aqueous environment where methylation occurs, shifting the MeHg optimum left (purple line). However if ecosystem chemistry (iron [Fe], reoxidation of sulfide, organic matter [OM]) allows for rapid sequestration of sulfide to large particles and sediments, the relaxation of the negative feedback of sulfide to sulfur-reducing prokaryotes (SRPs) will shift the MeHg optimum right (green line). _____	12-36
12.3.3.	Environmental Drivers of Mercury Methylation Potential _____	12-37

CONTENTS (Continued)

Figure 16-46	Patterns and temporal trends of nitrogen and sulfur deposition in Joshua Tree National Park and surrounding region in California. A and B show the 3-year average total deposition of nitrogen and sulfur for 2011–2013.	16-150
Figure 16-47	Patterns and temporal trends of nitrogen and sulfur deposition in Joshua Tree National Park and surrounding region in California. A shows the partitioning between oxidized and reduced nitrogen; B and C show the 3-year average total percentage of wet deposition of nitrogen and sulfur for 2011–2013.	16-151
Figure 16-48	Patterns and temporal trends of nitrogen and sulfur deposition in Joshua Tree National Park and surrounding region in California. The 25-year time series for wet deposition of nitrate, ammonium, sulfate, and hydrogen ion obtained from the National Atmospheric Deposition Program/National Trends Network monitoring site CA 67.	16-152
Figure 16-49	Patterns and temporal trends of nitrogen and sulfur deposition of Sequoia and Kings Canyons national parks and surrounding region in California. A and B show the 3-year average total deposition of nitrogen and sulfur for 2011–2013.	16-153
Figure 16-50	Patterns and temporal trends of nitrogen and sulfur deposition of Sequoia and Kings Canyons national parks and surrounding region in California. A shows the partitioning between oxidized and reduced nitrogen, indicated as the fraction of total nitrogen which is oxidized; B and C show the 3-year average total percentage of wet deposition of nitrogen and sulfur for 2011–2013.	16-154
Figure 16-51	Patterns and temporal trends of nitrogen and sulfur deposition of Sequoia and Kings Canyons national parks and surrounding region in California. A and B show the 25-year time series for wet deposition of nitrate, ammonium, sulfate, and hydrogen obtained from the National Atmospheric Deposition Program/National Trends Network monitoring sites CA99 and CA75.	16-155
Figure 16-52	Annual-averaged monthly footprint of reactive N deposition in Joshua Tree National Park (3.2 kg N/ha/yr) and Sequoia National Park (5.7 kg N/ha/yr). Also shown for each park is a pie chart of fractional contribution from emission sectors, as estimated by GEOS-Chem adjoint model.	16-157
16.6.3.	Critical Loads and Other Dose-Response Relationships	16-157
Figure 16-53	Composite critical load exceedance maps for all seven vegetation types included in the study of Fenn et al. (2010) showing the combined exceedance areas and the level of exceedance (kg N/ha/yr).	16-160
Table 16-30	Summary of recent empirical dose-response and critical load studies focused on the southern California case study area and published since Pardo et al. (2011c).	16-161
Table 16-31	Terrestrial critical and target load and exceedance modeling studies in southern California.	16-164
Table 16-32	Example surface water acidification studies in Sequoia and Kings Canyons National Parks and other Sequoia and Kings Canyons National Parks—relevant areas in the southern California case study region.	16-168
16.6.4.	Highlights of Additional Research Literature and Federal Reports since January 2008	16-172
Table 16-33	Key recent research literature focused on the case study region.	16-173

CLEAN AIR SCIENTIFIC ADVISORY COMMITTEE OXIDES OF NITROGEN, OXIDES OF SULFUR, AND PARTICULATE MATTER—ECOLOGICAL CRITERIA NAAQS REVIEW PANEL

Chair of Review Panel

Dr. Ivan J. Fernandez**—Distinguished Maine Professor, School of Forest Resources and Climate Change Institute, University of Maine, Orono, ME

Review Panel Members

Dr. Edith Allen—Professor of Plant Ecology, Department of Botany and Plant Sciences, University of California Riverside, Riverside, CA

Dr. Praveen Amar—Independent Consultant, Environment, Energy, and Climate Strategies, Lexington, MA

Dr. James Boyd—Senior Fellow and Director, Center for the Management of Ecological Wealth, Resources for the Future, Washington, DC

Dr. Elizabeth W. Boyer—Associate Professor of Water Resources, Department of Ecosystem Science and Management, Pennsylvania State University, University Park, PA

Dr. Douglas Burns—Research Hydrologist, New York Water Science Center, U.S. Geological Survey, Troy, NY

Ms. Lauraine Chestnut—Managing Economist, Stratus Consulting Inc., Boulder, CO

Dr. Charles T. Driscoll, Jr.—Distinguished Professor and University Professor of Environmental Systems Engineering, Department of Civil and Environmental Engineering, College of Engineering and Computer Science, Syracuse University, Syracuse, NY

Dr. Mark Fenn—Research Plant Pathologist, Pacific Southwest Research Station, USDA Forest Service, Riverside, CA

Dr. James Galloway—Sidman P. Poole Professor of Environmental Sciences, Department of Environmental Sciences, University of Virginia, Charlottesville, VA

Dr. Frank Gilliam, Professor—Department of Biological Sciences, Marshall University, Huntington, WV

Dr. Robert A. Goldstein—Senior Technical Executive for Water and Ecosystems, Electric Power Research Institute, Palo Alto, CA

Dr. Daven Henze—Assistant Professor and Charles C. Gates Faculty Fellow, Department of Mechanical Engineering, University of Colorado, Boulder, CO

Dr. Robert W. Howarth—David R. Atkinson Professor of Ecology & Environmental Biology, Department of Ecology and Evolutionary Biology, Cornell University, Ithaca, NY

Dr. Donna Kenski—Data Analysis Director, Lake Michigan Air Directors Consortium, Rosemont, IL

Dr. William McDowell—Professor of Environmental Science, Department of Natural Resources and the Environment, University of New Hampshire, Durham, NH

Dr. Erik Nelson—Assistant Professor, Department of Economics, Bowdoin College, Brunswick, ME

Dr. Hans Paerl—Kenan Professor of Marine and Environmental Sciences, Institute of Marine Sciences, University of North Carolina—Chapel Hill, Morehead City, NC

Mr. Richard L. Poirot—Air Quality Planning Chief, Air Quality and Climate Division, Vermont Department of Environmental Conservation, Montpelier, VT

Dr. Armistead (Ted) Russell—Howard T. Tellepsen Chair and Regents Professor of Civil and Environmental Engineering, Department of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, GA

Dr. Stephen E. Schwartz—Senior Scientist, Environmental and Climate Sciences Department, Brookhaven National Laboratory, Upton, NY

Dr. Kathleen Weathers—Senior Scientist, Cary Institute of Ecosystem Studies, Millbrook, NY

**Member of the statutory CASAC appointed by the U.S. EPA Administrator

Science Advisory Board Staff

Dr. Thomas Armitage—Designated Federal Officer, U.S. Environmental Protection Agency, Science Advisory Board (1400R), 1200 Pennsylvania Avenue, NW, Washington, D.C. 20460-0001, Phone: 202-564-2155, Fax: 202-565-2098, (Armitage.thomas@epa.gov)

ACRONYMS AND ABBREVIATIONS

Acronym/Abbreviation	Meaning	Acronym/Abbreviation	Meaning
ACCENT	Atmospheric Composition Change: the European Network of excellence	Ba	barium
AIRMoN	Atmospheric Integrated Research Monitoring Network	BBW	Bear Brook Watershed
AIRS	Atmospheric Infrared Sounder (instrument)	BBWM	Bear Brook Watershed, Maine
Al	aluminum	Bc or BC	base cation
Al ³⁺	aluminum ion	BCE	exchangeable base cations
Al _i	inorganic aluminum	BCS	base-cation surplus
Al ²⁺	aluminum ion	BCw	base cation weathering
Al _o	organic aluminum	BGC	Biogeochemical (model)
Al(OH) ₃	aluminum hydroxide	B-IBI	benthic index of biological integrity
ALSC	Adirondack Lake Survey Corporation	BMPs	best management practices
ALTM	Adirondack Long Term Monitoring	BNF	biological nitrogen fertilization
AMD	acid mine drainage	Br	bromine
ANC	acid neutralizing capacity	Br ⁻	bromide ion
ANPP	aboveground net primary production	Br ₂	molecular bromine
AOD	aerosol optical depth	BrCl	bromine chloride
AOSR	Athabasca oil sands region	BrO	bromine mooxide
AQCD	Air Quality Criteria Document	BUV	Backscatter Ultraviolet Spectrometer
AQEG	Air Quality Expert Group	BUVD	Beneficial Use Values Database
AQI	Air Quality Index	C	carbon; concentration
AQS	Air Quality System (database)	¹² C	carbon-12, stable isotope of carbon
Ar	argon	¹³ C	carbon-13, stable isotope of carbon
ARS	Agricultural Research Service	C _a	ambient air concentration
As	arsenic	Ca	calcium
ASI	Acid Stress Index	Ca ²⁺	calcium ion
asl	above sea level	CAA	Clean Air Act
ATMOS	Atmospheric Trace Molecule Spectroscopy	CAAA	Amendments to the Clean Air Act
ATTILA	type of Lagrangian model	CAAAC	Clean Air Act Advisory Committee
AUSPEX	Atmospheric Utility Signatures, Predictions, and Experiments	CaCl ₂	calcium chloride
AVIRIS	Airborne Visible and Infrared Imaging Spectrometer	CaCO ₃	calcium carbonate
		CALIPSO	Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (satellite)

Acronym/Abbreviation	Meaning	Acronym/Abbreviation	Meaning
Ca(NO ₃) ₂	calcium nitrate	CloudSat	NASA Earth observation satellite
Ca(OH) ₂	calcium hydroxide	CINO ₂	nitryl chloride
CAPMoN	Canadian Air and Precipitation Monitoring Network	CMAQ	Community Multiscale Air Quality (modeling system)
CaSO ₄ ·2H ₂ O	gypsum	CMSA	consolidated metropolitan statistical area
CASTNet	Clean Air Status and Trends Network	CO	carbon monoxide
CB4	Carbon Bond 4 (model)	CO ₂	carbon dioxide
Cd	cadmium	CO ₃ ⁻	carbonate
CEC	cation exchange capacity	CONUS	continental U.S.
CENTURY	model that simulates carbon, nitrogen, phosphorus, sulfur, and water dynamics in the soil-plant system at monthly intervals over time scales of centuries and millennia	CPUE	catch per unit effort
CFCs	chlorinated fluorocarbons	CRREL	U.S. Army Cold Regions Research and Engineering Laboratory
CG	cloud-to-ground (lightning flash)	CS	Consumer surplus
Chl <i>a</i>	chlorophyll <i>a</i>	CS ₂	carbon disulfide
CH ₄	methane	CSS	coastal sage scrub (ecosystem)
C ₂ H ₄	ethene	CTM	chemical transport model
C ₂ H ₆	ethane	Cu	copper
C ₃ H ₈	isoprene	CV	contingent valuation
CH ₃ CHO	acetaldehyde	CVM	contingent valuation method
CH ₃ C(O)	acetyl radical	Δ, δ	delta, difference; change
CH ₃ C(O)OO	acetyl peroxy radical	DayCent	model for daily biogeochemistry for forest, grassland, cropland, and savanna systems
CH ₂ I ₂	diiodomethane	DayCent-Chem	combination of DayCent-Chem and PHREEQC models
CH ₂ O	formaldehyde	DC	dichotomous choice
CH ₃ OOH	methyl hydroperoxide	DDRP	Direct Delayed Response Project
CH ₃ -S-CH ₃	dimethylsulfide, DMS	DDT	Damage Delay Time
CH ₃ -S-H	methyl mercaptan	DECOMP	decomposition model based on soil-plant system dynamics
(CH ₃) ₂ SO	dimethyl sulfoxide, DMSO	DEP	Department of Environmental Protection
CH ₃ SO ₃ H	methanesulfonic acid	DIC	dissolved inorganic carbon
CH ₃ -S-S-CH ₃	dimethyl disulfide, DMDS	DIN	dissolved inorganic nitrogen
C _i	interstitial air concentration	DMDS	dimethyl disulfide, CH ₃ -S-S-CH ₃
CL	critical load	DMS	dimethyl sulfide, CH ₃ -S-CH ₃
Cl	chlorine	DMSO	dimethylsulfoxide
Cl ⁻	chloride ion	DNDC	Denitrification-Decomposition (model)
Cl ₂	molecular chlorine		
CLaMS	type of Lagrangian model		

Acronym/Abbreviation	Meaning	Acronym/Abbreviation	Meaning
DO	dissolved oxygen	FISH	Fish in Sensitive Habitats (project)
DOC	dissolved organic carbon	FLEXPART	type of Lagrangian model
DON	dissolved organic nitrogen	ForSAFE	three-component model using nitrogen, carbon cycling, and soil chemistry
EBB	East Bear Brook	FRM	Federal Reference Method
EC	elemental carbon	FTIR	Fourier Transform Infrared Spectroscopy
EEAs	Essential Ecological Attributes	FW2	black carbon soot

PREFACE

Legislative Requirements for the Review of the National Ambient Air Quality Standards

1 Two sections of the Clean Air Act (CAA) govern the establishment, review, and revision
2 of the National Ambient Air Quality Standards (NAAQS). Section 108 [42 U.S. Code
3 (U.S.C.) 7408] directs the Administrator to identify and list certain air pollutants and then
4 to issue air quality criteria for those pollutants. The Administrator is to list those air
5 pollutants that in their “judgment, cause or contribute to air pollution which may
6 reasonably be anticipated to endanger public health or welfare,” “the presence of which
7 in the ambient air results from numerous or diverse mobile or stationary sources,” and
8 “for which ... [the Administrator] plans to issue air quality criteria ...” [42 U.S.C.
9 7408(a)(1); [CAA, 1990a](#)]. Air quality criteria are intended to “accurately reflect the
10 latest scientific knowledge useful in indicating the kind and extent of all identifiable
11 effects on public health or welfare, which may be expected from the presence of [a]
12 pollutant in the ambient air ...” [42 U.S.C. 7408(b)]. Section 109 [42 U.S.C. 7409;
13 [CAA, 1990b](#)] directs the Administrator to propose and promulgate “primary” and
14 “secondary” NAAQS for pollutants for which air quality criteria are issued.

15 Section 109(b)(1) defines a primary standard as one “the attainment and maintenance of
16 which in the judgment of the Administrator, based on such criteria and allowing an
17 adequate margin of safety, are requisite to protect the public health.”¹ A secondary
18 standard, as defined in Section 109(b)(2), must “specify a level of air quality the
19 attainment and maintenance of which, in the judgment of the Administrator, based on
20 such criteria, is requisite to protect the public welfare from any known or anticipated
21 adverse effects associated with the presence of [the] air pollutant in the ambient air.”²

22 In setting standards that are “requisite” to protect public health and welfare as provided in
23 Section 109(b), the U.S. EPA’s task is to establish standards that are neither more nor less
24 stringent than necessary for these purposes. In so doing, the U.S. EPA may not consider
25 the costs of implementing the standards.³ Likewise, “[a]ttainability and technological

¹ The legislative history of Section 109 indicates that a primary standard is to be set at “... the maximum permissible ambient air level ... which will protect the health of any [sensitive] group of the population,” and that for this purpose “reference should be made to a representative sample of persons comprising the sensitive group rather than to a single person in such a group” S. Rep. No. 91:1196, 91st Cong., 2d Sess. 10 (1970).

² Section 302(h) of the Act [42 U.S.C. 7602(h)] provides that all language referring to effects on welfare includes, but is not limited to, “effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being ...” ([CAA, 2005](#)).

³ See generally, *Whitman v. American Trucking Associations*, 531 U.S. 457, 465–472, 475–476 (2001).

1 feasibility are not relevant considerations in the promulgation of national ambient air
2 quality standards.”¹

3 Section 109(d)(1) requires that “not later than December 31, 1980, and at 5-year intervals
4 thereafter, the Administrator shall complete a thorough review of the criteria published
5 under Section 108 and the national ambient air quality standards ... and shall make such
6 revisions in such criteria and standards and promulgate such new standards as may be
7 appropriate” Section 109(d)(2) requires that an independent scientific review
8 committee “shall complete a review of the criteria ... and the national primary and
9 secondary ambient air quality standards ... and shall recommend to the Administrator any
10 new ... standards and revisions of existing criteria and standards as may be
11 appropriate” Since the early 1980s, this independent review function has been
12 performed by the Clean Air Scientific Advisory Committee (CASAC).²

Overview and History of the Reviews of the Secondary National Ambient Air Quality Standards for Nitrogen Dioxide, Sulfur Dioxide, and Particulate Matter

13 NAAQS are defined by four basic elements: indicator, averaging time, level, and form.
14 The indicator defines the pollutant to be measured in the ambient air for the purpose of
15 determining compliance with the standard. The averaging time defines the time period
16 over which air quality measurements are to be obtained and averaged or cumulated,
17 considering evidence of effects associated with various time periods of exposure. The
18 level of a standard defines the air quality concentration used (i.e., an ambient
19 concentration of the indicator pollutant) in determining whether the standard is achieved.
20 The form of the standard defines the air quality statistic that is compared to the level of
21 the standard in determining whether an area attains the standard. The Administrator
22 considers these four elements collectively in evaluating the protection to public health
23 provided by the primary NAAQS.

Nitrogen Dioxide Secondary National Ambient Air Quality Standards

24 The first air quality criteria and standards for oxides of nitrogen were issued in 1971
25 [([U.S. EPA, 1971](#)), 36 FR 8186]. Both the primary and secondary standards were set at
26 0.053 parts per million (ppm), as an annual arithmetic mean (36 FR 8186). In 1982, the

¹ See *American Petroleum Institute v. Costle*, 665 F. 2d at 1185.

² Lists of chartered CASAC members and of members of the CASAC Panels are available at:
<http://yosemite.epa.gov/sab/sabproduct.nsf/WebCASAC/CommitteesandMembership?OpenDocument>.

1 U.S. EPA published Air Quality Criteria for Oxides of Nitrogen ([U.S. EPA, 1982a](#)),
2 which updated the scientific criteria upon which the initial standards were based. On
3 February 23, 1984, the U.S. EPA proposed to retain these standards (49 FR 6866). After
4 taking into account public comments, the U.S. EPA published the final decision to retain
5 the existing standards on June 19, 1985 (50 FR 25532).

6 In November 1991, the U.S. EPA initiated another review and released an updated draft
7 air quality criteria document (AQCD) for review and comment by CASAC and the public
8 (56 FR 59285). The final AQCD was released later in 1993 ([U.S. EPA, 1993](#)). Staff of
9 the Office of Air Quality Planning and Standards (OAQPS) prepared a draft Staff Paper
10 that summarized and integrated the key studies and scientific evidence contained in the
11 revised air quality criteria document and identified the critical elements to be considered
12 in the review of the NO₂ NAAQS. The Staff Paper was reviewed by the CASAC and the
13 public in December 1994, and in September 1995, the U.S. EPA finalized the Staff Paper
14 ([U.S. EPA, 1995b](#)). On October 2, 1995, the Administrator announced her proposed
15 decision not to revise either the primary or secondary NAAQS for NO₂ based on the
16 information available in this review (60 FR 52874; October 11, 1995). After
17 consideration of public comments, the Administrator made a final determination that
18 revisions to neither the primary nor the secondary NAAQS for NO₂ were appropriate at
19 that time (61 FR 52852; October 8, 1996).

20 The most recent review of the secondary NAAQS standards for oxides of nitrogen was
21 performed jointly with a review of the secondary NAAQS for oxides of sulfur beginning
22 in 2005 (described below).

Sulfur Dioxide Secondary National Ambient Air Quality Standards

23 Based on the 1969 sulfur oxides criteria document ([HEW, 1969](#)), the U.S. EPA
24 promulgated the initial primary and secondary NAAQS for SO₂ on April 30, 1971 (36 FR
25 8186). The secondary standards were 0.02 ppm as an annual arithmetic mean and
26 0.5 ppm as a maximum 3-hour, not to be exceeded more than once per year. These
27 secondary standards were established on the basis of vegetation effects evidence
28 described in the 1970 criteria document. Based on additional data available in 1973,
29 revisions were made to Chapter 5 “Effects of Sulfur Oxide in the Atmosphere on
30 Vegetation” of the *Air Quality Criteria for Sulfur Oxides* ([U.S. EPA, 1973](#)), which led the
31 U.S. EPA to propose (38 FR 11355) and then finalize a revocation of the annual mean
32 secondary standard (38 FR 25678). At that time, the U.S. EPA additionally considered
33 welfare effects related to effects on materials, visibility, soils, and water. However, the

1 U.S. EPA concluded that either protection from such effects was afforded by the primary
2 standard or that sufficient data were not then available to develop criteria for standards
3 based on these effects (38 FR 25680).

4 In 1980, the U.S. EPA released a combined AQCD for sulfur oxides and particulate
5 matter for CASAC review. Following its review of a draft revised criteria document in
6 August 1980, the CASAC concluded that acidic deposition was a topic of extreme
7 scientific complexity, noting that a fundamental problem of addressing acid deposition in
8 a criteria document is that acidic deposition is produced by several pollutants, including
9 oxides of sulfur, oxides of nitrogen, and the fine particulate fraction of suspended
10 particles [([U.S. EPA, 1982b](#)), pp. 125–126]. Following CASAC closure on the criteria
11 document in December 1981, the U.S. EPA released a final AQCD ([U.S. EPA, 1982b](#)),
12 and the OAQPS prepared a Staff Paper that was released in November 1982 ([U.S. EPA,](#)
13 [1982c](#)). The issue of acidic deposition was not, however, assessed directly in the OAQPS
14 Staff Paper because the U.S. EPA followed the guidance given by CASAC.

15 In response to CASAC recommendations for a separate comprehensive discussion of
16 acidic deposition as part of the criteria documents, the U.S. EPA subsequently prepared
17 the following documents: *The Acidic Deposition Phenomenon and Its Effects: Critical*
18 *Assessment Review Papers, Volumes I and II* ([U.S. EPA, 1984a, b](#)) and *The Acidic*
19 *Deposition Phenomenon and Its Effects: Critical Assessment Document* [([Bennett et al.,](#)
20 [1985](#)); 53 FR 14935–14936]. Although these documents were not considered criteria
21 documents and had not undergone CASAC review, they represented the most
22 comprehensive summary of relevant scientific information completed by the U.S. EPA at
23 that point (58 FR 21355).

24 At about the same time in 1980 as the CASAC recommendation for a comprehensive
25 assessment of acidic deposition, Congress created the National Acid Precipitation
26 Assessment Program (NAPAP). During the 10-year course of this program, a series of
27 reports were issued and a final report was issued in 1990 ([NAPAP, 1991](#)).

28 On April 26, 1988, the U.S. EPA proposed not to revise the existing primary and
29 secondary standards. This proposal regarding the secondary SO₂ NAAQS was due to the
30 Administrator’s conclusions that (1) based upon the then-current scientific understanding
31 of the acidic deposition problem, it would be premature and unwise to prescribe any
32 regulatory control program at that time and (2) when the fundamental scientific
33 uncertainties had been reduced through ongoing research efforts, the U.S. EPA would
34 draft and support an appropriate set of control measures (53 FR 14926). Subsequent to
35 the proposal, Congress took up consideration of acidic deposition.

1 On November 15, 1990, Amendments to the CAA were passed by Congress and signed
2 into law by the President. In Title IV of these Amendments, Congress included a
3 statement of findings that had led them to take this action, including that: “(1) the
4 presence of acidic compounds and their precursors in the atmosphere and in deposition
5 from the atmosphere represents a threat to natural resources, ecosystems, materials,
6 visibility, and public health; (2) the problem of acid deposition is of national and
7 international significance; and that (3) current and future generations of Americans will
8 be adversely affected by delaying measures to remedy the problem...” The goal of
9 Title IV was to reduce emissions of SO₂ by 10 million tons and oxides of nitrogen
10 emissions by 2 million tons from 1980 emission levels in order to achieve reductions over
11 broad geographic regions/areas. In envisioning that further action might be necessary in
12 the long term, Congress included Section 404 of the 1990 Amendments. This section
13 requires the U.S. EPA to conduct a study on the feasibility and effectiveness of an acid
14 deposition standard or standards to protect “sensitive and critically sensitive aquatic and
15 terrestrial resources” and at the conclusion of the study, submit a report to Congress. Five
16 years later, the U.S. EPA submitted to Congress its report titled *Acid Deposition Standard
17 Feasibility Study: Report to Congress* ([U.S. EPA, 1995a](#)) in fulfillment of this
18 requirement. The Report to Congress concluded that establishing acid deposition
19 standards for sulfur and nitrogen deposition might at some point in the future be
20 technically feasible although appropriate deposition loads for these acidifying chemicals
21 could not be defined with reasonable certainty at that time.

22 The 1990 Amendments also added new language to sections of the CAA that pertain to
23 the scope or application of the secondary NAAQS designed to protect the public welfare.
24 Section 108(g) specified that “the Administrator may assess the risks to ecosystems from
25 exposure to criteria air pollutants (as identified by the Administrator at the
26 Administrator’s sole discretion).” The definition of public welfare in Section 302(h) was
27 expanded to state that the welfare effects identified should be protected from adverse
28 effects associated with criteria air pollutants “...whether caused by transformation,
29 conversion, or combination with other air pollutants.”

30 In response to these legislative initiatives, the U.S. EPA and other federal agencies
31 continued research on the causes and effects of acidic deposition and related welfare
32 effects of SO₂ and implemented an enhanced monitoring program to track progress
33 (58 FR 21357). In 1993, the U.S. EPA announced a decision not to revise the secondary
34 standard, concluding that revision to address acidic deposition and related SO₂ welfare
35 effects was not appropriate at that time (58 FR 21351). In reaching this decision, the
36 U.S. EPA took into account the significant reductions in SO₂ emissions, ambient SO₂
37 concentrations, and ultimately deposition expected to result from implementation of the
38 Title IV program, which was expected to significantly decrease the acidification of water

1 bodies and damage to forest ecosystems and to permit much of the existing damage to be
2 reversed with time (58 FR 21357). While recognizing that further action might be needed
3 to address acidic deposition in the longer term, the U.S. EPA judged it prudent to await
4 the results of the studies and research programs then underway, including those assessing
5 the comparative merits of secondary standards, acidic deposition standards, and other
6 approaches to control of acidic deposition and related effects, and then to determine
7 whether additional control measures should be adopted or recommended to Congress
8 (58 FR 21358).

9 In 2000, the U.S. EPA announced receipt of two items related to acidic deposition and the
10 NAAQS (65 FR 48699). The first was a petition submitted to the U.S. EPA in 1999 by
11 representatives of seven northeastern states for the promulgation of revised secondary
12 NAAQS for the criteria pollutants associated with the formation of acid rain (including
13 NO₂, SO₂, and fine particulate matter [PM_{2.5}]). The petition states that the language in
14 Section 302(h) of the CAA “clearly references the transformation of pollutants resulting
15 in the inevitable formation of sulfate and nitrate aerosols and/or their ultimate
16 environmental impacts as wet and dry deposition, clearly signaling Congressional intent
17 that the welfare damage occasioned by sulfur and nitrogen oxides be addressed through
18 the secondary standard provisions of Section 109 of the Act.” The petition further stated
19 that “recent federal studies, including the NAPAP Biennial Report to Congress: An
20 Integrated Assessment, document the continued—and increasing—damage being
21 inflicted by acid deposition to the lakes and forests of New York, New England, and
22 other parts of our nation, demonstrating that the Title IV program had proven
23 insufficient.” The petition also listed other adverse welfare effects associated with the
24 transformation of these criteria pollutants, including visibility impairment, eutrophication
25 of coastal estuaries, global warming, tropospheric ozone, and stratospheric ozone
26 depletion.

27 The second item was a related request from the U.S. Department of Interior (DOI) that
28 the U.S. EPA address many of the same adverse environmental effects associated with
29 the same types of air pollutants and with ozone that the DOI asserted were occurring in
30 national parks and wilderness areas (65 FR 48699). Included among the effects of
31 concern identified in the request were acidification of streams, surface waters and/or
32 soils, eutrophication of coastal waters, visibility impairment, and foliar injury from ozone
33 (65 FR 48701). The U.S. EPA requested comment on the issues raised by these requests,
34 stating that it would consider any relevant comments and information submitted, along
35 with the information provided by the petitioners and DOI, before making any decision
36 concerning a response to these requests for rulemaking, which if commenced would
37 include opportunity for public review and comment (65 FR 48701).

Particulate Matter Secondary National Ambient Air Quality Standards

1 The U.S. EPA first established NAAQS for particulate matter (PM) in 1971 (36 FR 8186,
2 April 30, 1971) based on the original AQCD ([NAPCA, 1969](#)). The AQCD assessed the
3 evidence for a variety of PM-associated welfare effects, including visibility impairment
4 and materials damage (e.g., soiling, corrosion). Based on evidence for such effects, the
5 secondary standards were set at 150 $\mu\text{g}/\text{m}^3$ for the 24-hour average not to be exceeded
6 more than once per year and 60 $\mu\text{g}/\text{m}^3$ for the annual geometric mean. The federal
7 reference method (FRM) specified for determining attainment of the original standards
8 was the high-volume sampler, which collects PM up to a nominal size of 25 to
9 45 micrometers (μm ; referred to as total suspended particulates or TSP).

10 In October 1979 (44 FR 56730; October 2, 1979), the U.S. EPA announced the first
11 periodic review of the air quality criteria and NAAQS for PM. Revised primary and
12 secondary standards were promulgated in 1987 (52 FR 24634; July 1, 1987). In the 1987
13 decision, the U.S. EPA changed the indicator for particles from TSP to PM_{10} to focus on
14 the subset of inhalable particles small enough to penetrate to the thoracic region of the
15 respiratory tract (including the tracheobronchial and alveolar regions) referred to as
16 thoracic particles.¹ The level of the 24-hour standards (primary and secondary) was set at
17 150 $\mu\text{g}/\text{m}^3$, and the form was one expected exceedance per year, on average, over 3 years.
18 The level of the annual standards (primary and secondary) was set at 50 $\mu\text{g}/\text{m}^3$, and the
19 form was annual arithmetic mean averaged over 3 years.

20 In April 1994, the U.S. EPA announced its plans for the second periodic review of the air
21 quality criteria and NAAQS for PM, and in 1997, the U.S. EPA promulgated revisions to
22 the NAAQS (62 FR 38652, July 18, 1997). In the 1997 decision, the U.S. EPA
23 determined that the fine and coarse fractions of PM_{10} should be considered separately.
24 This determination was based on evidence that serious health effects were associated with
25 short- and long-term exposures to fine particles in areas that met the existing PM_{10}
26 standards. The U.S. EPA added new standards using $\text{PM}_{2.5}$ as the indicator for fine
27 particles (with $\text{PM}_{2.5}$ referring to particles with a nominal mean aerodynamic diameter
28 less than or equal to 2.5 μm). These new standards were as follows: (1) an annual
29 standard with a level of 15.0 $\mu\text{g}/\text{m}^3$ based on the 3-year average of annual arithmetic
30 mean $\text{PM}_{2.5}$ concentrations from single or multiple community-oriented monitors and
31 (2) a 24-hour standard with a level of 65 $\mu\text{g}/\text{m}^3$ based on the 3-year average of the 98th

¹ PM_{10} refers to particles with a nominal mean aerodynamic diameter less than or equal to 10 μm . More specifically, 10 μm is the aerodynamic diameter for which the efficiency of particle collection is 50%. Larger particles are not excluded altogether but are collected with substantially decreasing efficiency while smaller particles are collected with increasing efficiency.

1 percentile of 24-hour PM_{2.5} concentrations at each monitor within an area. Also, the
2 U.S. EPA established a new reference method for the measurement of PM_{2.5} in the
3 ambient air and adopted rules for determining attainment of the new standards. To
4 continue to address the coarse fraction of PM₁₀ (referred to as thoracic coarse particles or
5 PM_{10-2.5}; generally including particles with a nominal mean aerodynamic diameter
6 greater than 2.5 µm and less than or equal to 10 µm), the U.S. EPA retained the annual
7 PM₁₀ standard and revised the form of the 24-hour PM₁₀ standard to be based on the 99th
8 percentile of 24-hour PM₁₀ concentrations at each monitor in an area. The U.S. EPA
9 revised the secondary standards by setting them equal in all respects to the primary
10 standards.

11 Following promulgation of the 1997 PM NAAQS, petitions for review were filed by a
12 large number of parties, addressing a broad range of issues. In May 1999, the U.S. Court
13 of Appeals for the District of Columbia Circuit (D.C. Circuit) upheld the U.S. EPA's
14 decision to establish fine particle standards, holding that "the growing empirical evidence
15 demonstrating a relationship between fine particle pollution and adverse health effects
16 amply justifies establishment of new fine particle standards." *American Trucking
17 Associations v. EPA*, 175 F. 3d 1027, 1055–56 (D.C. Cir., 1999). The D.C. Circuit also
18 found "ample support" for the U.S. EPA's decision to regulate coarse particle pollution,
19 but vacated the 1997 PM₁₀ standards, concluding that the U.S. EPA had not provided a
20 reasonable explanation justifying use of PM₁₀ as an indicator for coarse particles (175 F.
21 3d at 1054–55). Pursuant to the D.C. Circuit's decision, the U.S. EPA removed the
22 vacated 1997 PM₁₀ standards, and the pre-existing 1987 PM₁₀ standards remained in
23 place (65 FR 80776, December 22, 2000). The D.C. Circuit also upheld the U.S. EPA's
24 determination not to establish more stringent secondary standards for fine particles to
25 address effects on visibility (175 F. 3d at 1027).

26 The D.C. Circuit also addressed more general issues related to the NAAQS, including
27 issues related to the consideration of costs in setting NAAQS and the U.S. EPA's
28 approach to establishing the levels of NAAQS. Regarding the cost issue, the court
29 reaffirmed prior rulings holding that in setting NAAQS the U.S. EPA is "not permitted to
30 consider the cost of implementing those standards" (Id. at 1040–41). Regarding the levels
31 of NAAQS, the court held that the U.S. EPA's approach to establishing the level of the
32 standards in 1997 (i.e., both for PM and for the ozone NAAQS promulgated on the same
33 day) effected "an unconstitutional delegation of legislative authority" (Id. at 1034–40).
34 Although the court stated that "the factors U.S. EPA uses in determining the degree of
35 public health concern associated with different levels of ozone and PM are reasonable," it
36 remanded the rule to the U.S. EPA, stating that when the U.S. EPA considers these
37 factors for potential nonthreshold pollutants "what U.S. EPA lacks is any determinate
38 criterion for drawing lines" to determine where the standards should be set.

1 The D.C. Circuit’s holding on the cost and constitutional issues were appealed to the U.S.
2 Supreme Court. In February 2001, the Supreme Court issued a unanimous decision
3 upholding the U.S. EPA’s position on both the cost and constitutional issues. *Whitman v.*
4 *American Trucking Associations*, 531 U.S. 457, 464, 475–76. On the constitutional issue,
5 the Court held that the statutory requirement that NAAQS be “requisite” to protect public
6 health with an adequate margin of safety sufficiently guided the U.S. EPA’s discretion,
7 affirming the U.S. EPA’s approach of setting standards that are neither more nor less
8 stringent than necessary.¹

9 In October 1997, the U.S. EPA published its plans for the third periodic review of the air
10 quality criteria and NAAQS for PM (62 FR 55201; October 23, 1997). On September 21,
11 2006, the U.S. EPA announced its final decisions to revise the primary and secondary
12 NAAQS for PM to provide increased protection of public health and welfare,
13 respectively (71 FR 61144; October 17, 2006). With regard to the primary and secondary
14 standards for fine particles, the U.S. EPA revised the level of the 24-hour PM_{2.5} standards
15 to 35 µg/m³, retained the level of the annual PM_{2.5} standards at 15.0 µg/m³, and revised
16 the form of the annual PM_{2.5} standards by narrowing the constraints on the optional use of
17 spatial averaging. With regard to the primary and secondary standards for PM₁₀, the
18 U.S. EPA retained the 24-hour standards, with levels at 150 µg/m³, and revoked the
19 annual standards.² The Administrator judged that the available evidence generally did not
20 suggest a link between long-term exposure to existing ambient levels of coarse particles
21 and health or welfare effects. In addition, a new reference method was added for the
22 measurement of PM_{10–2.5} in the ambient air, in order to provide a basis for approving
23 federal equivalent methods (FEMs) and to promote the gathering of scientific data to
24 support future reviews of the PM NAAQS.

25 Several parties filed petitions for review following promulgation of the revised PM
26 NAAQS in 2006. These petitions addressed the following issues: (1) selecting the level of
27 the primary annual PM_{2.5} standard; (2) retaining PM₁₀ as the indicator of a standard for

¹ The Supreme Court remanded the case to the Court of Appeals for resolution of any remaining issues that had not been addressed in that court’s earlier rulings (Id. at 475–76). In a March 2002 decision, the Court of Appeals rejected all remaining challenges to the standards, holding that the U.S. EPA’s PM_{2.5} standards were reasonably supported by the administrative record and were not “arbitrary and capricious” *American Trucking Associations v. EPA*, 283 F. 3d 355, 369–72 (D.C. Cir. 2002).

² In the 2006 proposal, the U.S. EPA proposed to revise the 24-hour PM₁₀ standard in part by establishing a new PM_{10–2.5} indicator for thoracic coarse particles (i.e., particles generally between 2.5 and 10 µm in diameter). The U.S. EPA proposed to include any ambient mix of PM_{10–2.5} that was dominated by resuspended dust from high-density traffic on paved roads and by PM from industrial and construction sources. The U.S. EPA proposed to exclude any ambient mix of PM_{10–2.5} that was dominated by rural windblown dust and soils and by PM generated from agricultural and mining sources. In the final decision, the existing PM₁₀ standard was retained, in part due to an “inability...to effectively and precisely identify which ambient mixes are included in the [PM_{10–2.5}] indicator and which are not” (71 FR 61197; October 17, 2006).

1 thoracic coarse particles, retaining the level and form of the 24-hour PM₁₀ standard, and
2 revoking the PM₁₀ annual standard; and (3) setting the secondary PM_{2.5} standards
3 identical to the primary standards. On February 24, 2009, the U.S. Court of Appeals for
4 the District of Columbia Circuit issued its opinion in the case *American Farm Bureau*
5 *Federation v. EPA*, 559 F. 3d 512 (D.C. Cir. 2009). The court remanded the primary
6 annual PM_{2.5} NAAQS to the U.S. EPA because the U.S. EPA failed to adequately explain
7 why the standards provided the requisite protection from both short- and long-term
8 exposures to fine particles, including protection for at-risk populations (*American Farm*
9 *Bureau Federation v. EPA*, 559 F. 3d 512, 520–27; D.C. Cir. 2009). With regard to the
10 standards for PM₁₀, the court upheld the U.S. EPA’s decisions to retain the 24-hour PM₁₀
11 standard to provide protection from thoracic coarse particle exposures and to revoke the
12 annual PM₁₀ standard (*American Farm Bureau Federation*, 559 F. 2d at 533–38). With
13 regard to the secondary PM_{2.5} standards, the court remanded the standards to the
14 U.S. EPA because the Agency failed to adequately explain why setting the secondary PM
15 standards identical to the primary standards provided the required protection for public
16 welfare, including protection from visibility impairment (*American Farm Bureau*
17 *Federation*, 559 F. 2d at 528–32). The U.S. EPA responded to the court’s remands as
18 part of the next review of the PM NAAQS, which was initiated in 2007.

19 In June 2007, the U.S. EPA initiated the fourth periodic review of the air quality criteria
20 and the PM NAAQS by issuing a call for information in the *Federal Register* (72 FR
21 35462; June 28, 2007). In December 2012, the U.S. EPA announced its final decisions
22 with regard to the secondary PM standards, the U.S. EPA retained the 24-hour and annual
23 PM_{2.5} standards and the 24-hour PM₁₀ standard to address visibility and nonvisibility
24 welfare effects. On judicial review, the revised standards were upheld in all respects
25 (*NAM v. EPA*, 750 F.3d 921; D.C. Cir. 2014).

Most Recent Combined Review of the Oxides of Nitrogen and Oxides of Sulfur National Ambient Air Quality Standards

26 In 2005, the U.S. EPA initiated a joint review of the air quality criteria for oxides of
27 nitrogen and sulfur and the secondary NAAQS for NO₂ and SO₂. In so doing, the
28 U.S. EPA assessed the scientific information, associated risks, and standards relevant to
29 protecting the public welfare from adverse effects associated jointly with oxides of
30 nitrogen and sulfur. Although the U.S. EPA has historically adopted separate secondary
31 standards for oxides of nitrogen and oxides of sulfur, the U.S. EPA conducted a joint
32 review of these standards because oxides of nitrogen and sulfur and their associated
33 transformation products are linked from an atmospheric chemistry perspective, as well as

1 from an environmental effects perspective. The joint review was also responsive to the
2 National Research Council (NRC) recommendation for the U.S. EPA to consider
3 multiple pollutants, as appropriate, in forming the scientific basis for the NAAQS ([NRC,
4 2004](#)).

5 The review was initiated on December 13, 2005 with a call for information (70 FR
6 73236) for the development of a revised ISA. A draft Integrated Review Plan (IRP) was
7 released in October 2007, reviewed by CASAC; the final IRP was released in December
8 2007 ([U.S. EPA, 2007](#)). The first and second drafts of the ISA were released in
9 December 2007 and August 2008 (73 FR 10243), respectively, for CASAC and public
10 review. The final ISA ([U.S. EPA, 2008a](#)) was released in December 2008 (73 FR 75716).

11 Based on the scientific information in the ISA, the U.S. EPA developed a Risk and
12 Exposure Assessment (REA) to further assess the national impact of the effects
13 documented in the ISA. The Draft Scope and Methods Plan for Risk/Exposure
14 Assessment: Secondary NAAQS Review for Oxides of Nitrogen and Oxides of Sulfur
15 outlining the scope and design of the future REA was released in March 2008 (73 FR
16 10243). A first and second draft of the REA were released (August 2008 and June 2009)
17 for CASAC review and public comment. The final REA ([U.S. EPA, 2009c](#)) was released
18 in September 2009. Drawing on the information in the final REA and ISA, a first draft,
19 second draft, and final Policy Assessment (PA) were released in March 2010, September
20 2010, and January 2011, respectively ([U.S. EPA, 2011a](#)).

21 On August 1, 2011, based on consideration of the scientific information and quantitative
22 assessments, the U.S. EPA published a proposal to (1) retain the existing NO₂ and SO₂
23 secondary standards, (2) add secondary standards identical to the NO₂ and SO₂ primary
24 1-hour standards, and (3) not set a new multipollutant secondary standard in this review.
25 After consideration of public comments on the proposed standards and on design of a
26 new field pilot program to gather and analyze additional relevant data, the Administrator
27 signed a final decision in this rulemaking on March 20, 2012. The Administrator's
28 decision was that, while the current secondary standards were inadequate to protect
29 against adverse effects from deposition of oxides of nitrogen and sulfur, it was not
30 appropriate under Section 109(b) to set any new secondary standards at this time due to
31 the limitations in the available data and uncertainty as to the amount of protection the
32 metric developed in the review would provide against acidification effects across the
33 country (77 FR 20281). In addition, the Administrator decided that it was appropriate to
34 retain the current NO₂ and SO₂ secondary standards to address direct effects of gaseous
35 NO₂ and SO₂ on vegetation. Thus, taken together, the Administrator decided to retain and
36 not revise the current NO₂ and SO₂ secondary standards: an NO₂ standard set at a level of

1 0.053 ppm as an annual arithmetic average, and an SO₂ standard set at a level of 0.5 ppm
2 as a 3-hour average, not to be exceeded more than once per year (77 FR 20281).

3 The U.S. EPA’s decision to not set a secondary NAAQS for oxides of nitrogen and sulfur
4 even though the Administrator had concluded that the existing standards are not adequate
5 to protect against the adverse impacts of aquatic acidification on sensitive ecosystems
6 was challenged by the Center for Biological Diversity and other environmental groups.
7 The petitioners argued that having decided that the existing standards were not adequate
8 to protect against adverse public welfare effects such as damage to sensitive ecosystems,
9 the Administrator was required to identify the requisite level of protection for the public
10 welfare and to issue a NAAQS to achieve and maintain that level of protection. The D.C.
11 Circuit disagreed, finding that the U.S. EPA acted appropriately in not setting a
12 secondary standard given the U.S. EPA’s conclusions that “the available information was
13 insufficient to permit a reasoned judgment about whether any proposed standard would
14 be ‘requisite to protect the public welfare ...’” (*Center for Biological Diversity, et al. v.*
15 *EPA*, 749 F.3d 1079, 1087; 2014). In reaching this decision, the court noted that the
16 U.S. EPA had “explained in great detail” the profound uncertainties associated with
17 setting a secondary NAAQS to protect against aquatic acidification.

EXECUTIVE SUMMARY

Purpose and Scope of the Integrated Science Assessment

1 This *Integrated Science Assessment (ISA) for Oxides of Nitrogen, Oxides of Sulfur, and*
2 *Particulate Matter—Ecological Criteria* is a comprehensive evaluation and synthesis of
3 the most policy-relevant science aimed at characterizing the ecological effects caused by
4 these criteria pollutants.¹ These criteria pollutants are reviewed here together because
5 they all contribute to nitrogen (N) and sulfur (S) deposition, which causes substantial
6 ecological effects. In this document, the term “oxides of nitrogen” refer to total oxidized
7 N (NO_Y), including nitric oxide (NO) and nitrogen dioxide (NO₂) and all other oxidized
8 N containing compounds formed from NO and NO₂.² The term “oxides of sulfur”
9 includes gaseous sulfur oxides (e.g., sulfur dioxide [SO₂], sulfur monoxide [SO], disulfur
10 monoxide [S₂O], and sulfur trioxide [SO₃]) as well as particulate species, such as
11 ammonium sulfate [(NH₄)₂SO₄ ([U.S. EPA, 2011a](#))]. Particulate species include oxidized
12 sulfur species like sulfites (SO₃²⁻) and sulfates (SO₄²⁻), but among these two species
13 usually only sulfates make a major contribution to particulate mass. Throughout this
14 document SO_X is defined as the sum of SO₂ and particulate sulfate (SO₄²⁻), which
15 represent virtually all of the oxidized sulfur mass in the atmosphere.³ Particulate matter
16 (PM) is composed of some or all of the following components: nitrate (NO₃⁻), SO₄²⁻,
17 ammonium (NH₄⁺), metals, minerals (dust), and organic and elemental carbon.

18 This ISA serves as the scientific foundation for the review of the ecological effects
19 associated with the secondary (welfare-based) National Ambient Air Quality Standards
20 (NAAQS) for oxides of nitrogen, oxides of sulfur, and particulate matter. The health
21 effects of these criteria pollutants are considered in separate assessments as part of the
22 review of the primary (health-based) NAAQS for oxides of nitrogen ([U.S. EPA, 2016f](#)),
23 oxides of sulfur ([U.S. EPA, 2016e](#)), and particulate matter ([U.S. EPA, 2009a](#)).⁴ The

¹ The general process for developing an ISA, including the framework for evaluating weight of evidence and drawing scientific conclusions and causal judgments, is described in a companion document, *Preamble to the Integrated Science Assessments* ([U.S. EPA, 2015e](#)), www.epa.gov/isa.

² This ISA reserves the abbreviation NO_X strictly as the sum of NO and NO₂—consistent with its use in the atmospheric science community—and uses the term “oxides of nitrogen” to refer to the broader list of oxidized nitrogen species. Oxides of nitrogen refers to NO_Y as the total oxidized nitrogen in both gaseous and particulate forms. The major gaseous and particulate constituents of NO_Y include nitric oxide (NO), nitrogen dioxide (NO₂), nitric acid (HNO₃), peroxyacetyl nitrate (PAN), nitrous acid (HONO), organic nitrates, and particulate nitrate (NO₃). This ISA uses the definitions adopted by the atmospheric sciences community.

³ The same definition of SO_X used in the 2011 NO_XSO_X Policy Assessment ([U.S. EPA, 2011a](#)).

⁴ In this ISA, the blue electronic links can be used to navigate to cited materials as well as appendices, chapters, sections, tables, figures, and studies from this ISA.

1 Clean Air Act definition of welfare effects includes, but is not limited to, effects on soils,
2 water, wildlife, vegetation, visibility, weather, and climate, as well as effects on
3 man-made materials, economic values, and personal comfort and well-being.

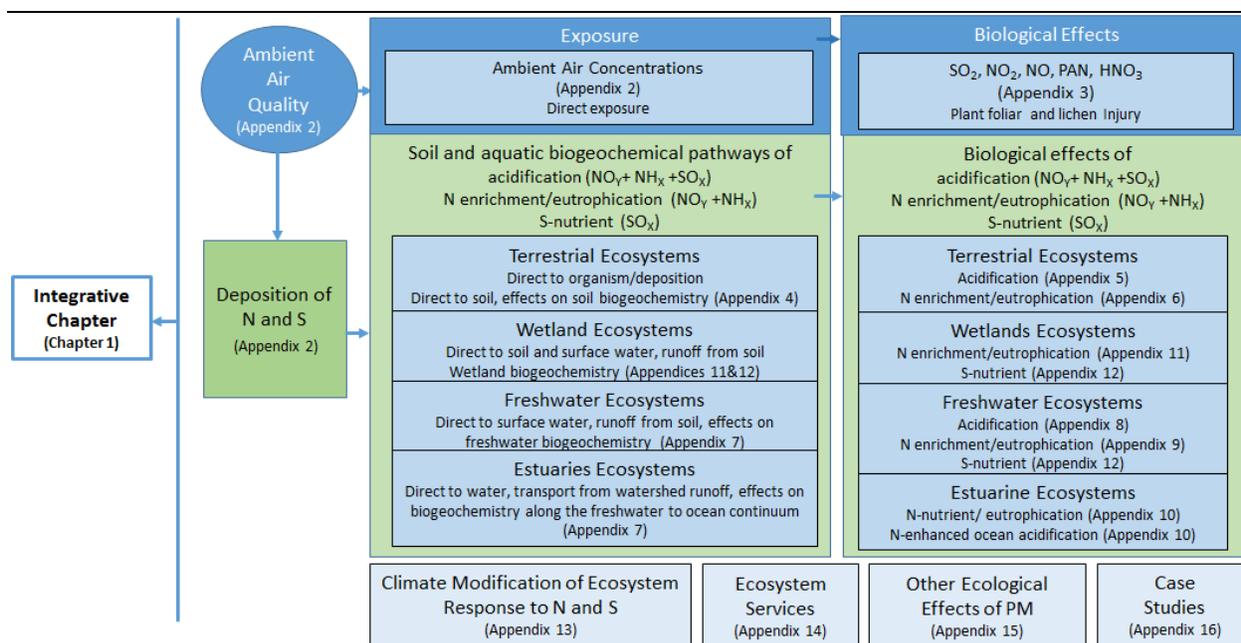

4 The current secondary NAAQS for oxides of nitrogen and oxides of sulfur were set to
5 protect against direct damage to vegetation by NO₂ or SO₂. The secondary NAAQS for
6 NO₂ is identical to the primary standard set in 1971: an annual average not to exceed
7 0.053 ppm nitrogen dioxide. The secondary NAAQS for SO₂, set in 1973, is a 3-hour
8 average of 0.5 ppm SO₂, not to be exceeded more than once per year. The current
9 secondary standards for PM are intended to address PM-related visibility and
10 nonvisibility welfare effects. These standards are a 3-year annual mean PM_{2.5}
11 concentration of 15 µg/m³, with the 24-hour average PM_{2.5} and PM₁₀ set at concentrations
12 of 35 µg/m³ and 150 µg/m³, respectively.

13 This ISA updates the 2008 *ISA for Oxides of Nitrogen and Oxides of Sulfur—Ecological*
14 *Criteria* [hereafter referred to as 2008 ISA ([U.S. EPA, 2008a](#))], as well as the ecological
15 portion of the 2009 *ISA for Particulate Matter* ([U.S. EPA, 2009a](#)) with studies and
16 reports published from January 2008 through May 2017. Some studies published more
17 recently than May 2017 are also included based on expert judgement. The U.S. EPA
18 conducted in-depth searches to identify peer-reviewed literature on relevant topics.
19 Subject-area experts and the public were also able to recommend studies and reports
20 during a kick-off workshop held at the U.S. EPA in March 2014 for oxides of nitrogen
21 and oxides of sulfur, and June 2016 for PM. The Clean Air Scientific Advisory
22 Committee (CASAC) recommended literature during the review of the first draft. To
23 fully describe the state of available science, the U.S. EPA also carried over the most
24 relevant studies from previous assessments to include in this ISA.

25 This ISA determines whether NO_y, SO_x, and PM concentrations in the air or depositing
26 from the air cause ecological effects. The ecological effects of deposition are grouped
27 into three main categories: (1) acidification (caused by NO_y, SO_x, and particulate forms
28 of N and S), (2) N enrichment/N driven eutrophication (caused by NO_y and particulate
29 forms of N), and (3) S enrichment (caused by SO_x and particulate forms of S). Ecological
30 effects are further subdivided into terrestrial, wetland, freshwater, and
31 estuarine/near-coastal ecosystems. These ecosystems and effects are linked by the
32 connectivity of terrestrial and aquatic habitats through biogeochemical pathways of N
33 and S.

34 A schematic of the document organization is given by [Figure ES-1](#). [Chapter 1](#) is the
35 integrative chapter that brings together key information on specific subject matter found
36 in the Appendices. [Appendix 1](#) is an introduction to the purpose and organization of
37 [Appendix 2–Appendix 16](#). [Appendix 2](#) characterizes the sources and atmospheric

1 processes involving NO_y, SO_x, and PM, as well as trends in ambient concentrations and
2 deposition. [Appendix 3](#) describes direct effects of gas-phase NO_y and SO_x on plants and
3 lichens. [Appendix 4](#) describes N and S deposition effects on terrestrial biogeochemistry,
4 and [Appendix 5](#) and [Appendix 6](#) describe the biological effects of terrestrial acidification
5 and terrestrial N enrichment, respectively. [Appendix 7](#) describes N and S deposition
6 effects on aquatic biogeochemistry. [Appendix 8](#) through [Appendix 10](#) respectively
7 characterize the biological effects of freshwater acidification, freshwater N enrichment,
8 and marine eutrophication. [Appendix 11](#) describes the effects of N deposition on
9 wetlands. [Appendix 12](#) describes the wetland and freshwater effects of S enrichment.
10 [Appendix 13](#) discusses the climate modification of ecosystem response to N and S
11 deposition, and [Appendix 14](#) presents information on N and S deposition effects on
12 ecosystem services. Information on the ecological effects of forms of PM beyond those
13 related to N or S deposition, is presented in [Appendix 15](#) [the nonecological welfare
14 effects associated with PM, such as visibility, climate, and material effects, are
15 considered as part of a separate review of PM (81 FR 87933, December 6, 2016)].
16 [Appendix 16](#) includes six locations in the U.S. selected as case study areas that are
17 candidates for additional analysis of risk and exposure. These candidate sites were
18 selected because they have abundant data on ecological effects.

HNO₃ = nitric acid; N = nitrogen; NH_x = reduced nitrogen; NO = nitric oxide; NO₂ = nitrogen dioxide; NO_x = NO + NO₂; PAN = peroxyacetyl nitrate; PM = particulate matter; S = sulfur; SO₂ = sulfur dioxide; SO_x = sulfur oxides.

Figure ES-1 Roadmap of the Integrated Science Assessment linking atmospheric concentrations and deposition, soil and aquatic biogeochemistry, and biological effects.

Emissions, Ambient Air Concentrations, and Deposition

1 The atmospheric chemistry from emission to deposition discussed in this ISA¹ is for the
 2 criteria pollutants NO_y, SO_x, and PM. NO_y and SO_x cause ecological effects in the gas
 3 phase and/or by N and S deposition to an ecosystem surface. Particulate matter (PM)
 4 effects discussed in this document are also mainly focused on N and S containing species,
 5 which together usually make up most of the PM_{2.5} mass in most areas of the U.S. NH_x
 6 (NH_x = NH₃ + NH₄⁺) includes both NH₃ and the PM component NH₄⁺. NH₃ is estimated
 7 to account for 19–63% of total observed inorganic N deposition; therefore, the
 8 contribution of NO_y, PM component NH₄⁺, and NH₃ to N deposition is discussed in this
 9 ISA.

10 Both gaseous and particulate forms of NO_y, SO_x, and NH_x contribute to atmospheric
 11 deposition. The major components of PM in the U.S. are NO₃⁻, SO₄²⁻, NH₄⁺, organic

¹ The term concentration is used throughout the ISA to denote either a mass per unit volume or a mixing ratio. The use of concentration to denote abundance expressed as mixing ratio is firmly entrenched in the literature; therefore, it is retained here, despite being technically incorrect.

1 carbon, and elemental carbon. Of these, NO_3^- , SO_4^{2-} , and NH_4^+ usually have a strong
2 influence on acid deposition, and NO_3^- and NH_4^+ , and in some cases organic N (organic
3 nitrates and reduced organic N), make a substantial contribution to N deposition.

4 The sources and precursors to gaseous and particulate forms of NO_y , SO_x , and NH_x vary.
5 The main contributors to acidifying precipitation are formed from precursor emissions of
6 the gases SO_2 and NO_x ($\text{NO} + \text{NO}_2$) ([Appendix 2.2](#)). Electricity generating units (EGUs)
7 are the source of most gaseous emissions of SO_2 . Notably, SO_2 emissions from EGUs
8 have been decreasing. NO_x emissions have a wider distribution of sources, with
9 substantial contributions from highway and off-highway vehicles, lightning, and EGUs.
10 Agriculture (fertilizer application and animal waste) is the main source of NH_3 . Primary
11 $\text{PM}_{2.5}$ and PM_{10} emissions are dominated by dust and fires, but much of the $\text{PM}_{2.5}$ mass in
12 the U.S. is produced by reaction of gas-phase precursors to form secondary $\text{PM}_{2.5}$, and the
13 majority of the mass is often due to N and S species produced by secondary $\text{PM}_{2.5}$
14 formation. The particulates NH_4^+ , NO_3^- , and SO_4^{2-} are primarily derived from the
15 gaseous precursors NH_3 , NO_x , and SO_2 ([Appendix 2.3](#)). In the Eastern U.S., NO_3^- and
16 SO_4^{2-} make up an even greater portion of $\text{PM}_{2.5}$ mass in areas where $\text{PM}_{2.5}$ mass is the
17 highest. Formation of particulate N and S is described in the 2009 *ISA for Particulate*
18 *Matter* ([U.S. EPA, 2009a](#)). An understanding of the sources, chemistry, and atmospheric
19 processes for these gas-phase and PM species is necessary to understand acidifying and N
20 deposition.

21 Since the passage of the Clean Air Act Amendments in 1990, emissions of NO_x
22 ($\text{NO} + \text{NO}_2$) and SO_2 have declined dramatically. Total emissions of SO_2 decreased by
23 72% from 1990 to 2011. Emissions of NO_x in the U.S. from highway vehicles and fuel
24 combustion declined 49% between 1990 and 2013, while nationwide annual average NO_2
25 concentrations decreased by 48% from 1990 to 2012 ([U.S. EPA, 2016f](#)). This has in turn
26 led to decreases in $\text{PM}_{2.5}$ concentrations because of a decline in SO_4^{2-} formed in the
27 atmosphere.

28 Averaged across the U.S., deposition of total N (oxidized + reduced N, in kg N/ha/yr) has
29 not changed over the past 25 years ([Appendix 2.7](#)). Although NO_x emissions have
30 declined in the continental U.S. (CONUS), emissions of NH_3 have increased in many
31 areas. There is large spatial variability in N deposition over the CONUS ([Chapter 1,](#)
32 [Figure 1-5](#)). According to National Atmospheric Deposition Program Total Deposition
33 Committee (TDEP) estimates for 2011–2013 ([Appendix 2.7](#)), at least one-third of the
34 CONUS is estimated to receive at least 10 kg N/ha/yr dry + wet deposition, with some
35 areas receiving more than 15 kg N/ha/yr. Estimates are likely too low for areas receiving
36 at least 10 kg N/ha/yr of deposition and for the overall amount of N deposited because

1 reduced organic N species are not routinely monitored or considered in air quality models
2 such as the Community Multiscale Air Quality Modeling System (CMAQ).

3 For S, wet deposition tends to dominate over dry deposition in large areas of the CONUS.
4 Dry deposition of particulate SO_4^{2-} is only a minor source of S, but there is considerably
5 more uncertainty associated with dry deposition to ecosystems than wet deposition.
6 Anthropogenic emissions of S and subsequent deposition have declined markedly since
7 the 1990s, with the most pronounced declines in the eastern U.S. Currently, the highest
8 values of total (wet + dry) SO_x deposition in the U.S. are in parts of the Ohio Valley
9 region, and range between 15 and 20 kg S/ha/yr.

10 Both N and S deposition contribute to acidification of ecosystems. The acidity of
11 rainwater has decreased, as indicated by the increase of rainwater pH across the U.S.
12 since 1990, coincident with decreases in the wet deposition of nitrate and sulfate.
13 However, widespread areas are still affected by acidifying precipitation, mainly in the
14 eastern U.S. (see [Appendix 2.7](#)). Total acidifying deposition (wet + dry N + S, expressed
15 as H^+ equivalents) fluxes for 2011 to 2013 ranged from a few hundred H^+
16 equivalents/ha/yr over much of the western U.S. to over 1,500 H^+ equivalents/ha/yr in a
17 broad swath encompassing the Midwest and the Mid-Atlantic regions, and in other
18 isolated hotspots surrounding areas of concentrated industrial or agricultural activity
19 ([Chapter 1, Figure 1-6](#)).

Ecological Effects

20 In this ISA, information on ecological effects from controlled exposure, field addition,
21 ambient deposition, and toxicological studies, among others, are integrated to form
22 conclusions about the causal nature of relationships between NO_y , SO_x , and PM and
23 ecological effects. Studies on the ecological effects are considered in relation to a range
24 of ambient concentration and deposition loads that are within two orders of magnitude of
25 current conditions [Preamble ([U.S. EPA, 2015e](#)), Section 5c]. A consistent and
26 transparent framework [Preamble ([U.S. EPA, 2015e](#)), Table II] is applied to classify the
27 ecological effect evidence according to a five-level hierarchy:

- 28 1. Causal relationship
- 29 2. Likely to be a causal relationship
- 30 3. Suggestive of, but not sufficient to infer, a causal relationship
- 31 4. Inadequate to infer a causal relationship
- 32 5. Not likely to be a causal relationship

33 The conclusions presented in [Table ES-1](#) are informed by recent findings integrated with
34 information from the 2008 ISA ([U.S. EPA, 2008a](#)). Important considerations include

1 judgments of error and uncertainty, as well as the coherence of findings integrated across
 2 studies of underlying geochemical and biological mechanisms. There are 20 causality
 3 statements in this ISA ([Table ES-1](#)). Fourteen are causal relationships repeated from the
 4 2008 ISA or modified from the 2008 ISA to include specific endpoints. For these
 5 causality statements, new research strengthens the evidence base and is consistent with
 6 the 2008 ISA. There is one likely causal relationship repeated from the 2009 ISA for
 7 Particulate Matter. Five are new endpoint categories not evaluated in the 2008 ISA: three
 8 with causal relationships, one with a likely causal relationship, and one suggestive of a
 9 causal relationship.

Table ES-1 Causal determinations for relationships between criteria pollutants and ecological effects from the 2008 NO_x/SO_x ISA or the 2009 ISA for particulate matter (PM), for other effects of PM, and the current draft Integrated Science Assessment.

C = carbon; Hg = mercury; HNO₃ = nitric acid; ISA = Integrated Science Assessment; N = nitrogen; NO = nitric oxide; NO₂ = nitrogen dioxide; PAN = peroxyacetyl nitrate; S = sulfur; SO₂ = sulfur dioxide.

^aThe 2008 ISA causality statements for gas-phase HNO₃ was phrased as, “changes in vegetation.”

^bThe 2008 ISA included two causality statements for terrestrial biogeochemistry which were phrased as, “relationship between acidifying deposition and changes in biogeochemistry” and “relationship between N deposition and the alteration of biogeochemical cycling of N.”

^cThe 2008 ISA causality statement for biological effects of N enrichment in terrestrial ecosystems was phrased as, “relationship between N deposition and the alteration of species richness, species composition, and biodiversity.”

^dThe 2008 ISA causality statement for biological effects of acidifying deposition in terrestrial ecosystems was phrased as, “relationship between acidifying deposition and changes in terrestrial biota.”

^eThe 2008 ISA included three causality statements for freshwater biogeochemistry phrased as, “relationship between acidifying deposition and changes in biogeochemistry related to aquatic ecosystems,” “relationship between N deposition and the alteration of biogeochemical cycling of N,” and “relationship between N deposition and the alteration of biogeochemical cycling of C.”

^fThe 2008 ISA causality statement for biological effects of acidifying deposition in freshwater ecosystems was phrased as, “relationship between acidifying deposition and changes in aquatic biota.”

^gThe 2008 ISA causality statement for biological effects of N deposition in freshwater ecosystems was phrased as, “relationship between N deposition and the alteration of species richness, species composition, and biodiversity in freshwater aquatic ecosystems.”

^hThe 2008 ISA causality statement for biological effects of N deposition to estuaries was phrased as, “relationship between N deposition and the alteration of species richness, species composition, and biodiversity in estuarine ecosystems.”

ⁱThe 2008 ISA causality statement for biological effects of S deposition effects on ecosystems was phrased as, “relationship between S deposition and increased methylation of Hg, in aquatic environments where the value of other factors is within adequate range for methylation.”

1
2 [Figure ES-2](#) presents a visualization of the causality statements integrated to a single
3 diagram. There is not a one-to-one correspondence between the number of causality
4 statements, of which there are 20, and the cells indicated to have causal relationships in
5 the diagram because some causal statements include effects across more than one level of
6 biological organization. The main findings are that gaseous NO_x and SO_x cause
7 phytotoxic effects, while N and S deposition cause alteration of (1) biogeochemical
8 components of soil and water chemistry and (2) multiple levels of biological organization
9 ranging from physiological processes to shifts in biodiversity and ecological function.

† Includes: NO, NO₂, HNO₃, SO₂, and PAN

Figure ES-2 Causal relationships between the criteria pollutants and ecological effects.

Direct Phytotoxic Effects of Gas-Phase Oxides of Nitrogen (NO_Y) and Oxides of Sulfur (SO_X)

1 The current NO₂ and SO₂ secondary NAAQS are set to protect against direct damage to
2 vegetation by exposure to gas-phase oxides of nitrogen and oxides of sulfur. Research
3 continues to support causal relationships between SO₂, NO₂, NO, peroxyacetyl nitrate
4 (PAN), HNO₃, and injury to vegetation ([Chapter 1, Table 1-1, Section 1.4; Appendix 3](#)),
5 but research that tests plant response to the lower exposure levels representative of
6 current atmospheric NO_Y and SO_X concentrations is limited. Therefore, little evidence is
7 available to inform whether current monitored concentrations of gas-phase NO_Y and SO_X
8 are high enough to injure vegetation.

Ecological Effects of Nitrogen and Sulfur Deposition

9 It is clear from the body of knowledge that NO_Y, SO_X, and PM contribute to total N and S
10 deposition. In turn, N and S deposition alter ecosystem biogeochemistry as well as
11 organismal physiology, resulting in harmful declines in biodiversity in terrestrial,
12 freshwater, wetland, and estuarine ecosystems in the U.S. Decreases in biodiversity mean
13 that some species become relatively less abundant and may be locally extirpated. In
14 addition to the loss of unique living species, the decline in total biodiversity can be
15 harmful because biodiversity is an important determinant of the stability of ecosystems
16 and the ability of ecosystems to provide services to humanity (see more on biodiversity in
17 [Chapter 1, Section 1.2.2.4](#)).

Acidification of Terrestrial and Freshwater Ecosystems

18
19 Several decades of research have documented that N and S deposition cause freshwater
20 and terrestrial ecosystem acidification in the U.S. New evidence strengthens the causal
21 relationships for ecosystem acidification determined in the 2008 ISA ([Chapter 1,](#)
22 [Table 1-1](#)).

23 Many of the terrestrial and freshwater ecosystems most sensitive to acidification in the
24 U.S. are found in the Northeast and the Southeast. In the West, freshwater and terrestrial
25 ecosystems acidified from deposition are currently limited in extent and occur mostly in
26 high-elevation sites. Watershed sensitivity to acid inputs depends on characteristics such
27 as underlying geology ([Appendix 4](#) and [Appendix 7](#)) and the sensitivity of species in the
28 local biological community ([Appendix 5](#) and [Appendix 8](#)). Regional heterogeneity of
29 deposition levels that cause ecological effects are in part due to historic exposure and
30 climate. The effects of acidifying deposition have been studied for several decades in the

1 Northeast and the southern Appalachian Mountains. Although S deposition is decreasing,
2 recent studies suggest biological recovery of previously acidified ecosystems is limited
3 ([Chapter 1, Section 1.12](#)).

4 Acidified aquatic habitats have lower species richness of fishes, macroinvertebrates, and
5 phytoplankton. The effects of acidifying deposition on aquatic ecosystems also include
6 physiological impairment or mortality of sensitive species and shifts in biodiversity of
7 both flora and fauna. Organisms at all trophic levels are affected by acidification, with
8 clear linkages to chemical indicators for effects on algae, zooplankton, benthic
9 invertebrates, and fish. Acid-neutralizing capacity (ANC) is a measure of the buffering
10 capacity of natural waters against acidification. Even though ANC does not directly alter
11 the health of biota, it is a key metric of acidification that relates to pH and aluminum.
12 Biological effects are primarily attributable to low pH and high inorganic aluminum
13 concentration. Characterization of ANC and its levels of concern have not changed
14 appreciably with the newly available information since the 2008 ISA. Few or no fish
15 species are found in lakes and streams that have very low ANC (near zero) and low pH
16 (near 5.0), and the number of fish species generally increases with higher ANC and pH
17 ([Appendix 8.3](#)). The fish lost to acidification include culturally and recreationally
18 important species.

19 Acidified terrestrial habitats are characterized by detrimental physiological effects to
20 vegetation, including inhibited growth and decreased plant health. Acidifying deposition
21 can decrease membrane stability and freezing tolerance in young red spruce needles. For
22 many species, calcium depletion from the soil and aluminum mobilization cause
23 decreased root uptake of calcium and disrupt fine root physiological functions. Reduced
24 availability of cations in the soil can also make trees more vulnerable to other stresses,
25 such as damage from insects and other pathogens. Within the eastern U.S., the
26 physiological effects of acidifying deposition have been well documented for several
27 culturally important tree species with known ecosystem services, particularly sugar maple
28 (*Acer saccharum*) and red spruce (*Picea rubens*). Evidence available before and since the
29 2008 ISA shows that there is consistent and coherent evidence among these species that
30 acidifying deposition can decrease foliar cold tolerance, increase rates of crown dieback,
31 decrease tree growth, suppress seedling regeneration, and increase mortality rates
32 ([Chapter 1, Section 1.5.3](#); [Appendix 5](#)). Since the 2008 ISA, studies from the northeastern
33 U.S. have shown that calcium addition can alleviate many of these effects, demonstrating
34 that acidification effects can be ameliorated in the short-term by soil amendments and
35 adding to the evidence that there is potential for recovery. Acidifying deposition has also
36 been linked to changes in forest understory plant community composition in the
37 northeastern U.S., grass and forb biodiversity in eight ecoregions across the U.S., and
38 decreased grassland plant species richness in Europe.

1 **Nitrogen (N) Enrichment/Eutrophication of Terrestrial, Wetland, and Aquatic**
2 **Ecosystems**

3 Terrestrial, wetland, freshwater, and estuarine ecosystems in the U.S. are affected by N
4 enrichment/eutrophication caused by N deposition. N enrichment/eutrophication refers to
5 N nutrient-driven changes in growth, physiology, and biodiversity. These effects have
6 been consistently documented across the U.S. for hundreds of species. New evidence
7 strengthens the causal relationships for ecosystem N enrichment/eutrophication
8 determined in the 2008 ISA ([Chapter 1, Table 1-1](#)), and several new causal relationships
9 have been identified.

10 The 2008 ISA documented that in sensitive terrestrial and wetland ecosystems, the N
11 enrichment effect starts with the accumulation of N in the soil. This increases the
12 availability of N, a nutrient that increases the growth of some species of soil microbes
13 and vascular plants at the expense of other species, which may decrease biodiversity.
14 Since the 2008 ISA, the largest increase in ecological evidence is for terrestrial N driven
15 enrichment/eutrophication effects ([Chapter 1, Section 1.5.1](#), [Section 1.5.2](#); [Appendix 4](#),
16 and [Appendix 6](#)). This new research confirms the causal relationship between N
17 deposition and ecological effects documented in the 2008 ISA and improves our
18 understanding of the mechanistic links that inform causal determinations between N
19 deposition, biogeochemistry, and biota in terrestrial ecosystems ([Chapter 1, Table 1-1](#)). A
20 new causal determination has been added to reflect more specific categories of effects to
21 include physiology, growth, and ecosystem productivity. Further, there is now stronger
22 empirical evidence from across most regions of the U.S. to quantify the levels of N
23 deposition (empirical critical loads [CLs]) that cause a myriad of ecological effects,
24 including: shifts in community composition and biodiversity declines in lichens and
25 grasses/forbs; tree growth and mortality; and increased nitrate leaching ([Chapter 1](#),
26 [Figure 1-7](#)).

27 Since the 2008 ISA, studies have strengthened the findings of N effects on decreasing
28 lichen and mycorrhizal fungi biodiversity and provided additional CL estimates. In
29 terrestrial ecosystems, new evidence supports that epiphytic lichens (an algal and or
30 cyanobacteria-fungal symbiont) and mycorrhizae (a plant-fungal symbiosis at the tips of
31 plant roots) are the organisms that are most sensitive to atmospheric N deposition and
32 acidifying deposition. Although lichens typically are only a small portion of terrestrial
33 biomass, these changes in lichen communities are meaningful because lichens provide
34 food and habitat for insects, birds, and mammals; contribute to nutrient and hydrologic
35 cycling; have many traditional human uses; and have considerable potential for
36 pharmaceutical use. Changes in the community composition of mycorrhizal fungi and
37 declines in mycorrhizal abundance have been observed in the U.S. These fungi are

1 important for supplying nutrients and water to plants, influencing soil C sequestration,
2 and producing fruiting bodies (mushrooms) used by humans and wildlife.

3 The effects of N deposition on tree growth are well documented. There is now evidence
4 of widespread species-specific effects of N deposition on tree growth and mortality in the
5 U.S. While tree growth has generally been enhanced by N deposition over the last several
6 decades, there is wide variation among species in mortality and growth in response to N
7 deposition. This information, however, has not been used yet to quantitatively assess
8 changes in tree community composition.

9 In wetlands, the 2008 ISA documented that wetlands receiving a larger fraction of their
10 total water budget in the form of precipitation are more sensitive to the effects of N
11 deposition. For example, bogs and fens (55–100% of hydrological input from rainfall) are
12 more sensitive to N deposition than coastal wetlands (10–20% as rainfall). Since the 2008
13 ISA, CLs for U.S. coastal and freshwater wetlands have been established. The CL for
14 freshwater wetlands is based on C cycling, as well as biodiversity represented by the
15 morphology and population dynamics of the purple pitcher plant (*Sarracenia purpurea*).
16 The CL for coastal wetlands is based on several different ecological endpoints, including
17 plant community composition, microbial activity, and biogeochemistry.

18 The 2008 ISA documented that the process of N eutrophication is similar in freshwater
19 and estuarine ecosystems and typically begins with a nutrient-stimulated algal bloom that
20 is followed by anoxic conditions. The lack of oxygen in the water due to the respiration
21 and decomposition of the algae affects higher trophic species. The contribution of N
22 deposition to total N loading varies among freshwater lakes and stream ecosystems.
23 Atmospheric deposition is the main source of new N to most headwater streams,
24 high-elevation lakes, and low-order streams far from the influence of other N sources like
25 agricultural runoff and wastewater effluent. N deposition was known at the time of the
26 2008 ISA to alter biogeochemical processes and nutrient ratios in recipient freshwater
27 ecosystems. New CLs support previous observations of increased productivity of
28 phytoplankton and algae, species changes, and reductions in diversity in atmospherically
29 N enriched lakes and streams. The productivity of many freshwater ecosystems is N
30 limited. Thus, even small amounts of N can shift nutrient ratios and affect the trophic
31 status of lakes and streams. As reported in the 2008 ISA and newer studies, a shift from
32 N limitation to either colimitation by N and P or limitation by P has been observed in
33 some alpine lakes in the U.S. and other countries, with these shifts correlated with
34 elevated N deposition.

35 At the time of the 2008 ISA, N was recognized as the major cause of harm to the majority
36 of estuaries in the U.S. Since 2008, new paleontological studies, observational studies,
37 and experiments have further characterized the effects of N on phytoplankton growth and

1 community dynamics, macroinvertebrate response, and other indices of biodiversity. For
2 this ISA, new information is consistent with the 2008 ISA, and the causal determination
3 has been updated to reflect more specific categories of effects to include total primary
4 production, altered growth, and total algal community biomass.

5 Since the 2008 ISA, studies have shown that coastal acidification can be exacerbated by
6 elevated N input. With increasing N inputs to coastal waters, CO₂ in the water column is
7 produced from the degradation of excess organic matter, as well as respiration of living
8 algae and seagrasses, which in turn can make the water more acidic. Coastal acidification
9 is projected to alter marine habitat, have a wide range of effects at the population and
10 community level, and impact food web processes. Newer studies show that organisms
11 that produce calcium carbonate shells are impacted by increasing acidification of ocean
12 waters. Decreased concentration of carbonate ions (which organisms such as calcareous
13 plankton, oysters, clams, sea urchins, and corals absorb to build shells) are observed in
14 acidic conditions. Changes in the carbonate system, including decreased pH, have been
15 shown to elicit biological responses in commercially important species from the New
16 England coast, and documented declines of oyster production on the U.S. West Coast are
17 linked to ocean acidification. Research on stressors associated with conditions of coastal
18 acidification and eutrophication suggests that interactions between elevated CO₂,
19 decreasing pH, and nutrient inputs are complex.

20 **Sulfur (S) Enrichment on Wetland and Freshwater Ecosystems**

21 SO_x deposition increases SO₄²⁻ concentration in surface waters. New evidence supports
22 links between aqueous sulfur concentrations in freshwater ecosystems and both mercury
23 methylation and sulfide toxicity ([Table ES-1](#)); however, quantitatively linking these
24 outcomes to atmospheric deposition remains a challenge.

25 Increasing SO₄²⁻ concentration in surface waters can stimulate the microbial
26 transformation of inorganic Hg into methylmercury (MeHg; [Appendix 12](#)). MeHg is the
27 most persistent and toxic form of Hg affecting animals in the natural environment.
28 Indicators of S deposition effects upon Hg methylation include increases in MeHg
29 concentrations or fraction of total Hg in water, sediments, and peat, as well as increases
30 in MeHg concentrations in periphyton, submerged aquatic plants, invertebrates, and fish.
31 New evidence confirms the relationship between aqueous concentrations of SO₄²⁻ and
32 MeHg, and broadens our understanding of where methylation occurs from the wetlands
33 and lakes reported in the 2008 ISA to include rivers, reservoirs, streams, and saturated
34 forest soils. Hg methylation occurs at anoxic-oxic boundaries in peat moss and
35 periphyton, as well as in wetland, lake, estuarine, and marine sediments. There are
36 published quantitative relationships between surface water SO₄²⁻ concentrations and
37 MeHg concentrations, MeHg and total Hg in water, and Hg load in larval mosquitoes and

1 fish. There is also evidence that decreasing sulfur deposition loads over time
2 (observational studies of SO_x deposition, experimental studies of simulated SO_x wet
3 deposition) result in lower concentrations of MeHg in water, invertebrates, and fish.

4 There is new evidence since the 2008 ISA to infer a causal relationship between S
5 deposition and sulfide phytotoxicity, which alters growth and productivity, species
6 physiology, species richness, community composition, and biodiversity in wetland and
7 freshwater ecosystems ([Appendix 12](#)). This new causal statement reflects new research
8 on sulfide phytotoxicity in North American wetlands, as the 2008 ISA described sulfide
9 phytotoxicity only in European ecosystems. Current levels of S deposition cause sulfide
10 toxicity in wetland and aquatic plants. Indicators of sulfide phytotoxicity caused by S
11 deposition include increases in water or sediment sulfide concentrations. Sulfide
12 negatively effects growth, competition, and persistence in several wetland species,
13 including the economically important species wild rice, and the keystone sawgrass
14 species in the Everglades marshes. To date, no published studies have established
15 regional sensitivities to sulfide phytotoxicity, although studies have observed its effects in
16 New York, Minnesota, and Florida freshwater marshes. There are no S deposition-based
17 critical loads for mercury methylation or sulfide phytotoxicity, although researchers have
18 proposed water quality values to protect biota against these effects in several ecosystems
19 ([Appendix 12](#)).

20 **Ecological Effects of Particulate Matter (PM) Other Than Those Associated with** 21 **Nitrogen (N) and Sulfur (S) Deposition**

22 There is a likely causal relationship between PM and ecological effects on biota, other
23 than those associated with N and S deposition ([Table ES-1](#); [Appendix 15](#)). Since
24 publication of the 2009 PM ISA, new literature has built upon the existing knowledge of
25 ecological effects associated with PM components, especially metals and organics. In
26 some instances, new techniques have enabled further characterization of the mechanisms
27 of PM on soil processes, vegetation, and effects on fauna. New studies provide additional
28 evidence for community-level responses to PM deposition, especially in soil microbial
29 communities. However, uncertainties remain due to the difficulty in quantifying
30 relationships between ambient concentrations of PM and ecosystem response.

31 **Ecosystem Services**

32 The ecosystem services literature has expanded since the 2008 ISA to include studies that
33 better characterize ecosystem service valuation and quantification related to acidification
34 and N enrichment/eutrophication.

35 New valuation studies for ecosystem acidification pair biogeochemical modeling and
36 benefit transfer equations informed by willingness-to-pay surveys, especially for the

1 Adirondacks and Shenandoah regions ([Appendix 14](#)). Despite this progress, for many
2 regions and specific services, poorly quantified relationships between deposition,
3 ecological effect, and services are the greatest challenge in developing specific data on
4 the economic benefits of emission reductions.

5 In the 2008 ISA, there were no publications that had specifically evaluated the effects of
6 N deposition on ecosystem services associated with N driven enrichment/eutrophication.
7 Since the 2008 ISA, several comprehensive studies have been published on the
8 ecosystems services related to N pollution in the U.S. These include an evaluation of
9 services affected by multiple N inputs (including N deposition) to the Chesapeake Bay, a
10 synthesis of the cost-benefits on N loading across the nation, and an analysis of how N
11 leaked from its intended area of application (e.g., agricultural fields) affects ecosystem
12 services of adjacent ecosystems. Most notably, new work identifies 1,104 unique chains
13 linking N deposition to human beneficiaries.

14 Considering the full body of literature on ecosystem services related to N and S, the
15 following conclusions are offered: (1) there is evidence that N and S emissions/deposition
16 have a range of effects on U.S. ecosystem services and their social value; (2) some
17 economic studies demonstrate such effects in broad terms, but it remains
18 methodologically difficult to derive economic costs and benefits associated with specific
19 regulatory decisions/standards; and (3) over a thousand relationships are now
20 documented between N and S air pollution and changes in final ecosystem goods and
21 services.

22 **Integrating across Ecosystems**

23 Overall, new evidence since the 2008 ISA increases the weight of evidence for ecological
24 effects, confirming concepts previously identified and improving quantification of
25 dose-response (or deposition-ecological indicator) relationships, particularly for N and S
26 deposition. The ecological effects are described by the causality determinations
27 ([Figure ES-3](#)). [Figure ES-3](#) reorganizes the information in [Figure ES-2](#) to offer a
28 visualization of the effects of NO_y, SO_x, and PM by ecosystem type (e.g., terrestrial,
29 wetland, freshwater, and estuarine). The gas-phase effects were not included in this
30 diagram. With this organization, the multiple effects occurring in each ecosystem due to
31 various pollution combinations of NO_y, SO_x, and PM are emphasized. Between two and
32 four different classes of pollutant effect may occur in each ecosystem type in the U.S. For
33 more information on key messages see the expanded discussion in [Chapter 1](#); detailed
34 information on specific ecosystem types and specific classes of pollutant effects included
35 in the ISA may be found in the Appendices.

CHAPTER 1 INTEGRATED SYNTHESIS

1.1 Introduction to This Integrated Science Assessment (ISA)

1.1.1 Purpose

1 The Integrated Science Assessment (ISA) is a comprehensive evaluation and synthesis of
2 the policy-relevant science. Policy-relevant science is that which is “useful in indicating
3 the kind and extent of all identifiable effects on public health or welfare which may be
4 expected from the presence of [a] pollutant in the ambient air,” as described in
5 Section 108 of the Clean Air Act ([CAA, 1990a](#)).¹ This ISA communicates critical science
6 judgments of the ecological criteria for oxides of nitrogen, oxides of sulfur, and
7 particulate matter. Accordingly, this ISA is the scientific foundation for the review of the
8 ecological effects of the current secondary (welfare-based) National Ambient Air Quality
9 Standards (NAAQS) for oxides of nitrogen, oxides of sulfur, and particulate matter. The
10 Clean Air Act definition of welfare effects includes, but is not limited to, effects on soils,
11 water, wildlife, vegetation, visibility, weather, and climate, as well as effects on
12 man-made materials, economic values, and personal comfort and well-being. The
13 nonecological welfare effects associated with particulate matter, such as climate and
14 visibility, are considered part of a separate, ongoing review of PM that is outlined in the
15 *Integrated Review Plan for the National Ambient Air Quality Standards for Particulate*
16 *Matter (IRP)* ([U.S. EPA, 2016d](#)). The human health effects for oxides of nitrogen, oxides
17 of sulfur, and particulate matter are evaluated in separate assessments conducted as part
18 of the review of the primary (human health-based) NAAQS for oxides of nitrogen ([U.S.](#)
19 [EPA, 2016f](#)), oxides of sulfur ([U.S. EPA, 2016e](#)), and as noted above, in the ongoing
20 review for particulate matter ([U.S. EPA, 2016d](#)).

21 Oxides of nitrogen, oxides of sulfur, and particulate matter (PM) are reviewed here
22 together because they are inter-related through complex chemical and physical
23 atmospheric processes and because they all contribute to nitrogen (N) and sulfur (S)
24 deposition, which in turn contributes to well-documented ecological effects. In this
25 document, the term “oxides of nitrogen” refers to all forms of oxidized nitrogen (N)
26 compounds, including NO, NO₂, and all other oxidized N containing compounds formed

¹ The general process for developing an ISA, including the framework for evaluating weight of evidence and drawing scientific conclusions and causal judgments, is described in a companion document, *Preamble to the Integrated Science Assessments* ([U.S. EPA, 2015e](#)).

1 from NO and NO₂.¹ Oxides of sulfur² are defined here to include sulfur monoxide (SO),
2 sulfur dioxide (SO₂), sulfur trioxide (SO₃), disulfur monoxide (S₂O), and sulfate (SO₄²⁻).
3 However, SO, SO₃, and S₂O are present at much lower ambient levels than SO₂ and SO₄²⁻
4 and are therefore not discussed further. Particulate matter is composed of some or all of
5 the following components: nitrate (NO₃⁻), SO₄²⁻, ammonium (NH₄⁺), metals, minerals
6 (dust), and organic and elemental carbon (C).

7 This ISA updates the 2008 *Integrated Science Assessment for Oxides of Nitrogen and*
8 *Sulfur—Ecological Criteria* [hereafter referred to as the 2008 ISA ([U.S. EPA, 2008a](#))], as
9 well as the ecological portion of the *Integrated Science Assessment for Particulate Matter*
10 ([U.S. EPA, 2009a](#)), with studies and reports published from January 2008 through May
11 2017. Thus, this ISA updates the state of the science that was available for the 2008 ISA,
12 which informed decisions on the secondary oxides of nitrogen and oxides of sulfur
13 NAAQS in the review completed on March 20, 2012. In the final rulemaking, the
14 Administrator’s decision was that, while the current secondary standards were inadequate
15 to protect against adverse effects from deposition of oxides of nitrogen and oxides of
16 sulfur, it was not appropriate under Section 109(b) to set any new secondary standards at
17 this time due to the limitations in the available data and uncertainty as to the amount of
18 protection the metric (Aquatic Acidification Index—see [Chapter 1.2.2.6](#)) developed in
19 the Policy Assessment ([U.S. EPA, 2011a](#)) would provide against acidification effects
20 across the country (77 FR 20281). In addition, the Administrator decided that it was
21 appropriate to retain the current nitrogen dioxide (NO₂) and sulfur dioxide (SO₂)
22 secondary standards to address direct effects of gaseous NO₂ and SO₂ on vegetation.
23 Thus, taken together, the Administrator decided to retain and not revise the current NO₂
24 and SO₂ secondary standards: an NO₂ standard set at a level of 0.053 ppm, as an annual
25 arithmetic average, and an SO₂ standard set at a level of 0.5 ppm, as a 3-hour average, not
26 to be exceeded more than once per year (77 FR 20281). The current secondary standards
27 for PM are intended to address PM-related related welfare effects, including visibility
28 impairment, ecological effects, effects on materials, and climate impacts. These standards
29 are a 3-year annual mean PM_{2.5} concentration of 15 µg/m³, with the 24-hour average
30 PM_{2.5} and PM₁₀ set at concentrations of 35 µg/m³ and 150 µg/m³, respectively.

¹ This ISA reserves the abbreviation NO_x strictly as the sum of NO and NO₂—consistent with that used in the atmospheric science community—and uses the term “oxides of nitrogen” to refer to the broader list of oxidized nitrogen species. Oxides of nitrogen refers to NO_y as the total oxidized nitrogen in both gaseous and particulate forms. The major gaseous and particulate constituents of NO_y include nitric oxide (NO), nitrogen dioxide (NO₂), nitric acid (HNO₃), peroxyacetyl nitrate (PAN), nitrous acid (HONO), organic nitrates, and particulate nitrate (NO₃). This ISA uses the definitions adopted by the atmospheric sciences community.

² Oxides of sulfur refers to the criteria pollutant category.

1 This new review of the secondary oxides of nitrogen, oxides of sulfur, and particulate
2 matter NAAQS is guided by several policy-relevant questions that were identified in *The*
3 *Integrated Review Plan for the Secondary National Ambient Air Quality Standard for*
4 *Nitrogen Oxides, Sulfur Oxides, and Particulate Matter* [hereafter referred to as the 2017
5 IRP, ([U.S. EPA, 2017b](#))].

6 To address these questions, this ISA aims to characterize the evidence available in the
7 peer-reviewed literature for ecological effects associated with:

- 8 • the major gaseous and particulate constituents of total oxidized N (NO_Y), which
9 include NO, NO₂, HNO₃, PAN, HONO, organic nitrates, and NO₃⁻;
- 10 • the major gaseous and particulate constituents of SO_X, which include SO₂ and
11 SO₄²⁻; and
- 12 • PM.

13 The assessment activities include:

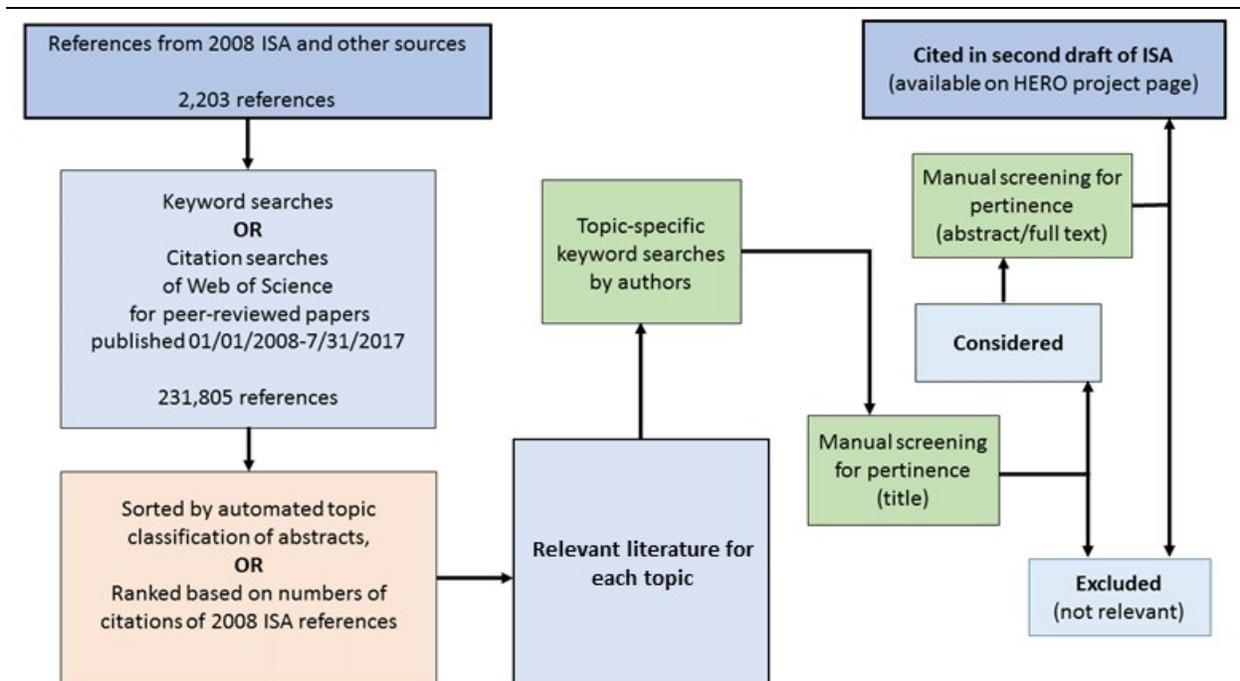

- 14 • Identifying policy-relevant literature.
- 15 • Evaluating strength, limitations, and consistency of findings.
- 16 • Integrating findings across scientific disciplines and across related ecological
17 outcomes.
- 18 • Considering important uncertainties identified in the interpretation of the scientific
19 evidence.
- 20 • Assessing policy-relevant issues related to quantifying ecological risks, such as
21 ambient air concentrations, deposition, durations, and patterns associated with
22 ecological effects; the relationship between ambient air concentrations, deposition,
23 and ecological response and the existence of thresholds below which effects do
24 not occur; and species and populations potentially at increased risk of ecological
25 effects.

26 New analyses with the goal of quantifying risk, such as new model runs, critical loads
27 exceedance maps, and quantified uncertainties regarding modeled scenarios are not
28 conducted in the ISA. These are types of analyses, if pursued, require the selection of
29 chemical or biological limits that define critical loads and represent adversity. These
30 analyses would also require choosing a time period over which to average deposition.
31 Such scope-of-analysis decisions are more appropriate for the Risk and Exposure
32 Assessment, as described in the 2017 IRP ([U.S. EPA, 2017b](#)). The information
33 summarized in this ISA will serve as the scientific foundation of the Risk and Exposure
34 and Policy Assessments during the current review of the secondary oxides of nitrogen,
35 oxides of sulfur, and particulate matter NAAQS.

1.1.2 Process and Development

1 The U.S. EPA uses a structured and transparent process to evaluate scientific information
2 and determine the causality of relationships between air pollution and ecological effects
3 [see Preamble ([U.S. EPA, 2015e](#))]. The ISA development includes approaches for
4 literature searches, criteria for selecting and evaluating relevant studies, and a framework
5 for evaluating the weight of evidence and forming causal determinations. As part of this
6 process, the ISA is reviewed by the public and by the Clean Air Scientific Advisory
7 Committee (CASAC), which is a formal independent panel of scientific experts. This ISA
8 informs the review of the secondary oxides of nitrogen, oxides of sulfur, and particulate
9 matter NAAQS and therefore integrates and synthesizes information characterizing NO_y,
10 SO_x, and PM air concentrations. It also examines deposition of these substances and their
11 ecological effects. Relevant studies include those examining atmospheric chemistry,
12 spatial and temporal trends, and deposition, as well as U.S. EPA analyses of air quality
13 and emissions data. Relevant ecological research includes geochemistry, microbiology,
14 physiology, toxicology, population biology, and community ecology. The research
15 includes laboratory and field additions, as well as gradient studies.

16 The U.S. EPA conducted literature searches to identify relevant peer-reviewed studies
17 published since the previous ISA (i.e., from January 2008 through December 2015;
18 [Chapter 1, Figure 1-1](#)).

HERO = Health and Environmental Research Online; ISA = Integrated Science Assessment.

Figure 1-1 Workflow for collecting relevant literature for the 2017 Integrated Science Assessment for Oxides of Nitrogen, Oxides of Sulfur, and Particulate Matter—Ecological Criteria.

1 Multiple search methods were used in the Web of Science database [Preamble ([U.S.](#)
 2 [EPA, 2015e](#)), [Appendix 2](#)], including searches by keyword and by citations of 2008 ISA
 3 references. Subject-area experts and the public were also permitted to recommend studies
 4 and reports during kick-off workshops held at the U.S. EPA in March 2014 for oxides of
 5 nitrogen and oxides of sulfur and in February 2015 for particulate matter. The new
 6 references were sorted by automated methods into topic areas based on wording in the
 7 publication’s abstract or numbers of citations of 2008 ISA references, and the resultant
 8 relevant literature was reviewed by the ISA authors. Studies were screened based on the
 9 title first and then by the abstract; studies that did not address a relevant research topic
 10 based on this screening were excluded. The U.S. EPA also identified studies from
 11 previous assessments as definitive works on particular topics to include in this ISA. The
 12 HERO project page for this ISA (<http://hero.epa.gov/heronet/NOxSOxPMeco>) contains
 13 the references that are cited in the ISA and electronic links to bibliographic information
 14 and abstracts.

1 *The Preamble to the Integrated Science Assessments* ([U.S. EPA, 2015e](#)) describes the
2 general framework for evaluating scientific information, including criteria for assessing
3 study quality and developing scientific conclusions. For ecological studies, emphasis is
4 placed on studies that characterize quantitative relationships between criteria pollutants
5 and ecological effects that occur at concentration and deposition levels relevant to current
6 ambient levels in the U.S. However, experimental studies with higher exposure
7 concentrations are included if they contribute to an understanding of mechanisms.

8 This ISA draws conclusions about relationships between NO_y, SO_x, and PM and
9 ecological effects by integrating information across scientific disciplines and related
10 ecological outcomes and synthesizing evidence from previous and recent studies.
11 Determinations are made about causation, not just association, and are based on
12 judgments of consistency, coherence, and scientific plausibility of observed effects, as
13 well as related uncertainties. The ISA uses a formal causal framework [Table II of the
14 Preamble ([U.S. EPA, 2015e](#))] which is based largely on the aspects for causality
15 proposed by Sir Bradford Hill to classify the weight of evidence according to the
16 five-level hierarchy summarized below.

- 17 • Causal relationship
- 18 • Likely to be a causal relationship
- 19 • Suggestive of, but not sufficient to infer, a causal relationship
- 20 • Inadequate to infer the presence or absence of a causal relationship
- 21 • Not likely to be a causal relationship

1.1.3 Organization

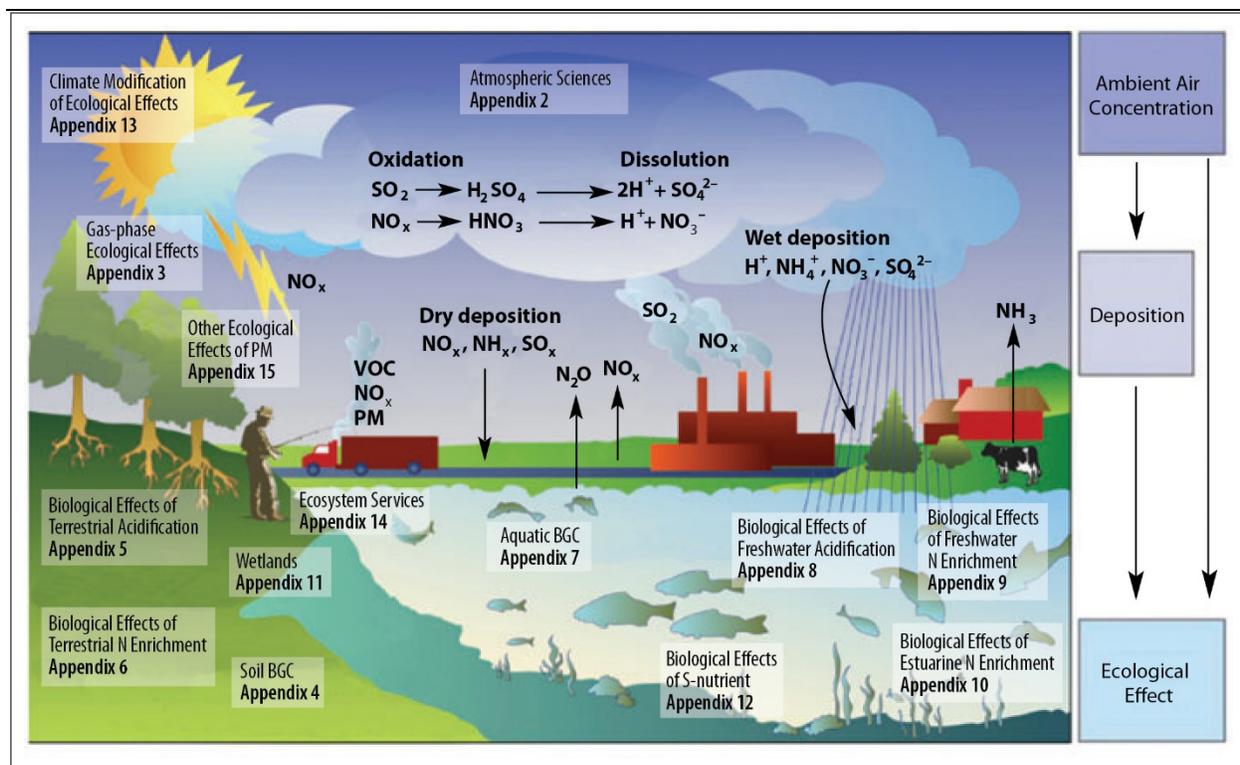

22 This ISA includes the [Preface](#) (legislative requirements and history of the secondary
23 oxides of nitrogen, oxides of sulfur, and particulate matter NAAQS), an [Executive](#)
24 [Summary](#), an Integrated Synthesis chapter, and 16 appendices. The general process for
25 developing an ISA is described in a companion document, *Preamble to the Integrated*
26 *Science Assessments* ([U.S. EPA, 2015e](#)). [Chapter 1](#) synthesizes the scientific evidence
27 that best informs policy-relevant questions that frame this review. [Appendix 1](#) is an
28 introduction to the appendices. [Appendix 2](#) characterizes the sources, atmospheric
29 processes, and the trends in ambient concentrations and deposition of NO_y, SO_x, and PM.
30 [Appendix 3](#) describes direct effects of NO_y and SO_x gases on plants and lichens.
31 [Appendix 4–Appendix 6](#) describe N and S deposition effects on terrestrial
32 biogeochemistry and the terrestrial biological effects of terrestrial acidification and N
33 enrichment. [Appendix 7](#) describes the effects of N and S deposition on aquatic
34 biogeochemistry. [Appendix 8–Appendix 10](#) characterize the biological effects of

1 freshwater acidification, freshwater N enrichment, and N enrichment in estuaries and
2 near-coastal systems. [Appendix 11](#) describes the effects of N deposition on wetlands, and
3 [Appendix 12](#) characterizes the ecological effects of S as a nutrient. [Appendix 13](#) presents
4 information on climate modification of ecosystem response to N and S, while ecosystem
5 services are discussed in [Appendix 14](#). [Appendix 15](#) is a review of the ecological effects
6 of forms of PM, which are not related to N or S deposition. Finally, [Appendix 16](#) presents
7 case studies for six locations in the U.S. (southern California, northeastern U.S., Rocky
8 Mountain National Park, southeastern Appalachia, Tampa Bay, and the Adirondacks)
9 where data are sufficient to well characterize the ecological effects of N and S deposition.
10 These sites would therefore make good candidates for further understanding the linkages
11 across various effects and ecosystems in a location to better assess risk and exposure.

1.2 Connections, Concepts, and Changes

1.2.1 Connections

12 Although scientific material in this ISA is divided into separate appendices for
13 atmospheric science and the multiple ecological effects, the strong links between the
14 atmosphere and terrestrial and aquatic ecosystems are acknowledged ([Chapter 1](#),
15 [Figure 1-2](#)). Emissions of NO_y, SO_x, and PM cause an accumulation of N and S in the
16 environment that creates a multitude of effects on terrestrial, wetland, and aquatic
17 ecosystems. Nitrogen is a vital component of all biological systems, serving as an
18 essential element to molecules such as amino acids and nucleic acids, which are among
19 the biochemical building blocks of life. As an organizing concept to understand the
20 effects of N within the environment, the sequence of transfers, transformations, and
21 environmental effects has been described as the “N cascade” ([Galloway and Cowling,](#)
22 [2002](#)). The concept of cascading effects also applies to S, which is also an essential
23 macronutrient.

Ca²⁺ = calcium ion; GHG = greenhouse gas; H⁺ = hydrogen ion; HNO₃ = nitric acid; H₂SO₄ = sulfuric acid; Mg²⁺ = magnesium ion; N = nitrogen; N₂O = nitrous oxide; NH₃ = ammonia; NH₄⁺ = ammonium; NH_x = NH₃ + NH₄⁺ + reduced organic nitrogen compounds; NO = nitric oxide; NO₂ = nitrogen dioxide; NO₃⁻ = nitrate; NO_x = NO + NO₂; PAN = peroxyacetyl nitrate; PM = particulate matter; SO₂ = sulfur dioxide; SO₄²⁻ = sulfate; SO_x = SO₂ + SO₄²⁻; VOC = volatile organic compounds.

The sum of reactive oxidized nitrogen species is referred to as NO_y (NO_y = NO + NO₂ + HNO₃ + 2N₂O₅ + HONO + NO₃⁻ + N₂O PAN + other organic nitrates). VOC refers to volatile organic compounds.

Although not explicitly indicated, wet and dry deposition of PM components (e.g., metals, minerals, and secondary organic aerosol) also occur and contribute to ecological effects.

Source: Modified from [U.S. EPA \(2008a\)](#).

Figure 1-2 Overview of atmospheric chemistry, deposition, and ecological effects of emissions of oxides of nitrogen, oxides of sulfur, and reduced nitrogen.

1.2.2 Concepts

- 1 This ISA draws on many methodological approaches and disciplines within the larger
- 2 scientific fields of ecology and atmospheric sciences. The studies discussed herein are
- 3 best understood in the context of some general concepts within these fields, such as
- 4 ecosystem scale, structure, and function ([Chapter 1.2.2.1](#)); deposition and source
- 5 apportionment to ecosystems ([Chapter 1.2.2.2](#)); critical loads [CL, ([Chapter 1.2.2.3](#))];
- 6 biodiversity ([Chapter 1.2.2.4](#)); the effects of reduced versus oxidized forms of N

1 [\(Chapter 1.2.2.5\)](#); and the metric developed in the previous secondary NAAQS review,
2 the Aquatic Acidification Index [AAI, [\(Chapter 1.2.2.6\)](#)].

3 Ecosystem structure comprises both biodiversity and geography. Biodiversity
4 encompasses many quantitative measures of the abundance and distribution of organisms
5 within a defined geographical area (for a more explicit definition, see [Chapter 1.2.2.1](#) and
6 [Chapter 1.2.2.4](#)). Ecosystem function refers to processes that control fluxes and pools of
7 matter and energy in the ecosystem ([Chapter 1.2.2.1](#)). The loss of biodiversity is a key
8 consequence of the air pollutants discussed in this ISA. The importance of preserving
9 biodiversity and ecosystem function contributes to the sustainability of ecosystem
10 services that benefit human welfare and society ([Chapter 1.2.2.4](#) and [Appendix 14](#)).

11 In human health assessments, dose-response relationships are used to identify
12 quantitative relationships between chemical exposure (dose) and health outcomes
13 (response), with emphasis on identifying thresholds, the lowest doses at which negative
14 health outcomes are observed. In ecology, CLs provide a similar quantitative relationship
15 between chemical dose (e.g., deposition) and specific, quantitative changes in ecological
16 properties or processes ([Chapter 1.2.2.3](#)). Use of CLs in evaluating the effects of
17 deposition upon ecosystems must consider how deposition compares to other
18 anthropogenic and ambient sources of N and S to these ecosystems ([Chapter 1.2.2.2](#)), as
19 well as the heterogeneous sensitivities of organisms and ecosystems to different chemical
20 forms of deposition ([Chapter 1.2.2.5](#)).

1.2.2.1 Ecosystem Scale, Structure, and Function

21 For this assessment, an ecosystem is defined as the interactive system formed from all
22 living organisms (biota) and their abiotic (chemical and physical) environment within a
23 given area ([IPCC, 2007a](#)). Ecosystem spatial boundaries are somewhat arbitrary,
24 depending on the focus of interest or study. Thus, the spatial extent of an ecosystem may
25 range from very small, well-circumscribed systems such as a small pond, to biomes at the
26 continental scale, or the entire globe ([U.S. EPA, 2008a](#)). Ecosystem spatial scale does not
27 always correlate with complexity. A small pond may be a complex system with multiple
28 trophic levels ranging from phytoplankton to invertebrates to several feeding guilds of
29 fish. A large lake, on the other hand, may be a very simple ecosystem, such as the Great
30 Salt Lake in Utah that covers approximately 1,700 square miles but contains only
31 bacteria, algae, diatoms, and two invertebrate species ([U.S. EPA, 2013b](#)). All ecosystems,
32 regardless of size or complexity, have multiple interactions between biota and abiotic
33 factors and a reduction in entropy through energy flow from autotrophs to top predators.
34 Ecosystems include both structural (geography and biodiversity; e.g., soil type and food

1 web trophic levels) and functional (flow of energy and matter; e.g., decomposition,
2 nitrification) attributes. Ecosystem changes are often considered undesirable if important
3 structural or functional components of the ecosystems are altered following pollutant
4 exposure ([U.S. EPA, 2013b, 1998a](#)).

5 Biotic or abiotic structure may define an ecosystem. Abiotic structure includes climatic
6 and edaphic components. Biological structure includes species abundance, richness,
7 distribution, evenness, and composition, measured at the population, species, community,
8 ecosystem, or global scale. A species (for eukaryotic organisms) is defined by a common
9 morphology, genetic history, geographic range of origin, and ability to interbreed and
10 produce fertile offspring. A population consists of interbreeding groups of individuals of
11 the same species that occupy a defined geographic space. Interacting populations of
12 different species occupying a common spatial area form a community ([Barnthouse et al.,
13 2008](#)). Community composition may also define an ecosystem type, such as a pine forest
14 or a tall grass prairie. Pollutants can affect the ecosystem structure at any of these levels
15 of biological organization ([Suter et al., 2005](#)).

16 Individual plants or animals may exhibit changes in metabolism, enzyme activities,
17 hormone function, or may suffer gross lesions, tumors, deformities, or other pathologies.
18 However, only some organism-level endpoints such as growth, survival, and reproductive
19 output have been definitively linked to effects at the population level and above ([U.S.
20 EPA, 2013b](#)). Population-level effects of pollutants include changes over time in
21 abundance or density (number of individuals in a defined area), age or sex structure, and
22 production or sustainable rates of harvest ([Barnthouse et al., 2008](#)). Community-level
23 attributes affected by pollutants include species richness, species abundance,
24 composition, evenness, dominance of one species over another, or size (area) of the
25 community ([U.S. EPA, 2013b](#)). Pollutants may affect communities in ways that are not
26 observable in organisms or populations ([Bartell, 2007](#)), including (1) effects resulting
27 from interactions between species, such as altering predation rates or competitive
28 advantage; (2) indirect effects, such as reducing or removing one species from the
29 assemblage and allowing another to emerge ([Petraitis and Latham, 1999](#)); and
30 (3) alterations in trophic structure.

31 Alternatively, ecosystems may be defined on a functional basis. “Function” refers to the
32 suite of processes and interactions among the ecosystem components that involve energy
33 or matter. Examples include water dynamics and the flux of trace gases such as rates of
34 photosynthesis, decomposition, nitrification, or carbon cycling. Pollutants may affect
35 biotic structure indirectly. For example, a pollutant may first alter abiotic conditions
36 (e.g., soil chemistry), which in turn influences biotic structure and function ([Bartell,
37 2007](#)).

1 Some ecosystems, and some aspects of particular ecosystems, are less vulnerable to
2 long-term consequences of pollutant exposure. Other ecosystems may be profoundly
3 altered if a single attribute is affected. Thus, spatial and temporal definitions of
4 ecosystem structure and function become an essential factor in defining impacted
5 ecosystem services and CLs of particular pollutants, either as single pollutants or in
6 combination with other stressors.

7 The main causal determinations of this ISA ([Chapter 1.2.3](#)) are that N and S deposition
8 affect ecosystem structure, with effects ranging from biogeochemical alterations in soil
9 and water chemistry to multiple levels of biological organization, including species-level
10 alterations of physiological processes, shifts in biodiversity and ecological function.

1.2.2.2 Deposition and Source Apportionment of Nitrogen (N) and Sulfur (S) to Ecosystems

11 Deposition of N and S results from a variety of human activities and atmospheric
12 processes. Emissions from stationary, mobile, and agricultural sources undergo
13 atmospheric transformation ([Chapter 1.3.1](#)) to form products that are more readily
14 deposited out of the air onto the land or waterscape ([Chapter 1.3.3](#)). The contribution of
15 atmospheric deposition to total loading for N and S varies within and among terrestrial,
16 wetland, freshwater, and estuarine ecosystems.

17 In the 2008 ISA, atmospheric deposition was identified as the main source of
18 anthropogenic N to unmanaged terrestrial ecosystems. This conclusion has been
19 confirmed by new studies on N sources to lands and waterways, which find
20 human-mediated watershed N inputs that range from <1.0 to 34.6 times the rate of
21 background N input ([Appendix 4.2](#)). Across all watersheds, atmospheric N deposition is
22 the second largest overall human-mediated N source and the largest N source to 33% of
23 watersheds. Current deposition levels in the U.S. are discussed in [Appendix 2](#) and
24 [Chapter 1.3.3](#). No new information has been published on nonatmospheric sources of S in
25 terrestrial ecosystems ([Appendix 4.2](#)); S inputs from the atmosphere are discussed in
26 [Appendix 2](#) and [Chapter 1.3.3](#).

27 In the 2008 ISA, atmospheric deposition was also identified as the main source of N to
28 some freshwater ecosystems, including headwater streams, high-elevation lakes, lower
29 order streams in undisturbed areas and freshwater wetlands (e.g., bogs and fens).
30 Evidence for the influence of N deposition on water chemistry has been further supported
31 by new studies that quantify the contribution of N deposition to total N loading in
32 freshwater lakes and streams, and which quantify atmospheric contributions during storm
33 events ([Table 7-1](#)). As shown in these studies, deposition can represent a substantial

1 portion of total N loading to surface waters. However, other nonpoint and point sources
2 of N dominate N inputs to high-order streams.

3 In fresh surface waters and wetlands, sources of S that contribute to enrichment effects
4 are the same sources of S that induce acidifying effects; these sources include weathering
5 of minerals in sediments and rocks, leaching from terrestrial S cycling, internal cycling,
6 and direct atmospheric deposition. The 2008 ISA showed that drought can release S
7 stored in wetlands or lake sediments, as bound sulfide (S^{2-}) is exposed to atmospheric
8 oxygen and oxidized to sulfate. Model of Acidification of Groundwater in Catchments
9 (MAGIC) modeling has shown that variable water levels due to climate change-induced
10 droughts can increase water sulfate concentrations, and observational research has shown
11 that drought increases lake S load by 5 kg S/ha/yr. New evidence confirms that
12 fluctuating water levels in wetlands increase SO_4^{2-} concentration in pulses following
13 water level recovery.

14 Sources of N in coastal areas may include direct deposition to the water surface, coastal
15 upwelling from oceanic waters, and transport from watersheds. Freshwater inflows to
16 estuaries may contain N from agriculture, urban, wastewater and atmospheric deposition
17 sources. Atmospheric deposition constitutes less than half of the total N supply in most,
18 but not all, estuaries ([Table 7-6](#)). Both point sources and nonpoint sources (including
19 runoff, as well as atmospheric deposition) have been identified as targets for mitigation of
20 N loading in coastal areas. The importance of atmospheric deposition as a cause of
21 estuarine eutrophication is determined by the relative contribution of the atmospheric
22 versus nonatmospheric sources of N input. Seawater contains high concentrations of
23 SO_4^{2-} , so atmospheric inputs of S are unlikely to contribute substantially to
24 biogeochemistry or biological effects in coastal areas.

1.2.2.3 Critical Loads Concept and General Approaches

25 The following section provides a discussion of important concepts regarding critical
26 loads. The definition of a critical load is, “a quantitative estimate of an exposure to one or
27 more pollutants below which significant harmful effects on specified sensitive elements
28 of the environment do not occur according to present knowledge” ([Nilsson and Grennfelt,
29 1988](#)). It is intended as background material to support better understanding of the critical
30 load calculations presented throughout the ISA. The main concepts presented here
31 include CLs as an organizing principle, CL heterogeneity across the landscape, more than
32 one critical load for a given location, the pros and cons of methods used to calculate
33 critical loads (e.g., empirical, steady-state, and dynamic), and a comparison of CLs versus
34 target loads. Uncertainty in calculating CLs is discussed in [Chapter 1.13](#).

1 Throughout this ISA, the CL concept is used as an organizing principle to relate
 2 atmospheric deposition to ecological endpoints that indicate impairment. The generally
 3 accepted definition of a CL is by [Nilsson and Grennfelt \(1988\)](#) as: “The quantitative
 4 estimate of an exposure to one or more pollutants below which significant harmful effects
 5 on specified sensitive elements of the environment do not occur according to present
 6 knowledge.” The development of a quantitative critical load estimate requires a number
 7 of steps. An illustrative example of the eight general steps is shown in [Chapter 1](#),
 8 [Figure 1-3](#).

1) Disturbance	Acidification				Eutrophication	
2) Receptor	Forest		Lake		Grassland	Lake
3) Biological indicator	Sugar Maple	Norway Spruce	Brook trout	Fish species richness	Species diversity	Primary productivity
4) Critical biological response	Failure to reproduce	Seedling death	Presence absence	Species loss	Species loss	Excess productivity
5) Chemical indicator	Soil % Base Saturation	Soil Ca/Al ratio	Lakewater ANC	Lakewater ANC	Soil C/N ratio	Lakewater NO ₃
6) Critical chemical limit	10%	1.0	0 µeq/L	50 µeq/L	20	10 µeq/L
7) Atmospheric pollutant	SO ₄ , NO ₃ , NH ₄	SO ₄ , NO ₃ , NH ₄	SO ₄ , NO ₃ , NH ₄	SO ₄ , NO ₃ , NH ₄	NO ₃ , NH ₄	NO ₃ , NH ₄
8) Critical pollutant load	???	???	???	???	???	???

Al = aluminum; ANC = acid-neutralizing capacity; C = carbon; Ca = calcium; L = liter; µeq = microequivalents; N = nitrogen; NH₄ = ammonium; NO₃ = nitrate; SO₄ = sulfate.

Source: [U.S. EPA \(2008a\)](#).

Figure 1-3 An example of the matrix of information considered in defining and calculating critical loads (see discussion in text). Note that multiple alternative biological indicators, critical biological responses, chemical indicators, and critical chemical limits could be used.

9
 10 It is important to recognize that there is no single “definitive” critical load for an
 11 ecological effect. Critical loads estimates reflect the current state of knowledge and the
 12 selected limits, indicators, and responses. Changes in scientific understanding may
 13 include, for example, new dose-response relationships, better resource maps and

1 inventories, larger survey data sets, continuing time-series monitoring, and improved
2 numerical models.

3 Calculating multiple critical loads for a given pollutant at a single location is not
4 uncommon due to the nested sequence of disturbances, receptors, and biological
5 indicators considered for a given pollutant. Multiple critical load values may also arise
6 from an inability to agree on a single definition of “harm.” Calculation of critical loads
7 for multiple definitions of “harm” may be deemed useful in subsequent discussions of the
8 analysis and in the decision-making steps that may follow critical load calculation.

9 The heterogeneity of all natural environments can affect responsiveness of ecosystems to
10 deposition load. As an example, the high spatial variability of soils almost guarantees that
11 for any reasonably sized soil-based “receptor” that might be defined in a CL analysis,
12 there will be a continuum of CL values for any indicator chosen. Although the range of
13 this continuum of values might be narrow, there is nevertheless an a priori expectation in
14 any critical load analysis that multiple values (or a range of values) will result from the
15 analysis. Given the heterogeneity of ecosystems affected by N and S deposition,
16 published critical load values for locations in the U.S. vary depending on both biological
17 and physical factors.

18 The three approaches to developing CLs (i.e., empirical observation, steady-state
19 modeling, and dynamic modeling) each have strengths and limitations. It is suggested
20 that the combined approach of calculating CLs from biogeochemical simulation models
21 in conjunction with empirical analyses is the most effective way to characterize the
22 effects of deposition to a given environment ([Fenn et al., 2015](#)).

23 An important advantage of empirical CLs is that they are based on measured (vs.
24 modeled) changes in ecological variables in response to N inputs. Consequently, the links
25 between N deposition and the measured response variable are direct; full process-level
26 knowledge is not required. Empirical CLs are important for validating CL values
27 determined with models ([Fenn et al., 2015](#)).

28 [Fenn et al. \(2015\)](#) discuss that the advantages of models, “are that ecosystem responses to
29 alternative scenarios can be tested. These might include changes in atmospheric
30 deposition, disturbance or climatic conditions, and responses to silvicultural treatments,
31 grazing, fire, and other disturbances. Simulation modeling allows temporal aspects of
32 ecosystem response in relation to CLs and CL exceedances to be evaluated, including
33 evaluation of historical and future conditions.”

34 Among the types of modeled CLs, two key ways that steady-state and dynamic modeling
35 differ is by how they assume ecosystem equilibrium and the required amount of input
36 data needed to parameterize the model. Steady-state models assume that the ecosystem is

1 in equilibrium with the critical load of deposition; therefore, the long-term sustainable
2 deposition is indicated. This is the relevant information needed to provide protection
3 from deposition in perpetuity as the system comes into equilibrium with the pollutant
4 critical load. In the U.S., few (if any) ecosystems qualify as steady-state systems.
5 Therefore, the assumption of equilibrium in the steady-state model is often false. The
6 steady-state models give no information concerning the time to achieve the equilibrium
7 or what may happen to the receptor along the path to equilibrium. The recovery of an
8 ecosystem based on a critical load from a steady-state model may take several hundred
9 years. In other words, the assumption that attainment of a deposition values below the
10 steady-state critical load will result in biological recovery within a specified time period
11 may not be valid. Dynamic models calculate time-dependent critical loads and therefore
12 do not assume an ecosystem that is in equilibrium. The time-dependent calculation is
13 relevant information to provide protection from damage by the pollutant within a specific
14 time frame. As a general rule, the shorter the time frame selected, the lower the critical
15 load.

16 Data requirements for steady-state models tend to be much lower than for dynamic
17 models. Therefore, the data required to conduct dynamic modeling are not available for
18 as many places as the data required to conduct steady-state modeling. The few
19 national-scale modeling efforts for both terrestrial and aquatic acidification are both done
20 with steady-state models for this reason.

21 The results of all three CL approaches are difficult to extrapolate across geographic
22 space. Spatially, variation in biological and biogeochemical processes imposed by
23 climate, geology, biota, and other environmental factors may alter the
24 deposition-response relationship. Empirical CLs may only be applied with confidence to
25 sites with highly similar biotic and environmental conditions ([Pardo et al., 2011a](#)). This is
26 particularly problematic in areas where deposition has received sparse research
27 attention—as is sometimes the case for CLs of N deposition related to N-driven
28 eutrophication ([Appendix 6.4](#)). Models may be run at different locations; however, the
29 data needed to parameterize them is not always available.

30 The traditional critical load has been defined ([Nilsson and Grennfelt, 1988](#)) as: “The
31 quantitative estimate of an exposure to one or more pollutants below which significant
32 harmful effects on specified sensitive elements of the environment do not occur
33 according to present knowledge.” [Fenn et al. \(2011b\)](#) have defined the “target load” as
34 follows: “The acceptable pollution load that is agreed upon by policy makers or land
35 managers. The target load is set below the critical load to provide a reasonable margin of
36 safety, but could be set higher than the critical load at least temporarily.” Target loads are

1 selected based on the level of ecosystem protection desired, economic considerations, and
2 stakeholder input at a given location.

1.2.2.4 The Importance of Biodiversity

3 There are causal relationships between N and/or S and biodiversity loss in terrestrial,
4 freshwater, wetland, and estuarine ecosystems in the U.S. ([Chapter 1, Table 1-1](#)). What
5 does it mean to lose biodiversity? Biodiversity loss not only represents the extirpation of
6 unique living species; several decades of research link biodiversity to ecosystem function
7 and ecosystem services in a wide variety of natural systems ([Hooper et al., 2012](#);
8 [Balvanera et al., 2006](#); [Tilman, 2000](#)). Numerous studies demonstrate that the number
9 and diversity of organisms in a system control the abundance of habitat for other species,
10 the biogeochemical cycling of nutrients and carbon, and the efficiency at which biotic
11 systems are able to transform limited resources into biomass ([Cardinale et al., 2011](#)).
12 Among plant communities, higher biodiversity leads to higher overall plant productivity
13 and greater retention of soil nutrients ([Reich et al., 2012](#); [Tilman, 2000](#)). In multitrophic
14 systems, higher prey diversity leads to both higher predator growth rates and a smaller
15 impact of predation on prey abundance ([Duffy et al., 2007](#)). Positive impacts of
16 biodiversity on ecosystem services have been documented in forests ([Gamfeldt et al.,](#)
17 [2013](#); [Zhang et al., 2012b](#)), grasslands ([Tilman et al., 2012](#)), arid and semiarid
18 ecosystems ([Maestre et al., 2012](#)), and marine systems ([Gamfeldt et al., 2015](#); [Worm et](#)
19 [al., 2006](#)) and include effects such as greater carbon storage, fruit production, wood
20 production, and nutrient cycling. In marine ecosystems, biodiversity loss has been linked
21 to increased rates of resource collapse and exponential decreases in water quality through
22 metrics such as higher numbers of beach closures and harmful algal blooms [HABs;
23 ([Worm et al., 2006](#))]. Notably, HABs are linked to increased disease prevalence among
24 humans, domestic animals/pets, and aquatic organisms ([Johnson et al., 2010](#)). In addition
25 to the relationship between HABs and disease, there is now empirical evidence from
26 many ecosystems of a broader link between declines in biodiversity and increased
27 transmission and severity of disease ([Johnson et al., 2015b](#)) caused by plant, wildlife, and
28 human pathogens. As a whole, these decades of research have produced an overwhelming
29 body of evidence indicating that the loss of biodiversity risks a deterioration of the
30 ecosystem goods and services that humanity depends on ([Gamfeldt et al., 2015](#); [Cardinale](#)
31 [et al., 2012](#)).

32 One of the most important consensus observations in biodiversity research is that
33 ecosystem processes are more stable (have less temporal variability) at higher levels of
34 diversity ([Cardinale et al., 2012](#); [McCann, 2000](#); [Naeem and Li, 1997](#); [Tilman and](#)
35 [Downing, 1994](#)). This stability occurs because species respond differently to

1 environmental variation. In diverse communities, is it more likely that declines in the
2 growth of one species caused by an environmental change will provide more resources
3 for competing species ([Cardinale et al., 2012](#); [Tilman, 2000](#)). This property was predicted
4 by economists and is similar to how more diversified investment portfolios provide
5 enhanced stability under fluctuating market conditions ([Doak et al., 1998](#); [Tilman et al.,
6 1998](#)). Notably, there is also consensus that the impact of biodiversity on ecosystem
7 processes is nonlinear, wherein declines in ecosystem processes accelerate as the number
8 of species in a system declines ([Cardinale et al., 2012](#)). Accelerating ecosystem service
9 declines in response to species loss may be due to multifunctionality, which suggests that
10 different ecosystem functions require the presence of different sets of species ([Isbell et
11 al., 2015](#); [Reich et al., 2012](#); [Zavaleta et al., 2010](#)). The increased stability of diverse
12 ecosystems makes these systems less vulnerable to environmental change or collapse
13 caused by external forces such as drought or human disturbance ([Isbell et al., 2015](#);
14 [Tilman et al., 2012](#); [Isbell et al., 2011](#); [Worm et al., 2006](#)). For example, coastal systems
15 with higher species diversity had lower rates of fishery collapse and extinction for
16 commercially important fish and invertebrate species, and large marine ecosystems with
17 higher fish diversity recovered more quickly from collapse ([Worm et al., 2006](#)). Thus,
18 there is strong evidence that high biodiversity helps sustain ecosystem services and also
19 makes these ecosystem services more resilient to environmental change.

1.2.2.5 Reduced versus Oxidized Nitrogen Effects across Ecosystems

20 Individual biochemical and geochemical processes involve specific chemical forms of N,
21 suggesting that there may be consequences in many ecosystems from the ongoing trend
22 of decreasing NO_y deposition and increasing NH_x deposition in many parts of the U.S.
23 ([Chapter 1.3](#)). The largest body of evidence that the effects of reduced versus oxidized N
24 may have different consequences for ecological structure and function is for estuaries
25 where the form of N delivered to some coastal areas of the U.S. is shifting from primarily
26 NO_3^- to an increase in reduced forms of N. Although unlikely to be attributed solely to
27 atmospheric sources due to the large contribution of N from wastewater, agriculture, and
28 other sources, inputs of $\text{NH}_3/\text{NH}_4^+$ selectively favor specific phytoplankton functional
29 groups (e.g., cyanobacteria, dinoflagellates) including harmful species ([Figure 10-7](#)).
30 Shifts in phytoplankton community composition to species that respond strongly to
31 reduced N have been observed in some coastal regions ([Appendix 10.3.2](#)). Growth of
32 some species of phytoplankton ([Appendix 10.2.2](#)) and macroalgae (seaweed;
33 [Appendix 10.2.3](#)) appear to be related to the form of N. There is also increasing evidence
34 in freshwater systems for the importance of N in harmful algal blooms (HABs), and
35 several studies have shown that the form of N influences freshwater algal species

1 composition ([Appendix 9.2.6.1](#)). In terrestrial systems, redox status of inorganic N seems
2 to have little influence on the biological responses to N deposition ([Appendix 4.3.12](#)).

3 Because some soil biogeochemical processes involve specific chemical forms of N
4 (e.g., denitrification, ammonium toxicity), there is the potential that biological responses
5 to N deposition (or N addition) could depend on whether the dominant form of deposited
6 N is oxidized (NO_y) or reduced (NH_x). Different responses to individual forms of N have
7 been observed for some soil biogeochemical processes ([Table 4-13](#)) and terrestrial
8 biological responses ([Table 6-1](#)). Moreover, a number of individual studies have
9 observed differential effects of NH_4^+ versus NO_3^- additions on plant community diversity
10 [e.g., ([Dias et al., 2014](#); [Kleijn et al., 2008](#))]. In general, however, meta-analyses in the
11 literature have tended to find no difference in the effects of individual forms of N on
12 terrestrial biological endpoints like plant productivity or microbial biomass ([Table 6-1](#)).
13 This result suggests that terrestrial community diversity is also generally not affected,
14 possibly because plant uptake of N is mediated by soil biogeochemical cycles that often
15 rapidly transform N between oxidized and reduced forms.

16 Evidence of wetland responses to different chemical forms of N come primarily from N
17 addition experiments conducted outside of the U.S. In European bogs and fens, both
18 forms of N addition decreased ecosystem N retention, but oxidized N addition caused
19 DON leaching, while reduced N caused DIN as well as cation leaching
20 ([Appendix 11.3.1.6](#)). Reduced N caused greater physiological stress or injury than
21 equivalent loads of oxidized N in moss species ([Appendix 11.4.5](#) and [Appendix 11.5.5](#)).

1.2.2.6 Scientific Advancements of the Aquatic Acidification Index (AAI)

22 The 2017 IRP ([U.S. EPA, 2017b](#)) described the Aquatic Acidification Index (AAI) as a
23 novel approach for a multipollutant standard intended to address deposition-related
24 effects that was developed in the 2011 NO_xSO_x Policy Assessment ([U.S. EPA, 2011a](#)).
25 Scientifically, the AAI represented an advancement in ecological methodology to
26 (1) calculate critical loads for aquatic acidification on a national scale, when previously
27 critical loads had been calculated on the spatial scale of a watershed and (2) provide a
28 uniform level of ecological protection at the national scale. These advancements were
29 accomplished by first aggregating critical loads calculated for the same chemical limit
30 within a defined spatial region. Next, the distribution of the “population” of critical load
31 values was evaluated, and the percentage of water bodies to protect was selected. The
32 AAI also presented novel advancement in atmospheric sciences, including (1) using
33 transference ratios to relate atmospheric concentrations of criteria pollutants to deposition
34 levels and (2) allowing quantification of criteria pollutants (NO_y and SO_x) and

1 noncriteria pollutant contributions to total acidifying deposition. As a scientific
2 publication, the AAI is documented in [Scheffe et al. \(2014\)](#). The AAI was originally
3 developed in the 2011 NO_xSO_x Policy Assessment ([U.S. EPA, 2011a](#)), and the equation
4 is described with terms that traditionally define a NAAQS [the indicator,¹ averaging
5 time,² form,³ and level⁴—further described in the 2017 IRP ([U.S. EPA, 2017b](#)).

6 Key scientific aspects of the AAI equation, as the form of a potential standard, are
7 described in the following excerpt from 2017 IRP ([U.S. EPA, 2017b](#)):

8 “The AAI, as described in the PA ([U.S. EPA, 2011a](#)), was constructed
9 from steady-state ecosystem modeling, and included atmospheric
10 transference ratios and deposition of reduced forms of nitrogen
11 (ammonia gas and ammonium ion, expressed as NH_x). These
12 nonoxidized forms of nitrogen were included since ecosystems respond
13 to total nitrogen deposition, whether from oxidized or reduced forms.
14 More specifically, the AAI equation was defined in terms of four
15 ecological and atmospheric factors and the ambient air indicators NO_y
16 and SO_x:

$$AAI = F1 - F2 - F3[NO_y] - F4[SO_x]$$

17 where $F1^5$ represents the ecosystems natural ability to provide
18 acid-neutralizing capacity (e.g., geology, plant uptake of nitrogen
19 deposition) and other processes; $F2^6$ represents acidifying deposition
20 associated with reduced forms of nitrogen, NH_x; and $F3^7$ and $F4^8$ are the

¹ The “indicator” of a standard defines the chemical species or mixture that is measured in determining whether an area attains the standard.

² The “averaging time” defines the time period over which ambient measurements are averaged (e.g., 1-hour, 8-hour, 24-hour, annual).

³ The “form” of a standard defines the air quality statistic that is compared to the level of the standard in determining whether an area attains the standard.

⁴ The “level” defines the allowable concentration of the criteria pollutant in the ambient air.

⁵ $F1$ is defined as: $ANC_{lim} + CL_r/Q_r$, with ANC_{lim} representing a target ANC level. With regard to CL_r , the PA developed distributions of calculated critical loads for a specific ecoregion; in setting an AAI-based standard, a percentile would need to be specified to reference the value of CL_r to be used in the AAI equation [[U.S. EPA, 2011a](#)], p. 7- 37]. The PA described the percentile as an aspect of the form for the standard [[U.S. EPA, 2011a](#)], section 7.7].

⁶ $F2$ is defined as: NH_x/Q_r , where NH_x is the deposition divided by Q_r [[U.S. EPA, 2011a](#)], p. 7-37].

⁷ $F3$ is defined as: TNO_y/Q_r , where TNO_y is the transference ratio that converts deposition of NO_y to ambient air concentrations of NO_y [[U.S. EPA, 2011a](#)], p. 7-37].

⁸ $F4$ is defined as: TSO_x/Q_r , where TSO_x is the transference ratio that converts deposition of SO_x to ambient air concentrations of SO_x [[U.S. EPA, 2011a](#)], p. 7-37].

1 transference ratios that convert concentrations of NO_Y and SO_X to related
2 deposition of nitrogen and sulfur [([U.S. EPA, 2011a](#)), Section 7.7].”

3 There are several other key scientific considerations included in the AAI that were
4 discussed in the 2011 NO_XSO_X Policy Assessment ([U.S. EPA, 2011a](#)):

- 5 • Spatial heterogeneity of factors in the AAI equation: The value of factors in the
6 AAI equation vary across the U.S. Factors could be calculated for a spatial
7 boundary based on ecologically similar landscape (e.g., Omernick ecoregion).
- 8 • Temporal heterogeneity: There is a relatively high degree of interannual
9 variability expected in the AAI because it is so strongly influenced by the amount
10 and pattern of precipitation that occurs within a region from year to year, therefore
11 averaging calculated annual AAI values over 3 to 5 years would provide
12 reasonable stability.
- 13 • Level: With regard to a level for the AAI, the 2011 NO_XSO_X Policy Assessment
14 ([U.S. EPA, 2011a](#)) concluded consideration should be given to a level within the
15 range of 20 to 75 $\mu\text{eq/L}$, noting that a target ANC value of 20 $\mu\text{eq/L}$ would be a
16 reasonable lower end of this range, so as to protect against chronic
17 acidification-related adverse impacts on fish populations which have been
18 characterized as severe at ANC values below this level.

1.2.3 Changes: New Evidence and Causal Determinations

19 Since the 2008 ISA, several conceptual changes have occurred in our understanding of
20 the sources of N deposition and in the relationship between atmospheric concentration
21 and deposition. ([Chapter 1.3](#) and [Appendix 2](#)). Models of N deposition rely on accurate
22 emissions data. Since the 2008 ISA, NO_X emissions have been decreasing but NH_X
23 emissions increasing. As a result, total reactive N emissions ($\text{NO}_X + \text{NH}_X$) have not only
24 remained steady, but their uncertainty has increased. This is because emissions estimates
25 that have the lowest levels of uncertainty are from stationary and mobile sources (the
26 main sources of NO_X), and higher levels of uncertainty are associated with agricultural
27 emissions (the main source of NH_X).

28 A better understanding of the relationship between atmospheric concentration and
29 deposition has resulted from advances in understanding bidirectional exchange of NH_3
30 and NO_X chemistry within canopies. These advances have led to the first efforts to
31 provide a detailed characterization of N and S deposition on a national scale, by using
32 both measured and modeled values with the goal of providing estimates of total sulfur
33 and nitrogen deposition across the U.S.

34 New evidence since the 2008 ISA increases in the weight of evidence for ecological
35 effects, confirming concepts previously identified and improving quantification of dose
36 (deposition)–response relationships, particularly for N deposition. The ecological effects

1 are described by the causality determinations. There are 20 causality statements in this
2 ISA ([Chapter 1, Table 1-1](#)). Fourteen are causal relationships repeated from the 2008 ISA
3 or modified from the 2008 ISA to include specific endpoints. One is a likely causal
4 relationship repeated from the 2009 PM ISA. Five are new endpoint categories not
5 evaluated in the 2008 ISA: three with causal relationships, one with a likely causal
6 relationship, and one suggestive of a causal relationship. [Chapter 1, Table 1-3](#) shows that
7 N and S deposition cause alteration of (1) biogeochemical components of soil and water
8 chemistry and (2) multiple levels of biological organization ranging from physiological
9 processes to shifts in biodiversity and ecological function ([Chapter 1, Figure 1-4](#)).

10 The current NO₂ and SO₂ secondary NAAQS are set to protect against direct damage to
11 vegetation by exposure to gas-phase oxides of nitrogen and oxides of sulfur. Research
12 continues to support causal relationships between SO₂, NO₂, NO, peroxyacetyl nitrate
13 (PAN), HNO₃, and injury to vegetation ([Chapter 1, Table 1-1](#)), but research that tests
14 plant response to the lower exposure levels that represent current atmospheric NO_y and
15 SO_x concentrations is limited. Therefore, little evidence is available to inform whether
16 current monitored concentrations of gas-phase NO_y and SO_x are high enough to injure
17 vegetation.

18 It is clear that NO_y, SO_x, and PM contribute to total N and S deposition, which alters the
19 biogeochemistry and the physiology of organisms, resulting in harmful declines in
20 biodiversity. Decreases in biodiversity mean that some species become relatively less
21 abundant and may be locally extirpated. The current period in Earth's history is the
22 Anthropocene. In addition to a spike in soil radiocarbon from nuclear bomb testing
23 ([Turney et al., 2018](#)), a defining attribute of the Anthropocene is global human-driven
24 mass extinctions of many species. The biodiversity loss reported in this assessment
25 contributes to the Anthropocene loss of biodiversity ([Rockstrom et al., 2009](#)). In addition
26 to the loss of unique living species, the decline in total biodiversity is harmful because
27 biodiversity is an important determinant of the stability of ecosystems and the ability of
28 ecosystems to provide services to humanity (see more on biodiversity in [Chapter 1.2.2.4](#)).

Figure 1-4 Causal relationships between the criteria pollutants and ecological effects.

1 Since the 2008 ISA, the largest increase in ecological evidence is for terrestrial N driven
2 eutrophication effects ([Chapter 1.5.1](#), [Chapter 1.5.2](#), [Appendix 4](#), and [Appendix 6](#)). This
3 new research confirms the causal relationship between N deposition and ecological
4 effects documented in the 2008 ISA and improves our understanding of the mechanistic
5 links that inform causal determinations between N deposition, biogeochemistry, and biota
6 in terrestrial ecosystems ([Chapter 1](#), [Table 1-1](#)). Further, there is now stronger empirical
7 evidence from across most regions of the U.S. to quantify the levels of N deposition
8 (empirical CLs) that cause biodiversity declines of lichens and grasses/forbs. There is
9 new evidence to quantify empirical CLs across much of the U.S. for nitrate leaching, tree
10 survivorship, and mycorrhizal biodiversity.

11 New research confirms that N + S deposition causes terrestrial ecosystem acidification, as
12 documented in the 2008 ISA ([Chapter 1](#), [Table 1-1](#)). New evidence to characterize
13 terrestrial acidification (soil biogeochemistry changes and biological effects) across large
14 regions of the U.S. is available; in particular, new modeling work has improved
15 calculation of CLs for soil acidification ([Chapter 1.5.3](#); [Appendix 4](#) and [Appendix 5](#)).

16 New evidence for freshwater acidification CLs builds on several decades of research
17 documenting freshwater acidification effects on aquatic biota in the U.S. and confirms the
18 causal relationships determined in the 2008 ISA ([Chapter 1](#), [Table 1-1](#)).

19 The sources of N driven eutrophication of fresh waters, estuaries, and wetlands include
20 atmospheric N deposition and N from agricultural and other wastewaters. New research
21 has helped show how these respective sources contribute to total loading. In freshwater
22 ecosystems where atmospheric deposition is the primary source of N, such as in high
23 alpine watersheds, new CLs support previous observations of increased algal
24 productivity, species changes, and reductions in diversity. New evidence also supports
25 clear links between aqueous sulfur concentrations in aquatic systems and both mercury
26 methylation and sulfide toxicity; however, quantitatively linking these outcomes to
27 atmospheric deposition remains a challenge.

28 Since the 2008 ISA, N enrichment has been recognized as a possible contributing factor
29 to increasing acidification of coastal environments. Dissolution of atmospheric
30 anthropogenic CO₂ into the ocean has led to long term decreases in pH. With increasing
31 N inputs to coastal waters, CO₂ in the water column is produced from degradation of
32 excess organic matter from changing land use, as well as respiration of living algae and
33 seagrasses, which in turn can make the water more acidic ([Appendix 10.5](#)). Increasing
34 acidification of coastal waters, which can be exacerbated by elevated N input, is
35 projected to alter marine habitat, have a wide range of effects at the population and
36 community level and affect food web processes. Nutrient-enhanced coastal acidification

1 has been documented in systems with strong thermal stratification with spatial or
2 temporal decoupling of production and respiration processes.

1.3 Emissions and Atmospheric Chemistry

3 The atmospheric chemistry from emission to deposition discussed in this ISA is for the
4 criteria pollutants NO_Y , SO_X , and PM. In addition to gas-phase chemical species, total N,
5 S and N + S deposition is a main focus.

6 A wide variety of N containing compounds (oxidized + reduced, and organic + inorganic)
7 contribute to wet and dry N deposition ([Appendix 2.1](#)). NH_X ($\text{NH}_X = \text{NH}_3 + \text{NH}_4^+$)
8 includes both the PM component NH_4^+ and NH_3 . NH_3 may account for 19–63% of total
9 observed inorganic N deposition, rather than NO_Y or PM; therefore, it is discussed in the
10 ISA to better understand how the criteria pollutants NO_Y and the PM component NH_4^+
11 contribute with NH_3 to cause N deposition. In addition, PM impacts discussed in this
12 document are also mainly focused on N and S containing species, which together usually
13 make up most of the $\text{PM}_{2.5}$ mass in most areas of the U.S., and have greater and better
14 understood ecological impacts than other PM components.

15 Both gaseous and particulate forms of NO_Y , SO_X , and NH_X contribute to atmospheric
16 deposition. The major components of particulate matter in the U.S. are NO_3^- , SO_4^{2-} ,
17 NH_4^+ , organic carbon, and elemental carbon. Of these, NO_3^- , SO_4^{2-} , and NH_4^+ usually
18 have a strong influence on acid deposition, and NO_3^- and NH_4^+ , and in some cases
19 organic nitrogen (organic nitrates and reduced organic N), make a substantial
20 contribution to N deposition.

21 Since the 2008 ISA, there have been a number of new developments including:

- 22 • Expansion of ambient monitoring networks to include NH_3 and NO_Y at selected
23 sites, and comparisons of monitoring methods with research-grade instruments
24 ([Appendix 2.4](#));
- 25 • Adoption of new methods, such as data-model fusion, to integrate deposition
26 information across the U.S. ([Appendix 2.5](#));
- 27 • Incorporation of bidirectional exchange into models of dry deposition
28 ([Appendix 2.5.2](#)); and
- 29 • Improvements in techniques using satellite-based measurements and
30 chemistry-transport model simulations to estimate emissions, concentrations, and
31 dry deposition of NO_2 , SO_2 , and NH_3 ([Appendix 2.6](#)).

1.3.1 Sources and Atmospheric Transformations

1 Both gaseous and particulate forms of N and S contribute to atmospheric deposition. The
2 main contributors to acidifying precipitation are H₂SO₄ and HNO₃, which are formed
3 from precursor emissions of SO₂ and NO_x (NO + NO₂) ([Appendix 2.2](#)). Gaseous
4 emissions of NH₃ and SO₂ are each dominated by a single source: agriculture (fertilizer
5 application and animal waste) for NH₃ and electricity generating units (EGUs) for SO₂.
6 Notably, SO₂ emissions from EGUs have been decreasing. NO_x emissions have a wider
7 distribution of sources, with substantial contributions from highway and off-highway
8 vehicles, lightning, and EGUs. Primary PM_{2.5} and PM₁₀ emissions are dominated by dust
9 and fires, but much of the PM_{2.5} mass in the U.S. is produced by reaction of gas-phase
10 precursors to form secondary PM_{2.5}, and the majority of the mass is often due to N and S
11 species produced by secondary PM_{2.5} formation. Because of this process, a sharp decrease
12 in SO₂ emissions in recent years has led to a corresponding decrease in SO₄²⁻ and PM_{2.5}
13 concentrations.

14 Major components of particulate N and S include NH₄⁺, NO₃⁻, and SO₄²⁻, which are
15 primarily derived from gaseous precursors NH₃, NO_x, and SO₂ ([Appendix 2.3](#)). In the
16 eastern U.S., NO₃⁻ and SO₄²⁻ make up an even greater portion of PM_{2.5} mass in areas
17 where PM_{2.5} mass is the highest. Formation of particulate N and S is described in the
18 2009 *ISA for Particulate Matter* ([U.S. EPA, 2009a](#)). An understanding of the sources,
19 chemistry, and atmospheric processes for these gas-phase and PM species provides a
20 background for understanding acidifying and N deposition.

1.3.2 Measurement and Modeling Techniques

21 Monitoring networks across the U.S. measure NO_y, SO_x, and NH_x species involved in
22 deposition ([Appendix 2.4.1](#)). The National Acid Deposition Program/National Trends
23 Network (NADP/NTN) has monitored precipitation chemistry for several decades at
24 many U.S. sites. The Clean Air Status and Trends Network (CASTNET) has monitored
25 concentrations of inorganic gas and particulate-phase N and S species since 1990.
26 Concentrations are combined with measurements of micrometeorology and surface
27 characteristics to infer dry deposition. Monitoring of NH₃ ([Appendix 2.5.3](#)) in the
28 Ammonia Monitoring Network (AmoN), part of the NADP network, was initiated at a
29 subset of CASTNET sites in 2007. The Interagency Monitoring of Protected Visual
30 Environments (IMPROVE) network and the Chemical Speciation Network (CSN)
31 measure PM and PM components including NH₄⁺, NO₃⁻, and SO₄²⁻, although these data
32 are not used to estimate deposition rates ([Appendix 2.4.1](#)).

1 Atmospheric N deposition rates are calculated from measurements and models. Direct
2 measurement of NO₂ has limited utility for quantifying NO_Y deposition rates. Because
3 NO_Y is composed of diverse chemical species with a wide range of deposition velocities
4 and compensation points, unmeasured component species of NO_Y and concentrations of
5 all NO_Y species in data-sparse regions must be provided by regional models in
6 conjunction with satellite data ([Appendix 2.4.2](#)).

7 Estimates of dry deposition ([Appendix 2.5.2](#)) over the contiguous U.S. (CONUS) are
8 inferred by atmospheric models, either regional-scale chemical transport models (CTMs)
9 or local-scale micrometeorological models, using CASTNET data. These models perform
10 well in predictions of long-term changes in PM_{2.5} sulfate, nitrate, and mass, but are both
11 subject to uncertainties in their treatment of small-scale turbulence, surface interactions,
12 and in particular, seasonal variability in NO₃⁻ deposition, mainly because of uncertainties
13 in NH₃ emissions. Consequently, dry deposition rates (and ratios of wet-to-dry
14 deposition) continue to be highly uncertain.

1.3.3 Spatial and Temporal Variability in Deposition

15 Emissions of SO₂ and NO_X (NO + NO₂) have declined dramatically since the passage of
16 the Clean Air Act Amendments in 1990. Emissions of NO_X in the U.S. from highway
17 vehicles and fuel combustion declined 49% between 1990 and 2013, while nationwide
18 annual average NO₂ concentrations decreased by 48% from 1990 to 2012 ISA ([U.S. EPA,
19 2016f](#)). Total emissions of SO₂ decreased by 72% from 1990 to 2011.

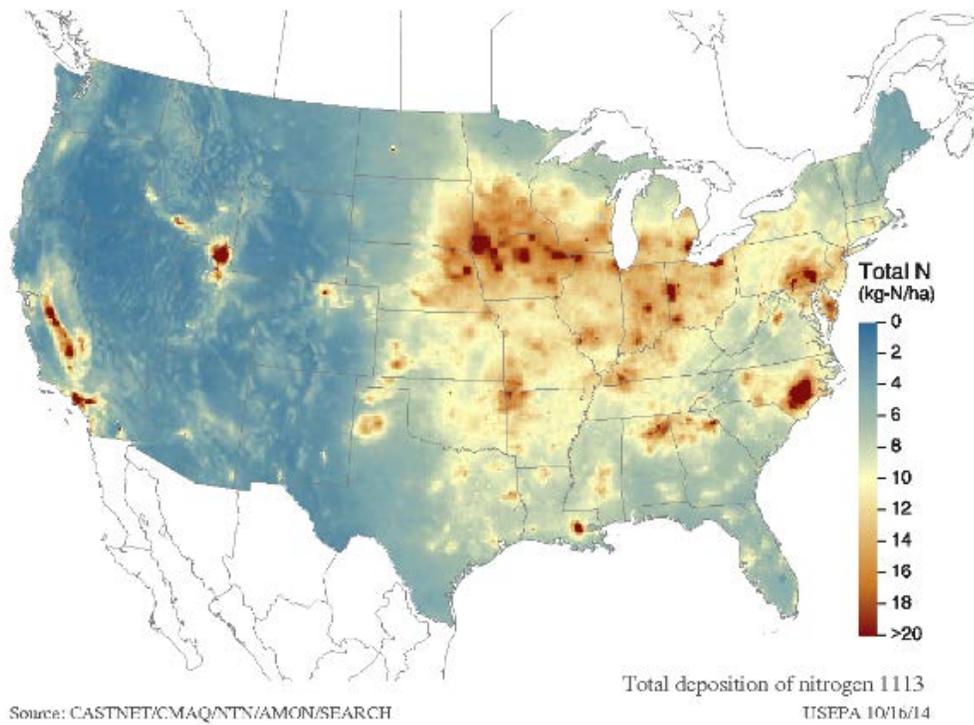

20 Overall deposition of total N (oxidized + reduced N) has not decreased over the past
21 25 years ([Appendix 2.7](#)). Although NO_X emissions have declined in the CONUS,
22 emissions of NH₃ have increased in many areas. The large spatial variability in N
23 deposition is evident in the map ([Chapter 1, Figure 1-5](#)) of average (2011 to 2013) annual
24 dry + wet deposition of NO_Y and NH_X over the CONUS estimated using the TDEP (Total
25 Deposition) modeling approach ([Appendix 2.7](#)), which combines output from the
26 Community Model for Air Quality (CMAQ) system with wet deposition from the
27 NADP/NTN ([Schwede and Lear, 2014b](#)).

28 According to TDEP estimates for 2011–2013 ([Appendix 2.7](#)), at least one-third of the
29 CONUS is estimated to receive at least 10 kg N/ha/yr dry + wet deposition, with some
30 areas receiving more than 15 kg N/ha/yr. It is likely that estimates for the spatial extent of
31 the areas receiving at least 10 kg N/ha/yr of deposition and the overall amount of N
32 deposited are too low because reduced organic N species are not routinely monitored or
33 considered in air quality models such as CMAQ.

1 In general, wet deposition of reduced N exceeds that of oxidized N across the CONUS.
2 Nationwide, deposition of N occurs mainly by dry deposition of HNO₃ and NH₃ (with
3 NH₃ dominant), according to estimates based on CASTNET and NADP data and CMAQ
4 modeling results ([Figure 2-4](#)). Hybrid satellite/modeling and CMAQ results indicate that
5 dry deposition of NO₂ is also a nontrivial source of deposited N in many areas. Over the
6 past 25 years, NADP/NTN data show that wet deposition of inorganic N
7 (oxidized + reduced) decreased in areas such as the Northeast, but remained constant or
8 increased in areas such as the central U.S. (see [Figure 2-32](#) in [Appendix 2.7](#)). Wet
9 deposition of total inorganic N has not tracked declines in NO_x emissions over the past
10 25 years, indicating that wet deposition of reduced inorganic N has increased in this
11 period.

12 For S deposition, wet deposition tends to dominate over dry deposition in large areas of
13 the CONUS. Dry deposition of particulate SO₄²⁻ is only a minor source of S.
14 Anthropogenic emissions of S and subsequent deposition have declined markedly since
15 the 1990s, with the most pronounced declines in the eastern U.S. Currently, the highest
16 values of total (wet + dry) SO_x deposition in the U.S. are in parts of the Ohio Valley
17 region, and range between 15 to 20 kg S/ha/yr ([Figure 2-35](#)).

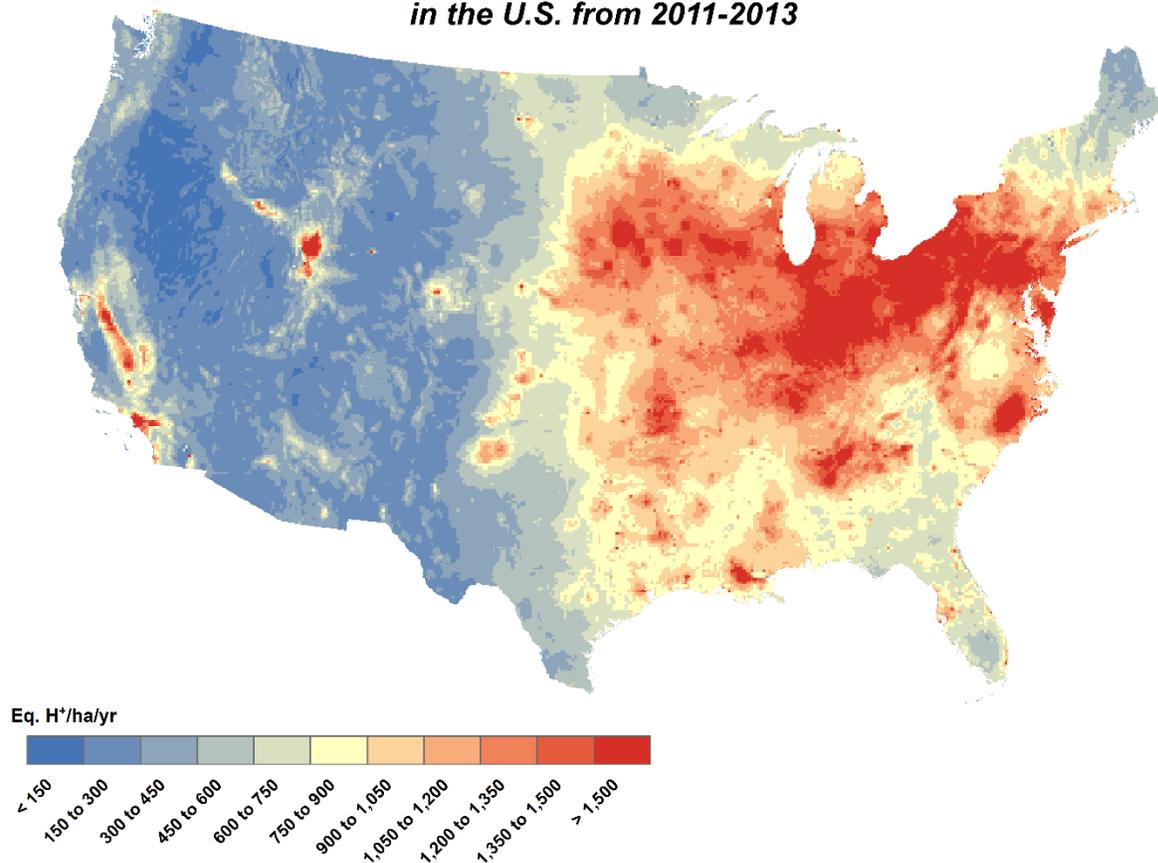

18 Both N and S deposition contribute to acidification of ecosystems. The pH of rainwater
19 has increased markedly across the U.S. since 1990, coincident with decreases in the wet
20 deposition of nitrate and sulfate. However, there are still widespread areas affected by
21 acidifying precipitation, mainly in the eastern U.S. (see [Appendix 2.7](#)). Total acidifying
22 deposition (wet + dry N + S, expressed as H⁺ equivalents) fluxes for 2011 to 2013 ranged
23 from a few hundred H⁺ equivalents/ha/yr over much of the western U.S. to over 1,500 H⁺
24 equivalents/ha/yr in a broad swath encompassing the Midwest and the Mid-Atlantic
25 regions, and in other isolated hotspots surrounding areas of concentrated industrial or
26 agricultural activity ([Chapter 1, Figure 1-6](#)).

ha = hectare; kg = kilogram; N = nitrogen.

***H⁺ Equivalents of Total Nitrogen and Sulfur Deposition
in the U.S. from 2011-2013***

Eq. = equivalents; H⁺ = hydrogen ion; ha = hectare; yr = year.
Source: NCEA using data from TDEP.

Figure 1-6 Total deposition of total oxidized nitrogen, reduced nitrogen, and oxidized sulfur expressed as H⁺ equivalents per hectare per year over the contiguous U.S. 2011–2013.

1
2 Dry deposition rates are a strong function of surface characteristics, which modify the
3 structure of surface layer turbulence and the resistance to uptake by vegetation
4 ([Appendix 2.5.2](#)). As a result, spatially aggregated estimates of dry deposition fluxes are
5 subject to sizable uncertainty, in addition to inherent uncertainties in the measurement of
6 species concentrations and in the inference of dry fluxes. Wet fluxes are not directly
7 influenced by surface characteristics (although orography affects transport and
8 precipitation) but are subject to smaller uncertainties in the measurement of rainfall and
9 chemistry.

1.4 Gas-Phase Direct Phytotoxic Effects

1 New evidence supports the causal determinations made in the 2008 ISA regarding
2 gas-phase effects on vegetation, and there are no new causal statements for gas-phase
3 effects. As in the 2008 ISA, the current ISA concludes that there are causal relationships
4 between SO₂, NO₂, NO, PAN, HNO₃, and injury to vegetation. This determination is
5 based on consistent, coherent, and biologically plausible evidence ([Appendix 3.2](#),
6 [Appendix 3.3](#), and [Appendix 3.4](#); [Chapter 1, Table 1-1](#)). The clearest evidence for these
7 conclusions comes from studies available at the time of the 2008 ISA. There have been
8 some additional studies since the 2008 ISA. The majority of evidence on the direct
9 effects of gaseous NO_y and SO_x comes from controlled exposure studies across many
10 species of vegetation. The majority of controlled exposure studies over the past several
11 decades have used concentrations of gas-phase NO_y and SO_x above current ambient
12 conditions observed in the U.S. Relevant information is lacking on exposures and effects
13 reflecting the more recent lower pollutant conditions. Therefore, there is little evidence
14 available to inform whether current monitored concentrations of gas-phase NO_y and SO_x
15 are high enough to injure vegetation.

1.4.1 Sulfur Dioxide

16 In the 2008 ISA, evidence was sufficient to infer a causal relationship between exposure
17 to SO₂ and injury to vegetation. The current secondary standard for SO₂ is a 3-hour
18 average of 0.50 ppm, which is designed to protect against acute foliar injury in
19 vegetation. There has been limited research on acute foliar injury since the 1982 PM-SO_x
20 Air Quality Criteria Document (AQCD), and there is no clear evidence of acute foliar
21 injury below the level of the current standard. The limited new research since 2008 adds
22 more evidence that SO₂ can have acute negative effects on vegetation but does not
23 change conclusions from 2008 ISA regarding the causal relationship between SO₂
24 exposure and vegetation damage or the SO₂ levels producing these effects (see
25 [Appendix 3.1](#)). Consistent with the 2008 ISA, **the body of evidence is sufficient to infer**
26 **a causal relationship between gas-phase SO₂ and injury to vegetation.**

27 Increased SO₂ exposure concentrations and longer exposure times are associated with
28 decreases in plant growth and yield. The 1982 PM-SO_x AQCD concluded that more
29 definitive concentration-response studies were needed before useable exposure metrics
30 could be identified. However, very few studies of the effects of SO₂ on the growth of
31 vegetation in the U.S. have been conducted since 1982. Recent studies from eastern
32 Europe indicate recovery of tree growth in response to decreases in SO₂ concentrations
33 since the 1980s and that annual SO₂ concentrations of 4 ppb decreased silver fir (*Abies*

1 *alba*) growth. In West Virginia, the growth of eastern red cedar (*Juniperus virginiana*)
2 trees increased with declines in SO₂ emissions since the 1980s.

1.4.2 Nitrogen Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate

3 In the 2008 ISA, evidence was sufficient to infer a causal relationship between exposure
4 to NO, NO₂, and PAN and injury to vegetation. It is well known that in sufficient
5 concentrations, NO, NO₂, and PAN can have phytotoxic effects on plants through
6 decreased photosynthesis and induction of visible foliar injury. However, the 1993
7 Oxides of Nitrogen AQCD concluded that concentrations of NO, NO₂, and PAN in the
8 atmosphere are rarely high enough to have phytotoxic effects on vegetation ([U.S. EPA,
9 1993](#)), and very little new research has been performed at concentrations currently
10 observed in the U.S. (see [Appendix 3.3](#)). Thus, consistent with the previous 2008 ISA,
11 **the body of evidence is sufficient to infer a causal relationship between gas-phase
12 NO, NO₂, and PAN and injury to vegetation.**

1.4.3 Nitric Acid

13 In the 2008 ISA, evidence was sufficient to infer a causal relationship between exposure
14 to HNO₃ and changes to vegetation. The 2008 ISA reported experimental exposure to
15 HNO₃ resulted in damage to the leaf cuticle of pine and oak seedlings, which may
16 predispose those plants to other stressors such as drought, pathogens, and other air
17 pollutants. Since the 2008 ISA, ([Padgett et al., 2009b](#)) investigated dry deposition of
18 HNO₃ on the foliage in a fumigation study and confirmed the earlier research. The 2008
19 ISA also reported several lines of evidence that past and current HNO₃ concentrations
20 may be contributing to the decline in lichen species in the Los Angeles basin. Subsequent
21 studies conducted in the Los Angeles basin since the 2008 ISA provide further evidence
22 of the impacts (see [Appendix 3.4](#)). These new studies continue to support the causal
23 findings of the 2008 ISA, such that **the body of evidence is sufficient to infer a causal
24 relationship between gas-phase HNO₃ and changes to vegetation.**

1.5 Terrestrial Ecosystem Nitrogen Enrichment and Acidification

25 For terrestrial ecosystems, new evidence reinforces causal findings from the 2008 ISA
26 and provides the basis for two new causal statements that reflect a more comprehensive
27 understanding of how N and acidifying deposition alter terrestrial ecosystem biota
28 ([Chapter 1, Table 1-1](#)). In general, N deposition may cause soil N enrichment and

1 stimulate the growth of opportunistic species. However, in sensitive soils, deposition of N
2 and/or S can cause soil acidification, which may decrease growth and cause mortality
3 among sensitive plant species. Atmospheric deposition of N and S alter the species
4 composition of terrestrial systems by one of four mechanisms: (1) nutrient enrichment
5 (eutrophication; [Appendix 4](#) and [Appendix 6](#)), (2) acidification ([Appendix 4](#) and
6 [Appendix 5](#)), (3) direct damage ([Appendix 3](#)), and (4) secondary effects (e.g., wildfire;
7 [Appendix 6](#)). Ecosystems and communities may be simultaneously affected by one or
8 more mechanisms depending on the sensitivity of environmental and biological
9 properties to each mechanism.

10 Despite the abundance of N in the environment, plants are unable to directly access the
11 large pools of N contained in the atmosphere as N₂ gas and in the soil as large organic
12 molecules. Consequently, the limited availability of reactive N often constrains biological
13 activity in terrestrial ecosystems. Thus, N deposition is considered nutrient enrichment
14 because N additions generally stimulate plant growth and productivity (cumulative
15 growth of all vegetation within a community), which has been recognized since the
16 second half of the 19th century. In comparison, the biological influence of acidifying
17 deposition is less ubiquitous and largely constrained to ecosystems with historically high
18 rates of deposition and vulnerable because of factors such as geology and climate. While
19 S is also an essential macronutrient, less S is required for growth than N, and areas
20 affected by acidifying deposition typically receive S at rates that greatly exceed biotic
21 demand. Instead, the impact of acidifying deposition stems from the disruptions to
22 biochemical processes caused by decreased pH and shifts in soil physiochemical
23 processes that decrease the supply of other essential nutrients (e.g., Ca, Mg) and increase
24 the mobilization of toxic forms of Al.

25 Current knowledge of soil biogeochemistry indicates soil N enrichment and soil
26 acidification occur in sensitive ecosystems across the U.S. at present levels of deposition.
27 Newly published work indicates decreasing SO₂ emissions and S deposition have led to
28 early signs of recovery from acidification in some northeastern watersheds, but areas in
29 the Southeast do not show recovery ([Appendix 4](#)). There are many well-defined soil
30 indicators related to the biological effects of acidifying (N + S) deposition. New evidence
31 uses these indicators to describe the status of ecosystems, either by empirical observation
32 or models. Soil indicators for acidification are more typically modeled than those for
33 eutrophication effects. There is an abundance of new information on biogeochemical
34 pools and processes, including a new conceptual framework for the N saturation of
35 terrestrial ecosystems.

36 The enrichment of terrestrial ecosystems by N deposition often increases plant
37 productivity and causes changes in physiology and growth rates that vary among species.

1 This has been observed for herbaceous plants and trees across ecoregions. The changing
2 growth rates transform competitive interactions between species, and as a consequence
3 lower species diversity is often observed with increasing N deposition within terrestrial
4 communities. The relationship between N deposition and community composition is
5 often derived empirically as critical loads. There are many new critical loads available
6 since the 2008 ISA, including those for lichens, herbaceous plants, and mycorrhizae.

7 The process of terrestrial acidification has been well understood and documented for
8 decades. Recent research, since the 2008 ISA, has confirmed and strengthened this
9 understanding and provided more quantitative information, especially across
10 regional-scale landscapes. A number of studies have evaluated the relationships between
11 soil chemistry indicators of acidification and ecosystem biological endpoints (see
12 [Table 5-6](#)), and some models are well established. There have been new advances in the
13 parameterization of acidification models to U.S. soils since the 2008 ISA ([Appendix 4.5](#))
14 resulting in better certainty of critical loads. Biological endpoints included in the
15 evaluations include physiological and community responses of trees and other vegetation
16 (such as lichens), soil biota, and fauna.

17 The following section summarizes the main effects of N and S deposition on terrestrial
18 ecosystems.

1.5.1 Soil Biogeochemistry

19 In the 2008 ISA, evidence was sufficient to infer causal relationships between
20 (1) acidifying deposition and changes in terrestrial biogeochemistry and (2) between N
21 deposition and terrestrial biogeochemical cycling of N. There is new evidence of how
22 deposition contributes to total loading in ecosystems, as well as new information from
23 addition, gradient, and time-series studies characterizing how deposition affects soil pools
24 and processes. Much of the new work focuses on the effects of N deposition, with
25 relatively little work focusing on S deposition. Soil N enrichment and soil acidification
26 occur in sensitive ecosystems across the U.S. at present levels of deposition. Decreasing
27 S emissions have led to early signs of recovery from acidification in some northeastern
28 watersheds, but areas in the Southeast do not show recovery. Deposition rates of total N
29 ($\text{NO}_Y + \text{NH}_X$) are relatively unchanged across much of the CONUS ([Appendix 2.7](#)).
30 Accordingly, there are no signs of recovery from N enrichment effects. Critical load
31 determinations have been made at the ecoregion scale for NO_3^- leaching. Critical loads
32 for biological effects are summarized below ([Chapter 1.5.1.2](#), [Chapter 1.5.2.2](#), and
33 [Chapter 1.5.3.3](#)). **The body of evidence is sufficient to infer a causal relationship**

1 **between N and S deposition and alteration of soil biogeochemistry in terrestrial**
 2 **ecosystems**, which is consistent with the conclusions of the 2008 ISA.

1.5.1.1 Soil Processes and Indicators

3 Deposition of N or N + S alters soil chemistry, which can have cascading effects on
 4 aquatic ecosystems (for effects on aquatic biology and chemistry see
 5 [Appendix 7–Appendix 10](#)). Soil acidification is a natural process that can be accelerated
 6 by N or S deposition. Deposition in the forms of HNO₃ and H₂SO₄ can directly acidify
 7 soils; however, deposition of reduced forms of N (e.g., NH_x) can also cause soil
 8 acidification by releasing hydrogen ions (H⁺) during the microbial oxidation of NH₄⁺ to
 9 NO₃⁻. There are a number of soil geochemical processes associated with acidification
 10 ([Chapter 1, Table 1-2](#)). Base cations counterbalance acid anions. Base cations are added
 11 to the soil solution by weathering and atmospheric deposition and are removed by
 12 leaching and biological uptake. Where acidifying deposition rates are high relative to
 13 base cation input, this deposition can deplete exchangeable base cation pools in soils.
 14 There are several useful indicators of soil acidification ([Chapter 1, Table 1-2](#)) that have
 15 quantitative relationships to biological responses ([Appendix 5](#)).

Table 1-2 Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Process			
N saturation	X	X	New empirical evidence suggests revising the N saturation concept, specifically it is now observed that NO ₃ ⁻ leaching can occur even if the ecosystem N capacity to retain N has not yet been saturated.
Soil N accumulation	X	X	New meta-analysis across ecosystem types confirms inorganic soil NO ₃ ⁻ concentration increases with N addition. New gradient study confirms that N concentration increases with N deposition. New addition study confirms increased soil N accumulation. New studies on Soil N accumulation are summarized in Table 4-3 .

Table 1-2 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
NO ₃ ⁻ leaching	X	X	<p>New meta-analysis confirms leaching increases with N additions. Regional-scale gradient analyses: <8 kg N/ha/yr onset of leaching; <1 kg N/ha/yr in European forests; in the NE U.S., 90% retention for sites receiving 7 kg N/ha/yr to 60% retention for sites receiving 11 kg N/ha/yr.</p> <p>New USFS critical loads for the onset of leaching: 8–10 kg N/ha/yr in eastern and western U.S., 17 kg N/ha/yr in the Sierra Nevada and San Bernardino Mountains. New studies on Soil N accumulation are summarized in Table 4-3.</p>
S accumulation and adsorption		X	<p>Some soils (notably in many watersheds in the SE U.S.) have the capacity to adsorb substantial quantities of S, with essentially no acidification of drainage water. Nevertheless, S adsorption capacity is finite, and under continual high S deposition loading, the adsorptive capacity of soil will eventually be exceeded.</p> <p>New studies of 27 watersheds in the SE indicate most will begin releasing SO₄²⁻ in the next two decades; NE watersheds show a net loss of S from soils now in response to decreased levels of atmospheric S deposition. New studies on soil S accumulation are summarized in Table 4-4.</p>
SO ₄ ²⁻ leaching		X	<p>Atmospheric S deposition generally increases leaching of SO₄²⁻ to surface waters. The amount of deposition that causes the onset of leaching varies across the landscape. New studies on soil SO₄²⁻ leaching are summarized in Table 4-4.</p>
Base cation leaching and exchange		X	<p>Base cation (Ca, Mg, K, Na) release from soil particles to the soil solution occurs in response to the input of acid anions (SO₄²⁻ and NO₃⁻) from deposition.</p> <p>New studies confirm base cation depletion continues to occur in the Rocky Mountains (threshold 28 kg N/ha/yr) and in U.K. grasslands, while in a NE forest, 17 yr of N addition did not cause further depletion. A meta-analysis suggests cation depletion early after increased deposition of acid anions, but this depletion tapers off with time. New studies on base cation leaching and exchange are summarized in Table 4-5.</p>
Al mobilization		X	<p>The threshold for inorganic Al mobilization from soil is <15–20% soil base saturation. This is an extremely important effect of acidifying deposition because inorganic monomeric Al is toxic to biota (Appendix 5 and Appendix 8). Inorganic Al is minimally soluble at pH 6.0, but solubility increases steeply at pH below 5.5.</p> <p>New studies on Al in soils are summarized in Table 4-6.</p>

Table 1-2 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Nitrification	X	X	Nitrification releases 2 mol hydrogen ion (H ⁺) per mol NH ₄ ⁺ converted to NO ₃ ⁻ , acidifying soils. As soil inorganic N accumulates, net nitrification rates often increase, and NO ₃ ⁻ can leach from the ecosystem. New N gradient and meta-analysis studies confirm N addition increases nitrification. New studies on nitrification are summarized in Table 4-6 .
Denitrification	X		Denitrification is the microbial reduction of NO ₃ ⁻ to NO ₂ ⁻ , NO, the greenhouse gas N ₂ O, and N ₂ , which occurs under anaerobic conditions. In Europe, soil switched from a source to a sink after two decades of N deposition exclusion. New meta-analysis confirms N addition increases denitrification rates. New studies on denitrification are summarized in Table 4-6 .
DOC leaching	X	X	In recent years, the DOC of many lakes and streams has risen, with the source likely from the soils in the adjacent terrestrial watershed. However, the mechanism causing the observed increase is unclear and may be due to a combination of soil recovery from acidification, changes in climate (e.g., temperature and precipitation), and N deposition among other mechanisms. New studies are summarized in Table 4-10 .
Decomposition	X	X	The addition of N can stimulate the breakdown of labile compounds that degrade during the initial stages of decomposition, but added N can suppress the decomposition of more recalcitrant material. There are new addition studies and meta-analysis on mechanisms and response trends. New studies are summarized in Table 4-8 .
Indicator			
Soil [N]	X	X	Increases in soil [N] indicate soil N accumulation and the size of the soil N pool that may be assimilated by organisms or mobilized via leaching.
Soil C:N ratio	X	X	Decreasing soil C:N linked to changes in decomposition and increases in nitrification and NO ₃ ⁻ leaching. <20–25 causes increased nitrification and elevated risk of NO ₃ ⁻ leaching in the U.S. and <25–30 for increased NO ₃ ⁻ leaching in Europe.
Soil base saturation		X	Increasing N + S deposition decreases the soil pool of exchangeable base cations. <15–20% exchange ion chemistry is dominated by inorganic Al and may cause injury to vegetation (see Appendix 5).

Table 1-2 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Soil Bc:Al ratio		X	Increasing N + S deposition decreases the soil pool of exchangeable base cations, often decreasing the Ca:Al ratio. Ca:Al <1.0 causes physiological stress, decreased growth, and mortality of sensitive plant species (see Appendix 5).
Fungi-to-bacteria ratio	X		New indicator: Increasing N deposition decreases the fungi-to-bacteria ratio and causes a transition from N to C limitation among soil food webs.

Al = aluminum; Al³⁺ = aluminum(III); Bc = base cations; C = carbon; Ca = calcium; DOC = dissolved organic carbon; H⁺ = hydrogen ion; ha = hectare; K = potassium; kg = kilogram; Mg = magnesium; N = nitrogen; N₂ = molecular (atmospheric) nitrogen; N₂O = nitrous oxide; Na = sodium; NE = northeastern; NH₄⁺ = ammonium; NO = nitric oxide; NO₂⁻ = nitrite; NO₃⁻ = nitrate; S = sulfur; SE = southeastern; SO₄²⁻ = sulfate; U.S. = United States; USFS = U.S. Forest Service; U.K. = United Kingdom; yr = year.

1

2 Some of the same processes and indicators associated with acidification are also

3 associated with the N enrichment of soils in response to the input of exogenous N

4 ([Appendix 4.3](#)). The 2008 ISA documented that the increase in global reactive N (defined

5 as NO_y + NH_x + organic N) that occurred over the previous century was largely due to

6 three main causes: (1) widespread cultivation of crops that promote conversion of N₂ gas

7 to organic N through biological N fixation, (2) fossil fuel combustion converting

8 atmospheric N₂ and fossil N to NO_x, and (3) the Haber-Bosch process, which converts

9 nonreactive N₂ to reactive N to sustain food production and some industrial activities

10 ([Galloway et al., 2003](#); [Galloway and Cowling, 2002](#)).

11 The 2008 ISA documented that atmospheric deposition of N can increase soil N. Soil N

12 accumulation is linked to increased N leaching and decreased retention of N. Critical

13 loads for the onset of elevated NO₃⁻ leaching are given in [Appendix 4.6.2.2](#).

14 The 2008 ISA described the conceptual model of N saturation, which occurs when N

15 input rates to terrestrial ecosystems exceed the uptake capacity of the soils and biota, and

16 is indicated by the onset of increased soil N leaching. However, more recent work has

17 revised the N saturation model in response to observations in which N leaching resulted

18 from N input rates that are faster than vegetation and soil uptake rates, thus distinguishing

19 capacity N saturation from kinetic N saturation. Budgets from 83 forested watersheds in

20 the northeast U.S. show that N retention averages 76% of the incoming atmospheric N

21 deposition and decreases from 90% retention at 7 kg N/ha/yr of deposition to 60%

22 retention at 11 kg N/ha/yr of deposition.

1 The 2008 ISA documented that N enrichment is associated with changes in microbially
2 mediated biogeochemical processes, including nitrification, denitrification, and
3 decomposition ([Appendix 4.3](#)). The addition of N can increase nitrification (the microbial
4 conversion of NH_4^+ to NO_3^-), which contributes to soil acidification. Nitrification is often
5 stimulated in soils with a C:N ratio below approximately 20 to 25, which can be
6 decreased by N deposition. The NO_3^- created by nitrification may be leached or
7 denitrified. Denitrification is the microbial reduction of NO_3^- to NO_2^- , NO, the
8 greenhouse gas N_2O , and N_2 , which occurs under anaerobic conditions. Several syntheses
9 have been published since 2008 evaluating N addition effects on denitrification and
10 nitrification in terrestrial ecosystems. A new meta-analysis shows N addition
11 substantially increases denitrification from many types of ecosystems (e.g., coniferous
12 forest, deciduous forest, tropical forest, wetland, grassland), except heathlands. Among
13 five chemical forms of N studied, NO_3^- addition showed the strongest stimulation of N_2O
14 emission. Using data extracted from 206 peer-reviewed papers, a second meta-analysis
15 observed that the largest changes in the ecosystem N cycle caused by N addition were
16 increased nitrification (154%), N_2O emissions (134%), and denitrification (84%).

17 About one-half of C fixed annually during photosynthesis by terrestrial vegetation is
18 allocated to belowground C processes; therefore, it is important to understand how N
19 affects belowground C to better understand changes in plant physiology, plant growth,
20 and ecosystem C cycling ([Appendix 6](#)). Many studies have shown that changes in
21 belowground C cycling do not always parallel shifts in aboveground C cycling, making
22 extrapolation from aboveground responses to belowground processes inappropriate. New
23 studies published since 2008 ([Appendix 4.3.10](#)) have generally found that N addition
24 increases aboveground litter inputs (+20%), inhibits CO_2 loss via microbial respiration
25 (-8%), and decreases microbial biomass carbon (-20%). Dissolved organic carbon
26 concentrations increased (+18%), suggesting C leaching loss may increase. The addition
27 of N increased the C pool size within the soil organic horizon (+17%), attributed to both
28 increased litter input and decreased decomposition (inferred from the lower microbial
29 respiration rates).

30 The effect of N on organic matter decomposition is an active area of research
31 ([Appendix 4.3.9](#)). Decomposition primarily occurs through the leaching of soluble
32 chemicals, the depolymerization of complex biomolecules by microbial extracellular
33 enzymes, and the microbial assimilation of nutrients. Bacteria and fungi are the primary
34 microbial decomposers of organic matter. Both microbial community composition (see
35 [Appendix 6](#)) and microbial enzyme activity can respond to shifts in inorganic N and
36 substrate availability. Within the literature, litter decay rates have long been correlated
37 with the ratio of N to C or lignin in litter. Based on these observations, it could be
38 assumed that added N would stimulate decomposition and the loss of C from soil pools.

1 However, the stimulatory effects of N on decomposition are limited to the early stages of
2 mass loss, and the addition of N slows the later stages of decomposition that are
3 controlled by the degradation of recalcitrant compounds. In general, N additions decrease
4 respiration from soil heterotrophs, but do not necessarily decrease total soil respiration
5 because heterotrophic respiration accounts for only a portion of the soil CO₂ efflux.

1.5.1.2 National-Scale Sensitivity and Critical Loads

6 As of the 2008 ISA, the regions of the U.S. with abundant acid-sensitive soils had been
7 well delineated. These acid-sensitive ecosystems are generally located in mountainous
8 terrain in the eastern U.S. and are underlain by bedrock resistant to weathering. However,
9 a similar delineation of the areas sensitive to the eutrophication effects of N had not yet
10 been completed. There is strong evidence demonstrating that biogeochemical sensitivity
11 to deposition-driven eutrophication and acidification is the result of historical loading,
12 geologic/soil conditions (e.g., mineral weathering and S adsorption), and/or natural
13 sources of N and S loading to the system. There is no single deposition level applicable to
14 all ecosystems in the U.S. marking the onset of eutrophication or acidification.

15 Several new publications report the results of field observations and modeling studies on
16 soil recovery from acidification, specifically in the northeastern U.S., and the lack of
17 recovery in the southern Appalachian Mountains ([Table 4-18](#)). New ecoregion-scale
18 terrestrial critical loads for NO₃⁻ leaching were published in 2011 and have been updated
19 by more recent published work. However, the most recent national-scale assessment of
20 soil acidification was published in 2007.

1.5.2 Biological Effects of Terrestrial Nitrogen Enrichment

21 The enrichment of terrestrial ecosystems by N deposition often increases plant
22 productivity and causes changes in physiology and growth rates that vary among species.
23 This combination of effects can alter the composition and decrease diversity of terrestrial
24 communities by transforming competitive interactions between species and changing the
25 availability of other essential resources, including light, water, and nutrients. Because N
26 deposition can cause both eutrophication and acidification and these processes can occur
27 simultaneously, the relationship between N deposition and community composition has
28 often been derived empirically. Many of the effects of N deposition are similar across
29 ecosystems and life forms because N is an essential macronutrient, but the composition
30 and magnitude of how these effects are expressed within an ecosystem can differ as a
31 result of biotic and abiotic influences. Consequently, as with the 2008 ISA, we have

1 grouped the effects of N deposition on physiology and biodiversity by biome (e.g., forest,
2 tundra, grassland, and arid lands), with further framing by life form (e.g., plants,
3 microorganisms) and functional groups (e.g., trees, herbaceous plants). In comparison,
4 the broadest CLs created by the scientific community are at the ecoregion level, in which
5 spatial boundaries across the landscape are typically defined based on ecological,
6 climatological, and geological differences.

7 The 2008 ISA documented consistent evidence that N additions increased plant
8 productivity across a wide range of terrestrial ecosystems. Since 2008, a large body of
9 new research on the biological effects of added N in terrestrial ecosystems has been
10 published from investigations of plant and microbial physiology, long-term
11 ecosystem-scale N addition experiments, regional and continental-scale monitoring
12 studies, and syntheses. These studies have been conducted in ecosystems representing
13 biomes in the U.S., including tundra, grasslands, arid and semiarid lands, and tropical,
14 temperate, and boreal forests. As a consequence of the breadth of this research, there is a
15 strong mechanistic and empirical understanding for many of the biological effects of
16 added N. **This body of evidence is sufficient to infer a causal relationship between N
17 deposition and the alteration of the physiology and growth of terrestrial organisms
18 and the productivity of terrestrial ecosystems.**

19 The varying effects of N deposition on the growth and physiology of individual species
20 have consequence for biodiversity. In the 2008 ISA, evidence was sufficient to infer a
21 causal relationship between N deposition and the alteration of species richness, species
22 composition, and biodiversity in terrestrial ecosystems. The 2008 ISA documented
23 consistent evidence of reduced species richness and altered community composition from
24 N addition studies in the U.S. and N deposition gradient studies in Europe for grassland
25 plant diversity, forest understory plants, and forest mycorrhizal fungi. There was also
26 consistent evidence of altered plant and mycorrhizal community composition from N
27 addition studies in arid and semiarid ecosystems, particularly in southern California.
28 There was little evidence of changes in forest overstory tree composition. Since the 2008
29 ISA, new research techniques have been developed to understand community
30 composition, a larger number of communities have been surveyed, and new regional and
31 continental-scale studies have made it possible to isolate the influence of N deposition
32 from other environmental factors. This new research has provided more extensive and
33 mechanistic evidence, and combined with the findings of the 2008 ISA, **this body of
34 evidence is sufficient to infer a causal relationship between N deposition and the
35 alteration of species richness, community composition, and biodiversity in
36 terrestrial ecosystems.**

1.5.2.1 Physiology and Biodiversity

1 At the time of the 2008 ISA, terrestrial ecologists had used meta-analyses to broadly
2 quantify the effects that N deposition can have on the growth of terrestrial plants,
3 concluding that N additions stimulate plant productivity by 20–30% in grasslands,
4 forests, tundra, and wetlands, increase aboveground productivity in herbaceous plant
5 communities, alter plant tissue chemistry, decrease biomass of mycorrhizal fungi, and
6 alter litter decomposition ([Appendix 6.6.1](#)). Recent research has provided further
7 coherent and consistent evidence that N additions stimulate plant growth and
8 productivity, but this research is still dominated by studies of temperate ecosystems and
9 aboveground plant responses ([Figure 6-1](#) and [Figure 6-2](#)).

10 In the 2008 ISA, the positive plant growth response to N deposition was attributed to
11 higher rates of photosynthesis. However, evidence for this is mixed: increases in
12 photosynthesis following N additions have been observed across a variety of plant
13 functional types, but higher rates of photosynthesis have not been consistently observed
14 in response to chronic N additions meant to simulate atmospheric deposition. There is
15 new support for another mechanism that would increase aboveground growth: decreases
16 in the quantity of C allocated by plants to roots, mycorrhizae, and root exudation. There
17 was evidence in the 2008 ISA that N additions increase aboveground biomass more than
18 belowground biomass, raising the shoot-to-root ratio among plants, but evidence is now
19 more consistent and widespread. Plants invest substantial amounts of C to support
20 mycorrhizal fungi, but there is evidence this investment declines when N is added to
21 terrestrial ecosystems. Similarly, there is mounting evidence that plants can increase root
22 exudation as N availability decreases.

23 Evidence that biodiversity change can be a consequence of N deposition has accumulated
24 since 2008 and includes new information for major taxonomic groups, including
25 herbaceous plants, overstory trees, and two groups of symbionts (lichens and
26 mycorrhizae). Evidence is now more widespread for decreases in lichen species richness
27 as the result of N deposition in the U.S. There are direct observations that N deposition in
28 the U.S. is changing mycorrhizal community composition and altering herbaceous plant
29 species richness across a broad range of ecosystems, including forests, grasslands, arid
30 and semiarid ecosystems, and alpine tundra. In addition, based on changes in mortality
31 and growth rates of dominant tree species, there is also indirect evidence that N
32 deposition is altering overstory tree community composition.

33 A substantial body of research linking changes in biodiversity to shifts in N availability
34 has been developed. Within this body of research, there is evidence that (1) rare species
35 are particularly vulnerable to loss and (2) organisms with specific traits will have either
36 positive or negative responses in growth and survival when N is added. Both mechanisms

1 can operate simultaneously and both mechanisms tie the changes in physiology, growth,
2 and productivity caused by increased N availability to declines in biodiversity.

3 As noted in [Appendix 4](#), soil microorganisms have important roles in regulating N and C
4 cycling. There are several mechanisms to alter soil microbial biomass and physiology,
5 including changes in soil pH, increases in inorganic N availability, shifts in soil food
6 webs, and changes in the quantity and quality of available C. There were some
7 observations in the 2008 ISA that added N decreases microbial biomass, but there is now
8 more evidence that added N generally negatively or neutrally affects microbial biomass C
9 and microbial biomass N ([Table 6-4](#)).

1.5.2.1.1 Forests

10 Forests occur within every U.S. state, but are most abundant in the eastern U.S., montane
11 and coastal portions of the western U.S., and Alaska. The distribution of forests is bound
12 by water availability, cold temperatures, and land management. In the 2008 ISA, there
13 was consistent evidence that N additions stimulated forest productivity, but these
14 responses varied widely and included both neutral and negative effects of N additions on
15 tree growth. However, there had been no empirical analyses of how atmospheric N
16 deposition altered forest productivity in the U.S. at broad scales. The 2008 ISA lacked
17 information on whether N deposition had any impact on the diversity and composition of
18 forest overstory trees, but did present evidence for changes in the composition of
19 herbaceous vegetation, epiphytic lichens, and microbial communities. The addition of
20 new research since the 2008 ISA provides coherent evidence that N deposition alters the
21 physiology, growth, and community composition of overstory trees, understory plants,
22 lichens, mycorrhizal fungi, soil microorganisms, and arthropods.

23 As of the 2008 ISA, most long-term N addition experiments were located in temperate
24 forests in the northeastern U.S. or in temperate or boreal forests in Europe. In these
25 studies, conifer species were less likely than broadleaf species to exhibit positive growth
26 responses to added N and more frequently exhibited increased mortality and decreased
27 growth. Since the 2008 ISA, a number of new observations from experiments, forest
28 inventory studies, model simulations, and data synthesis efforts have been published
29 quantifying increases in forest net primary productivity (NPP), net ecosystem
30 productivity (NEP), and ecosystem C storage ([Figure 6-3](#)). Overall, evidence is consistent
31 that N deposition increases forest ecosystem C storage, including specific evidence
32 indicating that current rates of N deposition in the northeastern U.S. broadly stimulate
33 aboveground forest productivity.

1 Many of the observations in the 2008 ISA about how long-term N additions affected
2 forest mortality and aboveground productivity have been reinforced by more recent
3 research, including long-term forest inventory data collected from across the eastern U.S.
4 and in Europe. Growth and mortality responses have apparent links to plant functional
5 traits; for example, several conifer species common to the northeastern U.S. exhibited
6 negative growth responses in both long-term N addition experiments and in an analysis of
7 forest inventory data. Tree species hosting arbuscular mycorrhizal fungi also showed
8 increased growth in response to N additions and N deposition.

9 Analyses of forest inventory from the eastern U.S. have not directly assessed changes in
10 overstory tree composition, but the evidence of species-specific effects on growth and
11 mortality observed in these studies suggest that changes in community composition are
12 occurring. These analyses represent an advancement in our understanding from the time
13 of the 2008 ISA, when the impact of N deposition on the composition of forest overstory
14 trees was unclear.

15 In comparison, there is direct evidence that N deposition is altering the composition of
16 forest understory plant communities. The evidence for altered forest understory plant
17 communities (also known as herbaceous layer or groundcover vegetation) comes from
18 both the 2008 ISA and from the more recent literature. Changes in understory plant
19 communities have been observed in monitoring plots along atmospheric N deposition
20 gradients in the U.S. and in Europe. In Europe, forest understory plant communities have
21 shifted toward more nutrient-demanding and shade-tolerant plant species.

22 Higher rates of aboveground tree growth in response to N deposition might be due to
23 shifts in C allocation away from belowground processes. Changes in C allocation in
24 response to additional N have been accompanied by decreases in the abundance of
25 mycorrhizal fungi and changes in mycorrhizal community composition ([Table 6-2](#),
26 [Table 6-14](#)). Evidence for composition change is particularly abundant in
27 ectomycorrhizal fungal communities ([Table 6-14](#)); there are fewer observations of how
28 arbuscular mycorrhizal fungal communities change in response to N additions ([Table 6-3](#);
29 [Table 6-16](#)). There are also numerous observations of altered total microbial (including
30 bacterial) biomass and community composition. For microbial biomass, most studies
31 identified since 2008 observed either negative or neutral effects of N additions, consistent
32 with results of syntheses published before the 2008 ISA ([Table 6-4](#)). Changes in soil
33 microbial community composition were identified along an N deposition gradient in
34 Europe and in all three N addition studies. The effects of N additions on individual
35 microbial taxonomic groups (bacteria, archaea, fungi, etc.) have been less consistent
36 ([Table 6-15](#)). Overall, there is evidence that N additions can decrease total microbial
37 biomass and alter microbial communities in forest soils.

1 Within soil food webs, soil microorganisms have both direct and indirect links to
2 arthropods. Because arthropods feed upon both microorganism and litter, they can be
3 important regulators of decomposition, nutrient cycling, and forest productivity. Several
4 studies have examined the response of forest arthropod communities to added N,
5 including a group of studies on insect herbivores conducted in southern California
6 ([Table 6-17](#)). There is coherent evidence that N additions can alter forest arthropod
7 communities.

8 Epiphytic lichens have long been recognized as sensitive to air pollution. Although these
9 organisms often make up a small portion of forest biomass, they have important roles in
10 hydrologic cycling, nutrient cycling, and as sources of food and habitat for other species.
11 New research on lichen community composition identified since the 2008 ISA has further
12 added to the consistent and coherent evidence that lichen communities in the U.S. and
13 Europe are sensitive to current levels of atmospheric N deposition ([Appendix 6.2.6](#);
14 [Table 6-23](#)). In particular, the U.S. Forest Service's Forest Inventory and Analysis
15 Program has ample data on the abundance of lichens throughout the U.S., and shifts in
16 lichen community composition clearly attributable to atmospheric N pollution have been
17 observed in forests throughout the West Coast, in the Rocky Mountains, and in
18 southeastern Alaska. Shifts in epiphytic lichen growth or physiology have been observed
19 along atmospheric N deposition gradients in the highly impacted area of southern
20 California, but also in more remote locations such as Wyoming and southeastern Alaska,
21 ([Table 6-5](#)). A number of experimental N studies have also created more detailed insight
22 into changes in lichen physiology processes. Overall, there is widespread evidence from
23 forests that N deposition can alter the growth, physiology, and biodiversity of trees,
24 herbaceous plants, lichens, soil microorganisms, and arthropods.

1.5.2.1.2 Tundra

25 Within the U.S., tundra ecosystems are limited to Arctic ecosystems in Alaska and to
26 relatively isolated, high elevation sites in the West. Although these ecosystems tend to be
27 remote, the influence of atmospheric N deposition is distinct and there was evidence in
28 the 2008 ISA indicating that alpine tundra plant communities were sensitive to
29 atmospheric N deposition. Alpine organisms may be more sensitive to N deposition
30 because of the unique nature of N cycling in these ecosystems, which tend to have limited
31 inorganic N availability. Since the 2008 ISA, numerous studies of tundra physiological,
32 productivity, and community composition responses to added N have been published,
33 providing further evidence that N deposition alters the growth and physiology of alpine
34 plant communities, including vascular plants (herbaceous and woody), bryophytes, and

1 lichens ([Appendix 6.2.4](#)), as well as evidence of altered soil microbial communities
2 ([Table 6-8](#); [Table 6-19](#)).

3 As in forests, increases in N content in response to additional N are widespread in tundra
4 plant communities ([Table 6-6](#)). Higher tissue N concentrations in response to added N
5 have been observed in multiple studies for vascular plants, bryophytes, and lichens. The
6 2008 ISA noted that plant growth and biomass responses tended to be species specific.
7 Subsequent studies have confirmed this result ([Table 6-6](#)), showing varying responses to
8 added N among ecosystem types, plant functional groups, and species. Whereas vascular
9 plants tend to show a positive response to added N, both bryophytes and lichens tend to
10 decrease in biomass and cover ([Table 6-5](#); [Table 6-6](#)).

11 Given the varying effects of N addition on species physiology and growth, the numerous
12 observations of N addition impacts on species richness, species diversity, and community
13 composition among vascular plants, bryophytes, and lichens in alpine and Arctic tundra
14 ecosystems are unsurprising ([Appendix 6.3.4](#); [Table 6-18](#)). Within the U.S., these
15 observations have included effects of N additions on plant community composition in
16 Colorado and Washington. In northern Europe, decreases in plant species richness along
17 atmospheric N deposition gradients have been documented. Overall, this new research
18 has provided further evidence that experimental N additions can alter plant biodiversity in
19 alpine and Arctic tundra ecosystems and has provided new evidence that current rates of
20 atmospheric N deposition in Europe are associated with a loss of plant species richness in
21 these ecosystems.

22 There are relatively few observations regarding the effect of N additions on total
23 microbial biomass or the biomass response of individual microbial taxonomic groups in
24 tundra ecosystems, and these results have also been largely inconsistent. However, new
25 research has provided evidence that N additions can alter microbial community
26 composition in alpine tundra ecosystems ([Table 6-8](#); [Table 6-19](#)).

1.5.2.1.3 Grasslands

27 Grasslands are most prevalent in the central U.S., yet also are widely distributed across
28 the U.S. in areas where woody vegetation is excluded by environmental factors or
29 management. There was widespread evidence at the time of the 2008 ISA that the
30 growth, physiology, and productivity of grassland plants could be altered by N
31 deposition. In addition, there were multiple lines of evidence in the 2008 ISA that
32 grassland plant, mycorrhizal, and microbial communities were sensitive to N inputs.
33 Combined with subsequent research, the evidence is clear that physiology, growth, and

1 community composition of plants, mycorrhizae, soil microorganisms, and arthropods are
2 sensitive to N inputs in grasslands.

3 Although NPP can be limited by multiple factors (e.g., water, herbivores, other nutrients)
4 in all ecosystems, these other limitations tend to be more marked in grasslands than
5 forests, making it harder to understand and predict the effects of increased N availability.
6 However, the general response is similar ([Appendix 6.2.5](#)): N additions stimulate NPP,
7 increase foliar N, and increase allocation to aboveground biomass (increased ratio of
8 shoot:root mass).

9 Evidence from the U.S. of grassland plant community composition change in the 2008
10 ISA was based on N addition studies in Mediterranean grasslands in California and
11 northern prairie ecosystems. However, large-scale assessments of biodiversity across
12 observed atmospheric N deposition gradients were restricted to Europe. Recent research
13 provides further evidence that N deposition reduces grassland biodiversity in the U.S. and
14 Europe ([Appendix 6.3.5](#)). Since 2008, there have been direct observations of reduced
15 species richness along atmospheric N deposition gradients for grasslands in the U.S. and
16 Europe. These gradient studies have documented an interaction with soil pH, noting that
17 N deposition causes a greater loss of species richness and a shift in community
18 composition at sites with lower pH. Together, these findings from deposition gradients in
19 the U.S. and Europe provide coherent evidence that N deposition causes shifts in plant
20 community composition and the loss of plant species richness through mechanisms of
21 both acidification and eutrophication. Experimental studies published since 2008 have
22 provided more insight into the mechanisms linking changes in plant and microbial
23 community composition to increased N availability, providing evidence that declines in
24 species richness increase with time and that competition for resources such as water may
25 exacerbate the effects of N addition on diversity.

26 Overall, the additional studies in grassland ecosystems have confirmed that many of the
27 responses observed in the older N addition studies also occur at present rates of
28 atmospheric N deposition. These changes include losses in forb species richness (which
29 make up the majority of grassland biodiversity), greater growth of grass species (which
30 make up the majority of grassland biomass), changes in reproductive rates, as well as
31 shifts in mycorrhizal ([Table 6-16](#)), soil microbial ([Table 6-20](#)), and arthropod
32 populations. In total, due to the prevalence of N limitation in grasslands and the
33 dominance by fast-growing species that can shift in abundance rapidly (in contrast to
34 forest trees), grasslands appear especially sensitive to N input rates comparable to N
35 deposition across much of the contiguous U.S.

1.5.2.1.4 Arid and Semiarid

1 Arid and semiarid ecosystems are abundant in areas of the western U.S. where climate or
2 orography create annually or seasonally dry conditions. At the time of the 2008 ISA, a
3 large amount of information was available on how N deposition affected the growth and
4 physiology of plants and microorganisms in arid and semiarid ecosystems, and there was
5 coherent evidence that plant communities in these ecosystems could be altered by the
6 added N. Evidence for these effects was particularly strong in coastal sage scrub (CSS),
7 chaparral, and Mojave Desert ecosystems in southern California. Within the CSS
8 ecosystems, N deposition has been linked to increased mortality in native shrubs,
9 decreased abundance of arbuscular mycorrhizal fungi, higher cover of invasive annual
10 plants, and increased wildfire activity. Similar increases in invasive annual plant cover
11 and fire frequency have also been attributed to N deposition in areas of the Mojave
12 Desert downwind of urban centers in southern California. Research since 2008 has
13 further documented these effects, with consistent evidence that N deposition can affect
14 the physiology, growth, and community composition of plants and soil microorganisms
15 in arid and semiarid systems.

16 The effects of N deposition on physiological and biogeochemical processes in arid and
17 semiarid ecosystems are even more clearly dependent on moisture availability than in
18 grasslands ([Appendix 6.2.6](#)). In these ecosystems, inorganic N often accumulates in the
19 soil during dry periods, and growth and physiological responses to additional N are only
20 observed when and where sufficient moisture is available. Two additional important
21 effects of aridity include (1) higher soil base saturation and pH that buffer these systems
22 from the acidification effects of N deposition and (2) spatially patchy nutrient availability
23 that develops beneath isolated shrub canopies. One important effect of N deposition on
24 arid and semiarid ecosystems is to decrease the patchiness of nutrient availability, which
25 promotes the growth of invasive annual plants in the spaces between the isolated shrubs.
26 The growth of these annual plants creates a more continuous fuel bed for wildfires,
27 increasing the prevalence of fire, and shifting plant community composition toward more
28 fire-adapted plant species.

29 Since 2008, increases in aboveground plant biomass or plant cover have been observed in
30 the U.S. in the Mojave and Sonoran Deserts, and in southern California chaparral, and
31 internationally in China and Spain ([Appendix 6.2.6](#)). Given the linkage to fire, it is
32 notable that there have been multiple observations of increased annual plant growth in the
33 Mojave Desert in response to added N.

34 New research has also provided further evidence that N deposition alters plant
35 communities in arid and semiarid ecosystems, particularly in southern California, but also
36 in other locations ([Appendix 6.3.6](#)). Many of these studies documented changes in plant

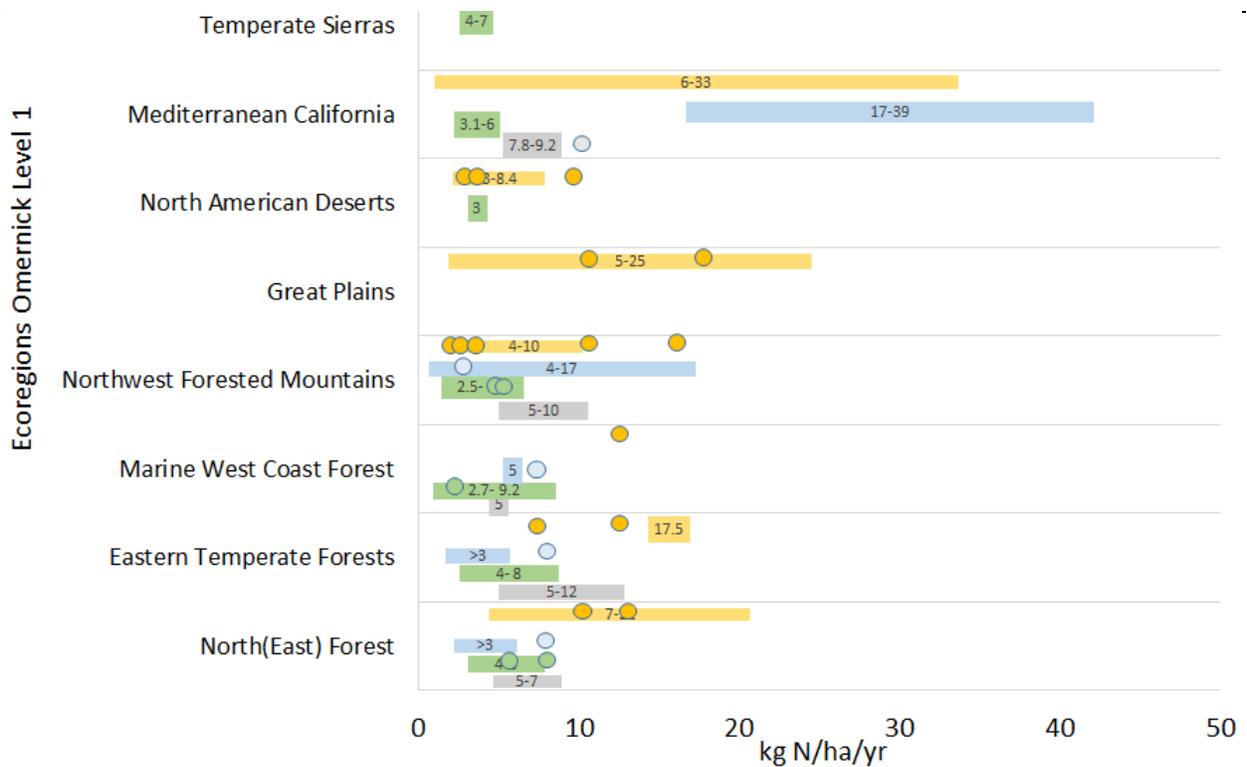

1 community composition, with fewer observations of plant species loss or changes in plant
2 diversity. Overall, this body of research has provided consistent and coherent evidence
3 that N deposition is altering the growth, physiology, and community composition of
4 plants in arid and semiarid ecosystems. Relative to plants, there are fewer studies of
5 microbial communities ([Table 6-12](#); [Table 6-22](#)), but these studies provided evidence that
6 N additions can alter the abundance, physiology, and community composition of soil
7 microorganisms in arid and semiarid ecosystems.

1.5.2.2 National-Scale Sensitivity and Critical Loads

8 At the time of the 2008 ISA, there had been little quantification of the extent and
9 distribution of N sensitivity in terrestrial ecosystems in the U.S. In the 2008 ISA, there
10 was no published U.S. national CL assessment. Since then, substantial work has been
11 done on quantifying N CLs for U.S. ecoregions. The most notable new work is the U.S.
12 Department of Agriculture—Forest Service (USDA—FS) *Assessment of Nitrogen*
13 *Deposition Effects and Empirical Critical Loads* ([Pardo et al., 2011a](#)). That assessment
14 was organized by Level 1 ecoregions, and where data were available, CLs calculations
15 were made for individual ecosystem types (e.g., forests within the Mediterranean
16 California ecoregion) and life forms (i.e., lichens, mycorrhizal fungi). This ISA largely
17 follows that structure, reporting terrestrial N CLs for life forms (e.g., herbaceous plants)
18 within each ecoregion, which is a geographically defined area within a broader biome
19 (e.g., forests) based on distinct physical and biological features (e.g., Northwest Forested
20 Mountains, Eastern Temperate Forests, etc.).

21 In general, higher N CLs were often reported for regions with higher ambient N
22 deposition. One explanation for this pattern is that when ecosystems experience elevated
23 N deposition, the current condition already represents a change from the condition before
24 elevated N deposition (i.e., a pristine or near-pristine state). This pattern would explain
25 why the empirical CL is often above the ambient deposition even as that deposition
26 increases in the same ecosystem type across a region ([Pardo et al., 2011a](#)).

27 Newer CL studies are presented in tandem with the CLs reported by [Pardo et al. \(2011a\)](#)
28 in [Table 6-28](#) and [Chapter 1, Figure 1-7](#). The majority of values for new CLs are within
29 the range of CLs identified by [Pardo et al. \(2011a\)](#). Notably, [Simkin et al. \(2016\)](#)
30 identified a new lower range of 7.9 kg N/ha/yr, and new lower CLs are denoted for alpine
31 ecosystems in the Northwest Forested Mountains ecoregion. There are also new CLs for
32 herbaceous species in two ecoregions that previously had no CL [[Table 6-28](#), ([Simkin et](#)
33 [al., 2016](#))].

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

The rectangles indicate the range of CLs designated by [Pardo et al. \(2011a\)](#); the circles indicate new papers that have specified CLs; data from [Table 6-28](#).

Recently, Clark et al. 2018 (In press) estimated CL exceedance areas for the conterminous U.S. over a more than 200 year period. Overall, this analysis showed that terrestrial N CLs have been exceeded for many decades in areas across the U.S. Exceedance areas peaked in 1995 for changes in lichen communities and plant community composition at 3.47 and 2.87 million km², respectively, before declining marginally by 2006. The minimum forest tree health CL was exceeded in 2.41 million km² by 1855 and did not change much over time, primarily because the relatively low CL compared to deposition values in the Eastern Temperate and Northern forest ecoregions.

1.5.3 Biological Effects of Acidification

1 Since publication of the 2008 ISA, the overarching understanding of terrestrial
2 acidification has not appreciably changed. Recent research has confirmed and
3 strengthened this understanding and provided more quantitative information, especially
4 across regional-scale landscapes. A number of studies have evaluated the relationships
5 between soil chemistry indicators of acidification and ecosystem biological endpoints
6 (see [Table 5-6](#)). Soil chemistry indicators examined in recent literature include
7 exchangeable base cations (Bc), soil pH, exchangeable acidity (H⁺ and Al), exchangeable
8 Bc:Al ratio, base saturation, and Al concentrations. The most common indicator used in
9 determining critical loads is the soil solution Bc:Al ratio. [Appendix 5.2.1](#) discusses the
10 uncertainty considerations when using this indicator. Biological endpoints included in the
11 evaluations consisted of physiological and community responses of trees and other
12 vegetation, lichens, soil biota, and fauna.

1.5.3.1 Physiology and Growth

13 In the 2008 ISA, evidence was sufficient to infer a causal relationship between acidifying
14 deposition and changes in terrestrial biota; the evidence included changes in plant
15 physiology, plant growth, and terrestrial biodiversity. The physiological effects of
16 acidification on terrestrial ecosystems in the U.S. were well characterized at the time of
17 the 2008 ISA and included slower growth and increased mortality among sensitive plant
18 species. Consistent and coherent evidence from multiple species and studies in 2008
19 showed that the biological effects of acidification on terrestrial ecosystems were
20 generally attributable to physiological impairment caused by Al toxicity and decreased
21 ability of plant roots to take up base cations (Section 3.2.2.3 of the 2008 ISA). Much of
22 the new evidence for the negative effects of acidifying deposition comes from Ca
23 addition experiments, in which the addition of Ca has alleviated many of the negative
24 plant physiological and growth effects. Consistent with the findings of the 2008 ISA, **the
25 body of evidence is sufficient to infer a causal relationship between acidifying N and
26 S deposition and the alteration of the physiology and growth of terrestrial organisms
27 and the productivity of terrestrial ecosystems.**

28 In the 2008 ISA, acidifying deposition, in combination with other stressors, was found to
29 be a likely contributor to physiological effects that led to the decline of sugar maple (*Acer
30 saccharum*) trees occurring in portions of the eastern U.S. with base-poor soils. Studies
31 since the 2008 ISA support these findings (see [Appendix 5.2.1.1](#)). For example, recent
32 field studies have shown relationships between soil chemical indicator threshold values
33 and tree responses. Substantial declines in sugar maple regeneration have been found at

1 soil base saturation levels <20%, which is consistent with the range reported in the 2008
2 ISA.

3 In new studies, sugar maple showed positive growth and regeneration responses to
4 increasing exchangeable base cations, base saturation, and soil pH, and negative
5 relationships with increasing exchangeable Al. In other studies, the growth, regeneration,
6 and physiological responses of sugar maple to the soil conditions created by acidifying
7 deposition were reversed or ameliorated by Ca additions. Similarly, the 2008 ISA
8 reported that processes associated with soil acidification contributed to physiological
9 stress, high mortality rates, and decreasing growth trends of red spruce (*Picea rubens*)
10 trees. New evidence from Ca addition studies provides further support for these
11 mechanisms (see [Appendix 5.2.1.2](#)). Added Ca reversed or ameliorated many of the
12 physiological responses to acidification.

13 In the 2008 ISA, there was limited information on the effects of acidification on other
14 tree species. Since the 2008 ISA, research has observed varying physiological sensitivity
15 to soil acidification among eight eastern U.S. tree species. New studies since the 2008
16 ISA have also added new information about the effects of acidifying deposition on forest
17 understory vegetation, grasslands, lichens, and higher trophic level organisms (snails and
18 salamanders) that support the terrestrial acidification conclusions of the 2008 ISA.

1.5.3.2 Biodiversity

19 The 2008 ISA noted strong evidence that acidifying deposition could alter terrestrial
20 community composition and cause a loss of terrestrial biodiversity. The physiological and
21 growth effects of acidifying deposition are not uniform across species, resulting in altered
22 species composition and decreased biodiversity whereby sensitive species are replaced by
23 more tolerant species. For example, increasing soil base cation availability was tied to
24 greater sugar maple growth and seedling colonization, whereas American beech (*Fagus*
25 *grandifolia*) was relatively more dominant on soils with lower base cation availability
26 (see [Appendix 5.2.1.3.1](#)). Measurements of soil acid-base chemistry have been used as a
27 predictor of understory species composition, with 50 understory species associated with
28 high soil base cation status. In another set of studies, soil acid-base chemistry was
29 correlated with soil biodiversity and community composition. For example, addition of
30 Ca resulted in changes in soil bacterial community composition and bacterial community
31 structure that were correlated with soil exchangeable Ca, pH, and P (see [Appendix 5.2.4](#)).
32 Based on research included in the 2008 ISA and these new studies, **the body of evidence**
33 **is sufficient to infer a causal relationship between acidifying N and S deposition and**

1 **the alteration of species richness, community composition, and biodiversity in**
2 **terrestrial ecosystems.**

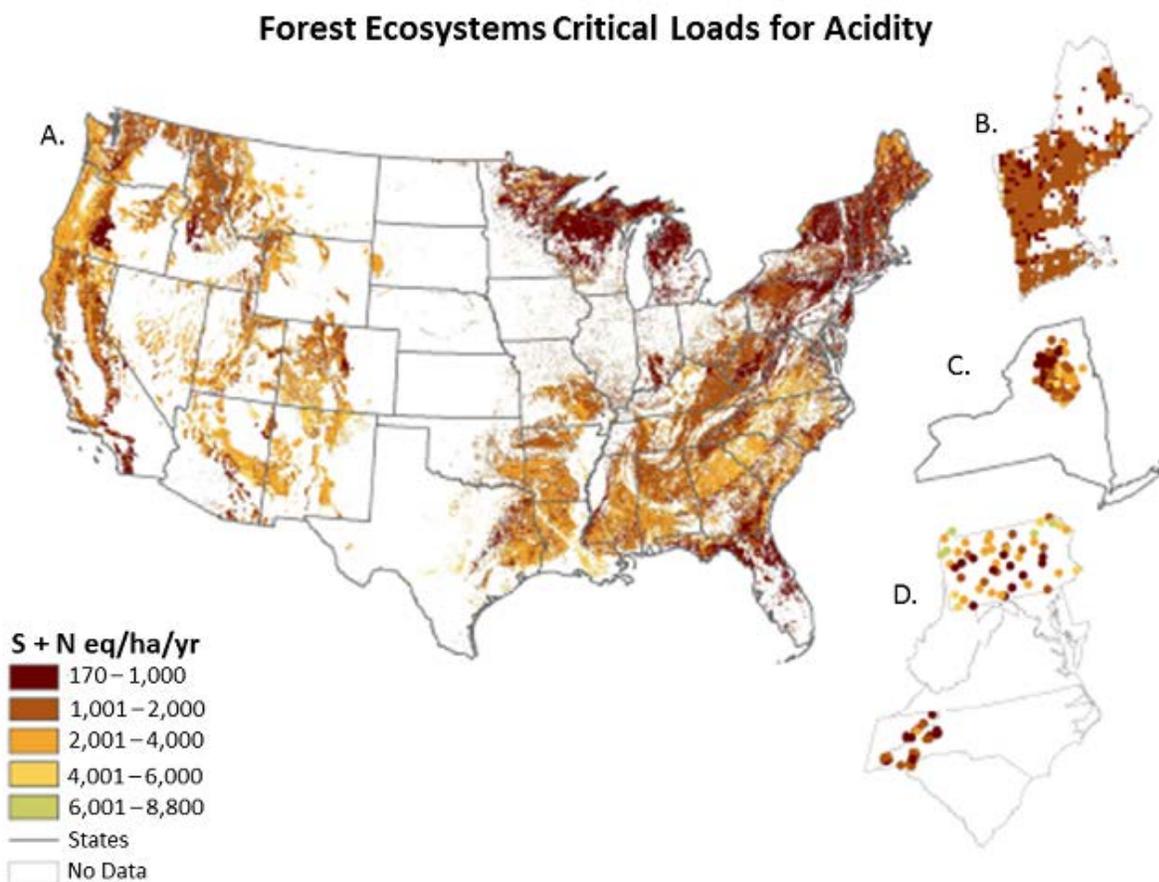

1.5.3.3 National-Scale Sensitivity and Critical Loads

3 The sensitivity of soils to acidifying deposition is discussed in detail in [Appendix 4](#). In
4 general, surficial geology is the principal factor governing the sensitivity of terrestrial
5 ecosystems soil to acidification from S and N deposition. Other factors that contribute to
6 the sensitivity of soils to acidifying deposition include topography, soil chemistry, and
7 land use. Several widely accepted models are currently used in the U.S. to assess the
8 terrestrial effects of S and N deposition ([Appendix 4.5](#)). These models are typically used
9 to evaluate acidification effects on biota by assigning a value of a soil parameter that
10 relates to the onset of a harmful biological effect. Since the 2008 ISA, estimates of base
11 cation weathering (BCw), which are input to soil acidification models, have improved for
12 application in the U.S. and have yielded new critical loads. Forests of the Adirondack
13 Mountains of New York, Green Mountains of Vermont, White Mountains of New
14 Hampshire, the Allegheny Plateau of Pennsylvania, and mountain tops and ridges forest
15 ecosystems in the southern Appalachians are the regions that are most sensitive to
16 terrestrial acidification from atmospheric deposition ([Appendix 3.2.4.2 of the 2008 ISA](#)).

17 Models used to determine critical loads of acidifying deposition included SMB, STA,
18 MAGIC, ForSAFE-VEG, and empirical models. Several models and extrapolation
19 methods to estimate BCw rates were also investigated. The PROFILE model was
20 evaluated as a model to estimate soil BCw rates to support estimates of SMB critical
21 loads in the U.S. (see [Appendix 4.5](#)). In general, recently published models used soil
22 solution Bc:Al ranging from 1.0 to 10.0 as an indicator to estimate CLs in North
23 America.

24 Ecosystem sensitivities to ambient N and S deposition were also characterized by
25 developing CLs and exceedances (see [Appendix 4.6](#); [Chapter 1, Figure 1-8](#), and
26 [Appendix 5.5](#)). Calculated CLs for forest plots based on the soil solution Bc:Al of 10.0 in
27 the northeastern U.S. ranged from 11 to 6,540 eq/ha/yr (eq quantifies the supply of
28 available H⁺ ions, combining the acidifying effects of N and S deposition), and 15–98%
29 of these plot-level CLs were exceeded by N and S deposition. In this region, correlation
30 analyses showed that the growth of 17 tree species were negatively correlated with CL
31 exceedance. In Pennsylvania, CLs based on the soil solution Bc:Al of 10.0 for hardwood
32 forests ranged from 4 to 10,503 eq/ha/yr and were exceeded by estimated N and S
33 deposition in the Year 2002 in 53% of the plots. Several studies found that CL and
34 exceedance determinations could be influenced by BCw rates, soil chemical indicators, N

1 retention, tree species-specific base cation uptake, and/or bulk (i.e., wet) versus total
2 deposition on CL estimates.

eq = equivalent; ha = hectare; yr = year.

(A) [McNulty et al. \(2007\)](#) critical loads are mapped at 1-km² grids (center map). For uncertainty, see [Li and McNulty \(2007\)](#).

(B.) [Duarte et al. \(2013\)](#) critical loads are mapped at 4-km² grids; (C. and D.) [Phelan et al. \(2014\)](#) critical loads are mapped for each sampling site (Pennsylvania). [McDonnell et al. \(2014b\)](#); [Sullivan et al. \(2011b\)](#); [Sullivan et al. \(2011a\)](#) critical loads are mapped as a single point at the center point of the watershed (New York and North Carolina).

Figure 1-8 Forest ecosystem critical loads for soil acidity related to base cation soil indicators.

1.6 Freshwater Ecosystem Nitrogen Enrichment and Acidification

1 For freshwater systems, new evidence reinforces causal findings from the 2008 ISA
2 ([Chapter 1, Table 1-1](#)). New evidence also expands the scope of existing causal findings
3 to include additional biota affected by N enrichment and acidifying deposition, and
4 supports quantification of these effects with new critical loads (see [Chapter 1.6.3.2](#)).
5 Freshwater systems include lakes (lentic systems) and rivers and streams (lotic systems).
6 In freshwater ecosystems, N may cause N enrichment/eutrophication. Aquatic
7 eutrophication occurs as increased productivity of algae and aquatic plants, altered
8 nutrient ratios, and sometimes decreased oxygen levels. Deposition of N, S, or N + S can
9 cause acidification, which affects watershed biogeochemical processes and surface water
10 chemistry. Freshwater N enrichment and acidification take place in sensitive ecosystems
11 across the U.S. at present levels of deposition and may occur simultaneously in some
12 water bodies.

13 New studies have added to the body of evidence in the 2008 ISA that N nutrient
14 enrichment and acidifying deposition alter freshwater biogeochemistry and subsequent
15 biological effects. There is new information on biogeochemical processes including
16 cycling of N and S. Both N enrichment/eutrophication and acidification can impact
17 physiology, survival, and biodiversity of sensitive aquatic biota. The 2008 ISA and new
18 studies provide examples of lakes and streams that show signs of eutrophication,
19 especially increased algal growth and shifts in algal biodiversity, in response to N
20 addition. The current causal statement for nutrient enrichment effects of N deposition
21 now includes altered algal growth and productivity as well as the endpoints of species
22 richness, community composition, and biodiversity reported in the 2008 ISA ([Chapter 1,](#)
23 [Table 1-1](#)). For biological effects of aquatic acidification, the current causal statement has
24 been expanded from the 2008 ISA to include the specific endpoints of physiological
25 impairment, alteration of species richness, community composition, and biodiversity
26 ([Chapter 1, Table 1-1](#)). New studies also show that despite reductions in acidifying
27 deposition, many aquatic ecosystems across the U.S. are still experiencing changes in
28 ecological structure and functioning at multiple trophic levels. Although there is evidence
29 for chemical recovery in many previously acidified ecosystems, biological recovery has
30 been limited ([Appendix 8.4](#)).

31 A number of freshwater monitoring efforts have facilitated the analysis of long-term
32 trends in surface water chemistry and ecological response in areas affected by acidifying
33 (N + S) deposition ([Appendix 7.1.3](#)). Many of these studies have been conducted in the
34 U.S., especially in the Northeast and the Appalachian Mountains. Although many of
35 these monitoring programs were in existence at the time of the 2008 ISA and were

1 considered in that analysis, more recent publications reflect the longer period of
2 monitoring record and strengthen previous conclusions. Surface water chemistry data
3 from long-term monitoring by federal, state, and local agencies as well as university
4 research groups and nonprofits has been combined into several publicly available
5 metadatabases ([Appendix 7.1.3.2](#)) enabling further regional trend analysis. Since the
6 early 2000s, U.S. EPA, together with the states, tribes, and other entities and individuals,
7 have collaborated on a series of statistically representative surveys (National Aquatic
8 Resource Surveys [NARS]) of the nation's waters, including surveys of lakes ([U.S. EPA,](#)
9 [2016h](#), [2009b](#)), streams ([U.S. EPA, 2016i](#)), wetlands ([U.S. EPA, 2016j](#)), and coastal
10 waters ([U.S. EPA, 2016g](#)). These periodic surveys, which are based on standard sampling
11 and analysis protocols and consistent quality assurance, include chemical and biological
12 indicators of nutrient enrichment and acidification ([Appendix 7.1.3](#)).

1.6.1 Freshwater Biogeochemistry

13 In the 2008 ISA, evidence was sufficient to infer a causal relationship between N and S
14 deposition and the alteration of biogeochemical cycling of N and C in freshwater
15 ecosystems, and between acidifying deposition and changes in biogeochemistry of fresh
16 waters. As documented in the 2008 ISA and by newer studies, biogeochemical processes
17 and surface water chemistry are influenced by characteristics of the catchment and the
18 receiving waters. A number of studies since 2008 have focused on improving
19 understanding of aquatic acidification and eutrophication processes mediated by N. Many
20 of these studies have focused on pathways of pollutant and other constituent movement
21 within ecosystems, including monitoring studies of various kinds. Chemical indicators of
22 N deposition identified by the 2008 ISA were NO_3^- and DIN concentrations in surface
23 waters. Increased N deposition to freshwater systems via runoff or direct atmospheric
24 deposition, especially to N limited and N and phosphorus (P) colimited systems, can alter
25 N cycling ([Appendix 7](#)) and stimulate primary production ([Appendix 9](#)). Data from
26 long-term monitoring, experimental manipulations, and modeling studies provide
27 consistent and coherent evidence for biogeochemical changes associated with acidifying
28 N and S deposition. The strongest evidence for a causal relationship between acidifying
29 deposition and aquatic biogeochemistry comes from studies of changes in surface water
30 chemistry. Surface water chemistry indicators of acidic conditions and acidification
31 effects include concentrations of SO_4^{2-} , NO_3^- , inorganic aluminum (Al), calcium (Ca),
32 sum and surplus of base cations, acid-neutralizing capacity (ANC), and surface water pH.
33 New information on biogeochemical cycling of N and S, acidifying deposition effects on
34 biogeochemical processes and changes to chemical indicators of surface water chemistry
35 associated with acidification and N nutrient enrichment is consistent with the conclusions

1 of the 2008 ISA, and **the body of evidence is sufficient to infer a causal relationship**
2 **between N and S deposition and the alteration of freshwater biogeochemistry.**

1.6.1.1 Freshwater Processes and Indicators

3 Key processes and geochemical indicators of freshwater acidification and N enrichment
4 ([Chapter 1, Table 1-3](#)) link to biological effects ([Appendix 8](#) and [Appendix 9](#)). Surface
5 water chemistry integrates the sum of soil and water processes that occur upstream within
6 a watershed. Several key biogeochemical processes cause or contribute to surface water
7 eutrophication and acidification, and these processes have been the focus of substantial
8 research over the last three decades. Since the 2008 ISA, experimental studies, isotopic
9 analyses, and monitoring and observational studies have further investigated the cycling
10 of S, N, C, and base cations; these studies substantiate and further quantify earlier
11 findings.

12 Nitrogen is deposited as NO_3^- , NH_4^+ , NH_3 , and/or organic N. Inorganic N is leached from
13 terrestrial ecosystems mainly as NO_3^- . In freshwater ecosystems, deposited NH_4^+ is taken
14 up by biota or nitrified to NO_3^- . Elevated NO_3^- concentrations in lakes and streams are a
15 biogeochemical indicator that a freshwater system is receiving excess N which will cause
16 acidification or eutrophication. Qualitatively, northeastern U.S. spatial patterns in surface
17 waters NO_3^- concentrations suggest an influence by atmospheric N deposition. However,
18 considerable variation in the relationship between stream chemistry and deposition was
19 associated with land use and watershed attributes. It was well known at the time of the
20 2008 ISA that key processes such as nitrification and denitrification are quantitatively
21 important portions of the N cycle and that they can be influenced by atmospheric inputs.
22 More recent research has further substantiated these earlier findings and provided
23 additional quantitative context ([Appendix 7.1.2.3](#)). Some new research suggests that
24 denitrification may, in some situations, produce more N_2O in relationship to surface
25 water NO_3^- concentration than was previously recognized.

26 Sulfur is deposited mainly as SO_4^{2-} , which is a mobile anion in many acid-sensitive
27 watersheds ([Appendix 4](#)). Deposition is not the only source of SO_4^{2-} to drainage waters.
28 Geologic sources of S, including iron sulfide minerals, can also contribute SO_4^{2-} to
29 surface waters. The 2008 ISA found that S deposition alters soil and drainage water
30 chemistry through sustained leaching of SO_4^{2-} , associated changes in soil chemistry, and
31 accumulation of S in the soil through adsorption and biological assimilation. Declines in
32 lake SO_4^{2-} concentrations have been observed in locations where S deposition has
33 decreased significantly such as in the Adirondack Mountains ([Appendix 7.1.5.1](#)). In
34 addition, internal watershed sources of S, which were earlier believed to be relatively

1 minor in the northeastern U.S., have and will likely continue to become proportionately
 2 more important as S deposition continues to decline. Reductions in SO_x deposition have
 3 not consistently resulted in increases of ANC in surface water.

Table 1-3 Summary of key aquatic geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Process			
NO ₃ ⁻ leaching into water bodies	X	X	Leaching from terrestrial ecosystems is an important source of NO ₃ ⁻ in freshwater ecosystems. See NO ₃ ⁻ leaching in Chapter 1, Table 1-2 .
SO ₄ ²⁻ leaching into water bodies		X	Leaching from terrestrial ecosystems is an important source of SO ₄ ²⁻ in freshwater ecosystems. See SO ₄ ²⁻ leaching in Chapter 1, Table 1-2 .
Nitrification	X	X	Nitrification is an acidifying process, releasing 2 mol hydrogen ion (H ⁺) per mol NH ₄ ⁺ converted to NO ₃ ⁻ . As the N cycle becomes enriched through cumulative N addition, net nitrification rates often increase, and NO ₃ ⁻ concentrations increase.
Denitrification	X		Denitrification is the microbial process that transforms NO ₃ ⁻ by anaerobically reducing it to NO ₂ ⁻ , NO, N ₂ O, and N ₂ .
DOC leaching into water bodies	X	X	DOC contributes to acidity of freshwater ecosystems. See DOC leaching in Chapter 1, Table 1-2 .
Indicator			
Surface water [NO ₃ ⁻]	X	X	Increased N deposition (to surface waters or to terrestrial watershed, see Chapter 1, Table 1-2) increases the water NO ₃ ⁻ concentration. High concentrations of NO ₃ ⁻ in lakes and streams, indicative of terrestrial ecosystem N saturation, have been found at a variety of locations throughout the U.S. (U.S. EPA, 2006c ; Stoddard, 1994). Comparison of preindustrial to modern estimates suggested elevated concentrations in water bodies as a result of N deposition (Fenn et al., 2011b).
Surface water DIN	X		Increased N deposition increases DIN in most freshwater aquatic environments, largely as NO ₃ ⁻
Surface water N:P ratios	X		Increased N deposition can alter the ratio of N to P in freshwater systems. Freshwater biota have different nutrient requirements and changes in nutrient ratios may alter species richness, community structure, and biodiversity, especially primary producers.

Table 1-3 (Continued): Summary of key aquatic geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Surface water [SO ₄ ²⁻]		X	Increased S deposition (to surface waters or to terrestrial watershed, see Chapter 1, Table 1-2) increases the water SO ₄ ²⁻ concentration. Comparison of preindustrial to modern estimates suggested elevated concentrations in water bodies as a result of S deposition.
Surface water (base cation)		X	Several studies in the eastern U.S. suggested that base cation concentrations in surface waters increased during the initial phases of acidification into the 1970s. This trend reversed, and base cations have decreased in response to decreasing SO ₄ ²⁻ and NO ₃ ⁻ concentrations. Many base cations (especially Ca ²⁺) are important nutrients for aquatic biota.
Surface water ANC		X	Increased N and S deposition decrease ANC. Surface water ANC correlates with other biologically influential chemical metrics, including pH, inorganic Al concentration, Ca concentration, and organic acidity. ANC <50–100 µeq/L typically poses a risk for species survival, species richness, and biodiversity.
Surface water pH		X	Surface water pH is a common alternative to ANC as an indicator of acidification, but ANC is a better indicator at pH >6.0, and is less sensitive to dissolved CO ₂ . N and S deposition are associated with decreasing pH in surface waters. Increasing pH trends in surface waters in the northeastern U.S. were common through the 1990s up to 2004, but the rates of change have been small (Driscoll et al., 2007a ; Driscoll et al., 2001a ; Driscoll et al., 2001b).
Surface water Inorganic Al		X	Acidifying N and S deposition increase mobilization of inorganic Al from terrestrial ecosystems into surface water, increasing surface water concentrations. Inorganic Al in surface waters is (1) widely toxic and (2) leaches from terrestrial ecosystems only in response to acidic conditions. Earlier studies demonstrated reduced growth and survival of various species of fish at inorganic Al concentrations between approximately 2 and 7.5 µmol/L. Most recently, 20% mortality of young-of-the year brook trout was documented in situ during a 30-day period with a median inorganic Al concentration of 2 µmol/L.

Al = aluminum; ANC = acid-neutralizing capacity; Ca = calcium; CO₂ = carbon dioxide; DIN = dissolved inorganic nitrogen; DOC = dissolved organic carbon; H⁺ = hydrogen ion; ha = hectare; kg = kilogram; L = liter; µeq = microequivalents; µmol = micromole; N = nitrogen; N₂ = molecular (atmospheric) nitrogen; N₂O = nitrous oxide; NE = northeast; NH₄⁺ = ammonium; NO = nitric oxide; NO₂ = nitrogen oxide; NO₃⁻ = nitrate; P = phosphorus; S = sulfur; SO₄²⁻ = sulfate; U.S. = United States; USFS = U.S. Forest Service; yr = year.

1

1.6.1.1.1 Acidification

2 The acidifying effects of N and S deposition in U.S. waters have been well characterized
3 for several decades. Traditionally acidification involves both chronic and episodic
4 processes. [Driscoll et al. \(2001b\)](#) characterized chronically acidic lakes and streams by
5 ANC of <0 µeq/L throughout the year, while episodic acidification occurs when ANC

1 falls below 0 $\mu\text{eq/L}$ only for hours to weeks. Chronic acidification refers to average
2 conditions and is often measured as summer and fall chemistry for lakes and as spring
3 baseflow chemistry for streams. Chronic conditions are no longer prevalent in regions of
4 the U.S. affected by acidic deposition (cf., [Fakhraei et al., 2016](#); [Fakhraei et al., 2014](#)).
5 Episodic acidification is associated with precipitation or snowmelt events when high
6 volumes of drainage water enter watersheds. Episodes generally cause changes in at least
7 two of the following chemical parameters: ANC, pH, base cations, SO_4^{2-} concentration,
8 NO_3^- concentration, inorganic Al concentration, organic acid anions, or DOC. New
9 studies show that both N and S contributed to episodic acidification over a 20-year period
10 at Bear Brook, ME (see [Appendix 7.1.5.1.2](#)). It is known that the biota in many
11 streams/lakes are impacted when the ANC is consistently below 50 $\mu\text{eq/L}$. For this
12 reason, there has been a shift away from focusing on chronic versus episodic condition.
13 For example, the U.S. EPA National Lakes Assessment used an ANC threshold of
14 $>50 \mu\text{eq/L}$ as indicative of nonacidified water bodies ([U.S. EPA, 2009b](#)).

15 The most widely used measure of surface-water acidification is ANC. As reported in the
16 2008 ISA and newer studies, ANC is the primary chemical indicator of historic
17 acidification and for predicting the recovery expected from decreasing atmospheric
18 deposition. ANC correlates with the surface water constituents (pH, Ca^{2+} , and inorganic
19 Al concentration) that contribute to or ameliorate acidity effects in biota. As reported in
20 the 2008 ISA, lake and stream ANC values decreased throughout much of the 20th
21 century in a large number of acid-sensitive lakes and streams throughout the eastern U.S.
22 This effect has been well documented in monitoring programs, paleolimnological studies,
23 and model simulations ([Appendix 7.1.5.1](#)). Biological indicators of acidification, such as
24 decreased fish species richness, are presented in [Appendix 8.3](#).

25 Surface water pH is another indicator of acidification. It also correlates with surface
26 water chemical constituents with biotic effects (inorganic Al, Ca^{2+} , and organic acids).
27 The 2008 ISA included the scientific consensus that low pH can have direct toxic effects
28 on aquatic species ([U.S. EPA, 2008a](#); [Driscoll et al., 2001b](#)). A pH value of 6.0 is the
29 level below which biota are at increased risk from acidification ([Appendix 8.3](#)). In the
30 2008 ISA, increasing trends in pH (decreasing acidification) were common in surface
31 waters in the northeastern U.S. through the 1990s and up to 2004 and have continued in
32 more recent times at many locations ([Appendix 7.1.2.5](#)). Rates of change have generally
33 been relatively small.

34 As stated in the 2008 ISA, the concentration of dissolved inorganic monomeric Al in
35 surface waters is an especially useful indicator of acidifying deposition because (1) it is
36 toxic to many aquatic species and (2) it leaches from soils only under acidic conditions
37 including acidifying deposition, acid mine drainage, or from rare geologic deposits.

1 Inorganic Al has well-documented effects on aquatic biota at specific thresholds
2 ([Appendix 8.3](#)) and is often the greatest threat to aquatic biota below pH 5.5. The 2008
3 ISA noted that concentrations of inorganic Al decreased slightly in some surface waters
4 in the northeastern U.S. in response to decreased levels of acidifying deposition
5 suggestive of chemical recovery of surface waters ([U.S. EPA, 2008a](#)), and this trend has
6 generally continued ([Appendix 7.1.5](#), see discussion on recovery [Chapter 1.11](#)).

7 Assessments of acidifying deposition effects dating from the 1980s and reported in the
8 2008 ISA showed SO_4^{2-} to be the primary acidifying ion in most acid-sensitive waters in
9 the U.S. The 2008 ISA, presented temporal data that showed a trend of increasing
10 concentrations of SO_4^{2-} in surface waters before the period of peak S emissions in the
11 early 1970s. After the peak, SO_4^{2-} surface water concentrations decreased in a
12 widespread trend. The rate of recovery varied by ecosystem and new studies indicate that
13 as atmospheric S deposition has declined, soils with large stores of historically deposited
14 S (e.g., the Blue Ridge Mountain region) have begun releasing this adsorbed S to
15 drainage water, ([Appendix 4](#)) preventing or slowing aquatic recovery.

16 As stated in the 2008 ISA, the quantitatively most important component of the overall
17 surface water acidification and chemical recovery responses has been change in base
18 cation supply. Decreases in base cation concentrations in surface waters in the eastern
19 U.S. have been ubiquitous over the past two to three decades and closely tied to trends in
20 SO_4^{2-} concentrations in surface waters. Change in base cation supply with surface water
21 acidification was highlighted in the assessment of [Charles and Christie \(1991\)](#) and in the
22 2008 ISA. Base cations are added to watershed soils by weathering of minerals and
23 atmospheric deposition, and are removed by uptake into growing vegetation or by
24 leaching. Acidic deposition increased leaching of base cations, as SO_4^{2-} anions in soil
25 solution carried along base cations to maintain the charge balance. In watersheds that
26 received high levels of historical acidic deposition, current exchangeable concentrations
27 of Ca^{2+} and other base cations are substantially reduced from likely preindustrial levels,
28 having been depleted by many years of acidic deposition. This base cation depletion in
29 watersheds constrains ANC and pH recovery of surface waters, as described in the 2008
30 ISA. New studies of base cations have further corroborated these earlier findings and
31 included experiments, modeling, and gradient studies.

32 Changes in DOC concentration or properties can impact the acid-base chemistry of
33 surface waters and perhaps the composition of aquatic biota. It has been recognized that
34 surface water DOC concentrations had decreased to some extent as a result of
35 acidification, and that DOC would likely increase with recovery. However, the strength
36 of this response and the magnitude of DOC changes have exceeded scientific predictions.
37 Recent research on this topic has been diverse and has included experiments, observation,

1 isotope studies, and synthesis and integration work. Overall, these studies illustrate large
2 increases in DOC with acidification recovery in some aquatic systems. Increases in DOC
3 constrain the extent of ANC and pH recovery, but decrease the toxicity of dissolved Al
4 by converting some of it from inorganic to organic forms ([Lawrence et al., 2013](#)).
5 However, DOC is not an indicator of recovery everywhere; some recovering sites have
6 not shown increasing trends in DOC.

1.6.1.1.2 Nitrogen Enrichment/Eutrophication

7 In aquatic systems, N is a nutrient that stimulates growth of primary producers (algae
8 and/or aquatic plants). Atmospheric deposition of N to freshwater systems can increase
9 the absolute supply of nutrients and alter N and P ratios. The freshwater ecosystems in
10 the U.S. most likely to be sensitive to nutrient enrichment from N deposition are
11 headwater streams, lower order streams, and alpine lakes, which have very low nutrients
12 and productivity and are far from local pollution sources [([U.S. EPA, 2008a](#)),
13 [Appendix 9.1.1.4](#)]. These nutrient shifts alter stoichiometric composition of water
14 chemistry, thereby shifting the nutrient status of lakes. Even small inputs of N in low
15 nutrient water bodies can affect biogeochemical processing of N and increase the
16 productivity of photosynthesizing organisms, resulting in a larger pool of fixed carbon
17 (C). Nutrient enrichment leads to changes in aquatic assemblages and biodiversity in
18 freshwater ([Appendix 9](#)) and coastal regions ([Appendix 10](#)).

19 Indicators of altered N cycling include changes in the concentrations of NO_3^- in surface
20 waters. The concentration of NO_3^- in drainage water provides an index of the balance
21 between removal and addition of N to terrestrial ecosystems. Studies of several types
22 have been conducted in recent years to elucidate these processes and include
23 experimental studies, isotopic analyses, and monitoring and observational studies. Both
24 water column and sediment N transformations have been further characterized
25 ([Appendix 7.1.2.3](#)). New research since the 2008 ISA suggests that denitrification may,
26 in some situations, play a larger role than was previously recognized in removing
27 oxidized N from the watershed.

28 As reported in the 2008 ISA and in newer studies, atmospheric N has been positively
29 correlated to total N in lakes along gradients of atmospheric deposition and N deposition
30 in some high-deposition lakes has changed the nutrient status of these lakes from a more
31 or less balanced (mainly N deficient) state to more consistently P limited conditions
32 ([Appendix 9.2.4](#)). Since the 2008 ISA, several studies have reported increases in P
33 deposition to water bodies in the U.S., possibly effecting shifts from N to P limitation or
34 colimitation, as well as P deposition prolonging N limitation ([Appendix 9.1.1.2](#)). In
35 higher order streams, N deposition typically mixes with N derived from other

1 nonatmospheric sources, including urban/suburban point and nonpoint sources, industrial
2 sources, and agricultural sources, with atmospheric sources typically being most
3 pronounced during high-flow conditions ([Table 7-2](#)).

1.6.1.2 Models

4 Models used to assess the effects of N and S deposition on U.S. ecosystems were
5 reviewed in the 2008 ISA (Annex A). Several of the models used for terrestrial
6 ecosystems (see [Chapter 1.5.3.3](#)) such as MAGIC and PnET/BGC are also applicable to
7 aquatic systems. Both of these models have been widely applied, mainly to relatively
8 small, upland watersheds. Three other models, Spatially Referenced Regressions on
9 Watershed Attributes (SPARROW), Watershed Assessment Tool for Evaluating
10 Reduction Scenarios for Nitrogen (WATERS-N), and Surface Water Assessment Tool
11 (SWAT) have been used to evaluate N loading to mixed-use watersheds in larger river
12 systems. A model that has been applied to the analysis of nutrient enrichment in aquatic
13 systems is AQUATOX, which simulates nutrient dynamics and effects on aquatic biota.
14 Few new freshwater acidification or eutrophication models have been developed and
15 published since 2008. A new national water quality modeling system (Hydrologic and
16 Water Quality System, HAWQS) is under development by Texas A&M University and
17 the USDA for the U.S. EPA's Office of Water (<https://epahawqs.tamu.edu/>). The model
18 is intended to assist resource managers and policy makers in evaluating the effectiveness
19 of water pollution control efforts. Freshwater eutrophication and acidification models are
20 described in greater detail in [Appendix 7.1.4.2](#).

1.6.1.3 National-Scale Sensitivity

21 Sensitivity of lakes, streams, and rivers to biogeochemical changes associated with N and
22 S deposition varies across the U.S. The biogeochemical sensitivity to acidifying
23 deposition will be discussed together with biological sensitivity in [Chapter 1.6.2.2](#).
24 Sensitivity to N enrichment will be discussed with biological sensitivity in
25 [Chapter 1.6.3.2](#).

1.6.2 Biological Effects of Freshwater Nitrogen Enrichment

26 In the 2008 ISA, evidence was sufficient to infer a causal relationship between N
27 deposition and the alteration of species richness, community composition, and
28 biodiversity in freshwater ecosystems. The freshwater systems most affected by nutrient

1 enrichment due to atmospheric deposition of N were remote oligotrophic high-elevation
2 lakes with low N retention capacity. In these ecosystems, N changes the biota, especially
3 by increasing algal growth and shifting algal communities. Freshwater organism
4 responses to N enrichment can be assessed through biological indicators, including
5 chlorophyll *a*, phytoplankton and periphyton (algae attached to a substrate) biomass,
6 diatoms, and trophic status. The current causal statement has been expanded to include
7 effects on algal growth and productivity ([Chapter 1, Table 1-1](#)). New evidence since 2008
8 of N enrichment includes paleolimnology, phytoplankton community dynamics,
9 macroinvertebrate response, and indices of biodiversity. This new evidence is consistent
10 with the conclusions and strengthens the evidence base of the 2008 ISA, and together, **the**
11 **body of evidence is sufficient to infer a causal relationship between N deposition and**
12 **changes in biota including altered growth and productivity, species richness,**
13 **community composition, and biodiversity due to N enrichment in freshwater**
14 **ecosystems.**

1.6.2.1 Physiology and Biodiversity Effects

15 Inputs of N to freshwater systems stimulate algal growth, which leads to a cascade of
16 effects on algal community composition and biodiversity. Algal species have differential
17 responses to N loading and shifts in nutrient ratios, so dominant species may change in
18 response to N enrichment. As reported in the 2008 ISA and in newer studies, shifts in
19 nutrient limitation from N limitation to colimitation by N and P, or to P limitation, have
20 been observed in some alpine lakes. New biodiversity studies are summarized in
21 [Table 9-3](#). Since the 2008 ISA, several meta-analyses have reported an increase in P
22 deposition to water bodies, highlighting the need to account for how sustained P
23 deposition can modify the effects of anthropogenically emitted N deposition on
24 productivity ([Appendix 9.1.1.4](#)). P addition delayed the shift to P limitation (prolonged N
25 limitation) for phytoplankton.

1.6.2.1.1 Primary Producers

26 The body of evidence for biological effects of N enrichment in remote freshwater
27 systems (where atmospheric deposition is the predominant source of N) is greatest for
28 phytoplankton, the base of the freshwater food web. The majority of studies focused on
29 phytoplankton, although several new studies indicate that both benthic and pelagic
30 primary producers respond to N inputs, and at least some studies have shown that
31 periphyton outcompeted phytoplankton for limiting nutrients ([Appendix 9.3.3](#)). The 2008
32 ISA and new studies include lake surveys, fertilization experiments, and nutrient

1 bioassays that show a relationship between increased N concentrations and increased
2 pelagic and benthic algal productivity (measured by chlorophyll *a* concentration). An
3 increase in lake phytoplankton biomass with increasing N deposition was reported in the
4 Snowy Range in Wyoming and in Europe. New studies in the Colorado Rocky
5 Mountains, where atmospheric deposition ranged from 2 to 7 kg N/ha/yr, found
6 correlations between higher chlorophyll *a* and higher rates of deposition
7 ([Appendix 9.2.1](#)).

8 The 2008 ISA and newer studies ([Table 9-1](#) and [Appendix 9.3.2](#)) show a general shift in
9 algal dominance from chrysophytes that dominate low N lakes to cyanophytes and
10 chlorophytes in higher N lakes. Two nitrophilous species of diatom, *Asterionella formosa*
11 and *Fragilaria crotonensis*, serve as indicators of N enrichment in lakes; however,
12 increased relative abundance of *A. formosa* has also been attributed to lake warming in
13 some regions where N deposition is decreasing ([Appendix 9.2.3](#)). New studies show that
14 glacial meltwater has higher NO₃⁻ relative to snow meltwater with different influences on
15 algal community composition in some regions of the U.S. ([Appendix 9.3.2](#)). In a
16 comparison of lakes in the Rockies with different meltwater sources, fossil diatom
17 richness in snowpack-fed lakes was at least double the richness of lakes with both glacial
18 and snow meltwater inputs; however, alterations in phytoplankton community structure
19 were not observed in lakes in the Northern Cascade Mountains, WA. Some shifts in algal
20 biodiversity observed in high-elevation waters are attributed to climate change or nutrient
21 effects and climate as costressors ([Appendix 13](#)).

22 Since the 2008 ISA further studies have shown that both trophic interactions and DOC
23 modify ecosystem response to N loading. DOC affects acidity and N cycling and is
24 increasing in some U.S. surface waters ([Appendix 7.1.2.9](#)). In a whole lake N fertilization
25 study ([Appendix 9.3.2.3](#)), observed changes in community composition of phytoplankton
26 were related to DOC rather than N addition to small N limited boreal lakes.

27 The role of N in freshwater HAB formation has been further researched since the
28 2008 ISA. Additional evidence continues to show that availability and form of N
29 influences algal bloom composition and toxicity, and inputs of inorganic N selectively
30 favor some HAB species, including those that produce microcystin. Microcystin is
31 prevalent in U.S. waters as reported in recent regional and national surveys. Although the
32 risk of HAB formation is low in high-elevation oligotrophic water bodies where N
33 deposition is the dominant source of N, transport of atmospheric inputs can exacerbate
34 eutrophic conditions in downstream water bodies. Increased understanding of the role of
35 N as a limiting nutrient in many freshwater systems has led to recommendations to
36 consider both N and P in nutrient-reduction strategies.

1 Few studies in the U.S. have considered the effects of atmospheric deposition on aquatic
2 macrophytes, although declines in macrophyte occurrence were noted in a new survey of
3 Lake Tahoe that compared the lake's biota with that from a survey conducted in the
4 1960s ([Caires et al., 2013](#)). Atmospheric N contributions are a substantial portion
5 (approximately 57%) of the total N loading to Lake Tahoe.

1.6.2.1.2 Zooplankton

6 Compared to changes in primary producers, biological responses to N deposition at
7 higher trophic levels are not well characterized, but atmospheric N can alter food web
8 interactions (see [Appendix 9.3.4](#)). A few studies in the 2008 ISA and newer studies
9 showed zooplankton responses to N related shifts in phytoplankton biomass potentially
10 altering food web interactions.

1.6.2.1.3 Macroinvertebrates

11 Only a limited number of studies published since the 2008 ISA have linked atmospheric
12 N deposition to taxonomic shifts and declines in invertebrates ([Appendix 9.3.5](#)). These
13 studies do not attribute shifts in the abundance of higher invertebrates to N deposition
14 alone, as there are interactions with climate and invasive species. New studies provide
15 additional evidence that trophic interactions may moderate algal growth following
16 nutrient loading. In Lake Tahoe, which receives 57% of N inputs from atmospheric
17 sources, endemic invertebrate taxa have declined 80 to 100% since the 1960s due to
18 nutrient inputs and invasive species.

1.6.2.2 National-Scale Sensitivity and Critical Loads

19 New data have not appreciably changed the identification of sensitive lakes and streams
20 in the U.S. Nutrient enrichment effects from N most likely occur in undisturbed,
21 low-nutrient headwater, and lower order streams and lakes at higher elevations in the
22 western U.S. ([Appendix 9.1](#)), including the Snowy Range in Wyoming, the Sierra
23 Nevada, and the Colorado Front Range. A portion of these lakes and streams where
24 effects are observed are in Class I wilderness areas. The responses of high-elevation lakes
25 vary with catchment characteristics ([Appendix 9.1](#)) and N deposition estimates at these
26 high elevation sites are associated with considerable uncertainty, and there is greater
27 uncertainty for estimates of dry deposition ([Appendix 2](#)). In these systems, even low

1 inputs of atmospheric N can shift N limitation to colimitation by N and P, or to P
2 limitation ([Appendix 9.2.4](#)), altering algal species composition and productivity.

3 In the 2008 ISA, diatom assemblage shifts were reported at N deposition rates as low as
4 1.5 kg N/yr. Additionally, a hindcasting exercise in remote alpine Rocky Mountain
5 National Park lakes associated algal changes between 1850 and 1964 with an increase in
6 wet N deposition of 1.5 kg N/ha/yr. Since the 2008 ISA, empirical and modeled CLs for
7 the U.S. have been estimated based on surface water NO_3^- concentration, diatom
8 community shifts, and phytoplankton biomass nutrient limitation shifts indicative of a
9 shift from N limitation to P limitation. A critical load ranging from 3.5 to 6.0 kg N/ha/yr
10 was identified for high-elevation lakes in the eastern U.S. based on the nutrient
11 enrichment inflection point [where NO_3^- concentrations increase in response to
12 increasing N deposition ([Baron et al., 2011b](#))]. Another critical load of 8.0 kg N/ha/yr for
13 eastern lakes based on the value of N deposition at which significant increases in surface
14 water NO_3^- concentrations occur was estimated by ([Pardo et al., 2011c](#)). In both Grand
15 Teton and Yellowstone National Parks critical loads for total N deposition ranged from
16 $<1.5 + 1.0$ kg N/ha/yr to $>4.0 + 1.0$ kg N/ha/yr ([Nanus et al., 2017](#)). Exceedance
17 estimates were as high as 48% of the Greater Yellowstone area study region, depending
18 on the threshold value of NO_3^- concentration in lakewater selected as indicative of
19 biological harm. An empirical CL of 4.1 kg N/ha/yr above which phytoplankton biomass
20 P limitation is more likely than N limitation was identified by [Williams et al. \(2017b\)](#)
21 for the western U.S. Modeled critical loads ranged from 2.8 to 5.2 kg N/ha/yr, and a
22 performance analysis indicated that a Cl of 2.0 kg N/ha/yr would likely reduce the
23 occurrence of false negatives to near zero.

1.6.3 Biological Effects of Freshwater Acidification

24 The 2008 ISA found evidence sufficient to infer a causal relationship between acidifying
25 deposition and changes in aquatic biota, including strong evidence that acidified aquatic
26 habitats had lower species richness of fishes, macroinvertebrates, and phytoplankton. The
27 effects of acidifying deposition on aquatic ecosystems also include physiological
28 impairment or mortality of sensitive species and shifts in biodiversity of both flora and
29 fauna. Organisms at all trophic levels are affected by acidification, with clear linkages to
30 chemical indicators for effects on algae, benthic invertebrates, and fish ([Table 8-9](#)).
31 Biological effects are primarily attributable to low pH and high inorganic Al
32 concentration. ANC integrates chemical components of acidification ([Chapter 1](#),
33 [Table 1-2](#)), and surface water acidification models project ANC rather than pH and
34 inorganic Al concentrations. However, ANC does not directly alter the health of biota.

1 Effects of acidification on fish species are especially well characterized and many species
2 are harmed. Both in situ and lifestage experiments in fish support thresholds of chemical
3 indicators for biological effects. Most of these effects were documented in a rigorous
4 review of acidification effects on aquatic biota that was included in the 2008 ISA.
5 Overall, the updated research synthesized in this ISA reflects incremental improvements
6 in scientific knowledge of aquatic biological effects and indicators of acidification as
7 compared with knowledge summarized in the 2008 ISA. The fundamental understanding
8 of mechanisms has not changed, and the causal relationships between acidifying
9 deposition and biological effects on aquatic ecosystems are now, and were in 2008, well
10 supported. New studies also show that despite reductions in acidifying deposition,
11 alterations in aquatic biodiversity and ecosystem functioning caused by acidification
12 persist. Although there is evidence for chemical recovery in many ecosystems, biological
13 recovery has been limited ([Chapter 1.6.2.2](#)). New research is consistent with the causal
14 determination in the 2008 ISA and has strengthened the evidence base for these effects.
15 The current causal statement has been expanded to include specific endpoints of
16 physiological impairment, as well as effects at higher levels of biological organization
17 ([Chapter 1, Table 1-1](#)). **The body of evidence is sufficient to infer a causal relationship**
18 **between acidifying deposition and changes in biota including physiological**
19 **impairment and alteration of species richness, community composition, and**
20 **biodiversity in freshwater ecosystems.**

1.6.3.1 Physiology and Biodiversity Effects

21 The deterioration in water quality caused by acidification affects the physiology,
22 survivorship, and biodiversity of many species from several taxonomic groups and at
23 multiple trophic levels. As stated in the 2008 ISA, biological effects are primarily
24 attributable to low pH (or ANC) and high inorganic Al concentrations under chronic or
25 episodic acidic conditions. During acidification episodes, water chemistry may exceed
26 the acid tolerance of resident aquatic biota, with effects that include fish mortalities,
27 changes in species composition, and declines in species richness across multiple taxa.
28 Studies reviewed in the 2008 ISA showed that the earlier aquatic lifestages were
29 particularly sensitive to acidification. New effects thresholds have been identified for
30 aquatic organisms consistent with observations in the 2008 ISA ([Table 8-10](#)). New
31 evidence is congruent with findings in the 2008 ISA that high levels of acidification (to
32 pH values below 5 and ANC lower than the range of 50 to 100 $\mu\text{eq/L}$) eliminate sensitive
33 species from freshwater streams. This information is reviewed below.

1.6.3.1.1 Primary Producers

1 Phytoplankton are primary producers at the base of the aquatic food web. These
2 photosynthetic organisms vary in tolerance of acidic conditions and include diatoms,
3 cyanobacteria, dinoflagellates, and other algal groups. The 2008 ISA reported reduced
4 species richness of freshwater plankton in response to acidification-related decreases in
5 pH and increases in inorganic Al. Effects were most prevalent when pH decreased to the
6 5 to 6 range. Effects on productivity are uncertain. Since the 2008 ISA, several
7 paleolimnological and field studies have further linked phytoplankton community shifts
8 to chemical indicators of acidification ([Appendix 8.3](#)). For example, [Lacoul et al. \(2011\)](#)
9 reviewed information on the effects of acidification and observed that the largest declines
10 in phytoplankton species richness occur over a pH range of 4.7 to 5.6 in Atlantic Canada.

1.6.3.1.2 Zooplankton

11 Zooplankton, the animal forms of plankton, comprise many groups of freshwater
12 unicellular and multicellular organisms including protozoans, rotifers, cladocerans, and
13 copepods. Zooplankton feed on phytoplankton or other zooplankton. Decreases in ANC
14 and pH and increases in inorganic Al concentration have been shown to contribute to the
15 loss of zooplankton species or abundance in lakes. In the 2008 ISA, thresholds for
16 zooplankton community alteration were between pH 5 and 6. In the Adirondacks, a
17 decrease in pH from 6 to 5 decreased zooplankton richness in lakes, and at ANC <0,
18 zooplankton richness was only 45% of the richness in unacidified lakes. Newer studies
19 support effects in a similar pH range (see [Appendix 8.3.1.2](#)). Zooplankton have also been
20 used as indicators of biological recovery ([Appendix 8.4.2](#)).

1.6.3.1.3 Benthic Invertebrates

21 Acidification has strong impacts on aquatic invertebrates because H⁺ and Al are directly
22 toxic to sediment-associated invertebrates like bivalves, worms, gastropods, and insect
23 larvae. In the 2008 ISA and in new studies in [Appendix 8.3.3](#), decreases in ANC and pH
24 and increases in inorganic Al concentration contribute to declines in abundance or
25 extirpation of benthic invertebrate species in streams. Acidification to pH values below 5
26 eliminates mayflies (Ephemeroptera), a taxa indicative of stream water quality, along
27 with other aquatic organisms. Since the 2008 ISA, a survey of benthic macroinvertebrates
28 by [Baldigo et al. \(2009\)](#) in the Adirondack Mountains indicated that macroinvertebrate
29 communities were intact at a pH above 6.4, with moderate acidification effects at pH 5.1
30 to 5.7, and severe acidification effects at a pH less than 5.1. Similarly, thresholds of pH

1 5.2 to 6.1 were identified for sensitive invertebrates from Atlantic Canada
2 ([Appendix 8.3.3](#)).

1.6.3.1.4 Fish

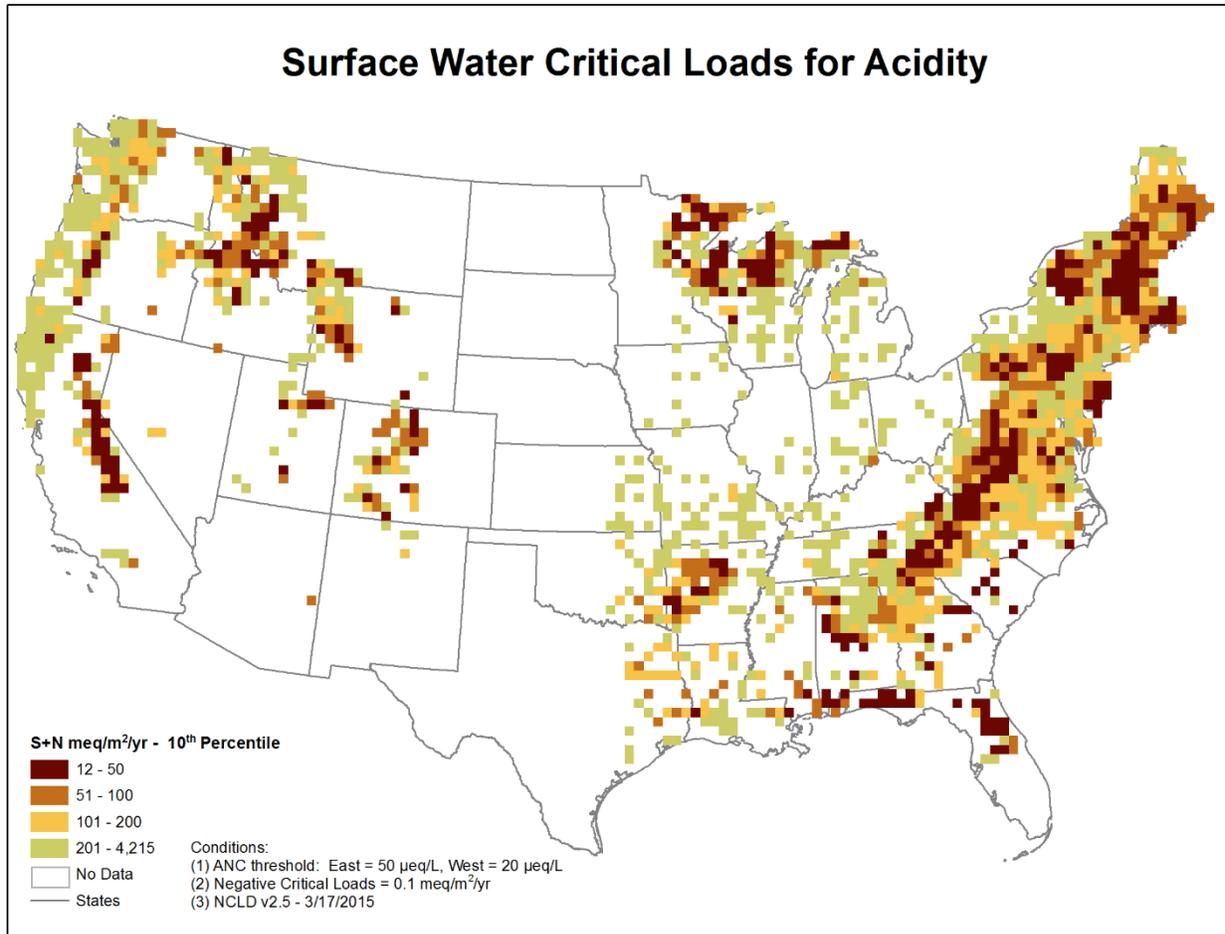

3 The effects of low pH and ANC and of high inorganic Al concentrations have been well
4 characterized in fish for many decades ([Appendix 8.3.6](#)). The 2008 ISA reported that
5 acidification impairs gill function and can cause respiratory and circulatory failure in fish.
6 Sensitivity to pH and inorganic Al varies among fish species, and among lifestages within
7 species, with early lifestages more sensitive to acidification. The most commonly studied
8 species were brown trout (*Salmo trutta*), brook trout (*Salvelinus fontinalis*), and Atlantic
9 salmon (*Salmo salar*). Studies published since the 2008 ISA, especially in Atlantic
10 salmon, add to the existing information on sublethal effects confirming variation in
11 sensitivity among lifestages ([Appendix 8.3.6.1](#)). Since 2008, new studies include
12 acidification effects upon migratory activities and upon behavior. New studies on fish
13 show behavioral effects at pH <6.6 ([Appendix 8.3.6.5](#)).

14 As summarized in [Baker et al. \(1990a\)](#) and the 2008 ISA, fish populations in acidified
15 streams and lakes of Europe and North America have declined, and some have been
16 eliminated as a result of atmospheric deposition of N and S and the resulting changes in
17 pH, ANC, and inorganic Al concentrations in surface waters. There is often a positive
18 relationship between pH and the number of fish species, particularly between pH 5.0 and
19 6.5. Additional pH thresholds published since the 2008 ISA ([Table 8-2](#)) support this
20 range, and several new studies consider the role of DOC in controlling pH and
21 subsequent effects on biota. In the 2008 ISA and in new research, few or no fish species
22 are found in lakes and streams that have very low ANC (near zero; [Figure 8-4](#) and
23 [Table 8-3](#)) and low pH (near 5.0). The number of fish species generally increases at
24 higher ANC and pH values. Al is very toxic to fish, and thresholds to elevated
25 concentrations of this metal in acidified waters are summarized in [Table 8-4](#).

1.6.3.2 National-Scale Sensitivity, Biological Recovery, and Critical Loads

26 The extent and distribution of acid-sensitive freshwater ecosystems and sensitive regions
27 in the U.S. were well known at the time of the 2008 ISA. Measured data on lake and
28 stream ANC across the U.S. exhibit clear spatial patterns ([Figure 8-11](#)). Surface waters in
29 the U.S. that are most sensitive to acidification are largely found in the Northeast,
30 southern Appalachian Mountains, Florida, the upper Midwest, and the mountainous West
31 ([Chapter 1, Figure 1-9](#)). Levels of acidifying deposition in the West are low in most

1 areas, acidic surface waters rare, and the extent of chronic surface water acidification to
2 date has been very limited. However, episodic acidification occurs in both the East and
3 West at sensitive locations, and this is partly natural and partly caused by humans.
4 Geographic patterns in acidification sensitivity vary in response to spatial differences in
5 geology, hydrologic flow paths, presence and depth of glacial till, climate, and other
6 factors ([Appendix 8.5.1](#)). In the eastern U.S., acid-sensitive ecosystems are generally
7 located in upland, mountainous terrain underlain by weathering-resistant bedrock. Some
8 of the most in-depth studies of the effects of acid stress on fish were conducted in streams
9 in Shenandoah National Park in Virginia and in lakes in the Adirondack Mountains of
10 New York. Effects on fish have also been documented in acid-sensitive streams of the
11 Catskill Mountains of southeastern New York, and the Appalachian Mountains from
12 Pennsylvania to Tennessee and South Carolina.

ANC = acid-neutralizing capacity; meq = milliequivalent yr = year.

Biological recovery in acid-affected areas is discussed in [Chapter 1.11](#). Typically biological recovery occurs only if chemical recovery ([Appendix 7.1.5.1](#)) is sufficient to allow growth, survival, and reproduction of acid-sensitive plants and animals. Surface water chemistry recovery varies by region with the strongest evidence for improvement in the Northeast and little or no recovery in central Appalachian streams. Acidification and recovery of fresh waters will also be affected by the physical, chemical, and biological modifications to acid inputs projected to occur with changes in annual mean temperature and magnitude of precipitation ([Appendix 8.5.3](#)). As reported in the 2008 ISA and in new studies, biological recovery lags behind chemical recovery in many

1 systems (see [Appendix 8.4](#)). The time required for biological recovery is unknown and
2 only partial biological recovery may be possible.

3 Since the 2008 ISA, considerable CL research has focused on aquatic acidification in the
4 U.S. The CLs for deposition are expressed in eq/ha/yr of S, N, or S + N because one or
5 both pollutants could be contributing to the observed effects. New empirical CLs include
6 571 eq N/ha/yr in the Northeast and 286 eq N/ha/yr in the West to prevent episodic
7 acidification in high-elevation lakes and to maintain an ANC of 74 eq/ha/yr in
8 high-elevation lakes of the Sierra Nevada ([Table 8-7](#)). Steady-state CLs have been
9 derived at many locations since the 2008 ISA ([Table 8-8](#)). Steady-state CLs of acidifying
10 deposition for lakes in the Adirondack Mountains (1,620 eq/ha/yr) and for the central
11 Appalachian streams (3,700 eq/ha/yr) were calculated to maintain a surface water ANC
12 of 50 $\mu\text{eq/L}$ on an annual basis ([NAPAP, 2011](#)). CL values of less than 500 eq/ha/yr were
13 calculated for one-third of streams in the Blue Ridge ecoregion, to maintain stream ANC
14 at 50 $\mu\text{eq/L}$. For lakes in Class I and II wilderness areas in the Sierra Nevada, CLs for
15 acidifying deposition in 2008 were estimated at ANC values of 0, 5, 10, and 20 $\mu\text{eq/L}$,
16 which span the range of minimum ANC values observed in Sierra Nevada lakes. The
17 median CL for granitic watersheds based on a critical ANC limit of 10 $\mu\text{eq/L}$ was
18 149 eq/ha/yr. Slightly more than one-third of these lakes had estimated rates of acidifying
19 deposition higher than their CL.

20 In addition to the steady-state and empirical loads described above, CL estimates have
21 been derived from dynamic modeling ([Appendix 8.5.4](#)). For example, there is new work
22 on simulated past and future effects of N and S on stream chemistry in the Appalachians
23 and Adirondack Mountain lakes. In 12 watersheds in the Great Smoky Mountain
24 National Park, target levels of ANC to protect aquatic life were used and ranged from
25 minimal (0 $\mu\text{eq/L}$) to considerable protection (50 $\mu\text{eq/L}$). For the 12 study streams, target
26 levels of $\text{NO}_3^- + \text{SO}_4^{2-}$ deposition ranged from 270 to 3,370 eq/ha/yr to reach an ANC of
27 0 $\mu\text{eq/L}$ by 2050 and 0–1,400 eq/ha/yr to reach an ANC of 50 $\mu\text{eq/L}$ by 2050. However,
28 the majority of streams could not achieve the ANC target of 50 $\mu\text{eq/L}$. Modeling also
29 suggests that complete recovery from acidification may not be possible by the Year 2100
30 at all sites in the southern Blue Ridge region ([Sullivan et al., 2011b](#)) even if S emissions
31 cease entirely. In Shenandoah National Park, MAGIC modeling based on simulations of
32 14 streams identified a target load of about 188 eq kg S/ha/yr to achieve an
33 ANC = 50 $\mu\text{eq/L}$ (preindustrial level based on hindcast simulations) in 2100 in sensitive
34 streams. In a dynamic modeling simulation in the Adirondacks Mountains, about 30% of
35 the lakes in the region had a target load <500 eq/ha/yr to protect lake ANC to 50 $\mu\text{eq/L}$
36 ([Sullivan et al., 2012a](#)). Future decreases in SO_4^{2-} deposition are suggested to be more
37 effective in that region in increasing Adirondack lake water ANC than equivalent
38 decreases in NO_3^- deposition. In another modeling study of 20 Adirondack watersheds,

1 estimates of preindustrial ANC for the study lakes ranged from 18 to 190 $\mu\text{eq/L}$, and
2 simulations estimate that lake ANC have decreased by 26 to 100 $\mu\text{eq/L}$ as a legacy of
3 acidification.

1.7 Estuarine and Near-Coastal Ecosystem Nitrogen Enrichment and Acidification

4 For estuaries (areas where fresh water from rivers meets the salt water of oceans) and
5 near-coastal systems, causal determinations from the 2008 ISA are further supported and
6 strengthened by additional studies, and there are two new causal statements on the
7 emerging topic of nutrient-enhanced coastal acidification ([Chapter 1, Table 1-1](#)).
8 Estuaries support a large biodiversity of flora and fauna and play a role in nutrient
9 cycling. N from atmospheric and other sources contributes to increased primary
10 productivity, leading to eutrophication ([Figure 10-1](#)), and N pollution is the major cause
11 of harm to the majority of estuaries in the U.S. ([Appendix 10](#)). Source apportionment
12 data in the 2008 ISA and newer studies indicate that atmospheric contributions to
13 estuarine N are heterogeneous across the U.S., ranging from <10% to approximately 70%
14 of total estuary N inputs ([Table 7-6](#)). In estuaries, increasing nutrient over-enrichment
15 leading to eutrophication is indicated by water quality deterioration, resulting in
16 numerous harmful effects, including areas of low dissolved oxygen (DO) concentration
17 (hypoxic zones), species mortality, and HABs. New studies support the 2008 ISA's
18 causal findings that increased N loading to coastal areas can alter biogeochemical
19 processes and lead to shifts in community composition, reduced biodiversity, and
20 mortality of biota. The current causal statement of biological effects of N enrichment in
21 estuarine ecosystems has been expanded to include total primary production, altered
22 growth, and total algal community biomass ([Chapter 1, Table 1-1](#)). Since the 2008 ISA, it
23 has been suggested that, in addition to atmospheric sources of CO_2 , nutrient-enhanced
24 productivity may contribute to acidification of coastal waters. New causal determinations
25 have been added to the current ISA on N deposition and increased nutrient enhanced
26 coastal acidification and associated biological effects ([Chapter 1, Table 1-1](#)). Increased
27 ocean acidification interferes with the ability of some organisms to build shells, although
28 the contribution of nutrient-enhanced coastal acidification is not yet understood.

1.7.1 Estuary and Near-Coastal Biogeochemistry

29 In the 2008 ISA, the evidence was sufficient to infer a causal relationship between
30 reactive N deposition and biogeochemical cycling of N and C in estuarine and
31 near-coastal marine systems. Evidence reviewed in the 2008 ISA, along with new studies

1 indicate elevated N inputs to coastal areas can alter key processes that influence N and C
2 cycling in near-coastal environments. As N fluxes to coastal areas have increased in
3 recent decades in many parts of the U.S., the varying rates of different N cycling
4 processes within estuaries themselves can also affect the magnitude of eutrophication
5 experienced as a result of external N enrichment. Nitrogen additions not only cause the
6 total pool of N to be larger, but may also perturb N cycling in such a way that the system
7 may exacerbate eutrophication to a greater extent than expected based on N additions
8 alone. Research conducted since the 2008 ISA has shown that many of these N cycling
9 processes are more important in the estuarine environment than previously understood.
10 The removal of N through denitrification is a valuable ecosystem service in terms of
11 constraining the extent and magnitude of eutrophication. Additional research has
12 established dissimilatory NO_3^- reduction to NH_4^+ (DNRA) as a more important N
13 reduction pathway in some estuaries. Ammonium produced via DNRA can lead to
14 enhanced productivity and respiration, which may exacerbate hypoxia. Recent studies
15 indicate that DNRA rates are higher in warmer months and can also take up a larger
16 percentage of total N reduction activity when temperatures are higher. The roles of
17 sedimentary microbial processes of denitrification and anammox have been further
18 characterized. New research has shown that the community of N fixing microorganisms
19 is more diverse in estuarine and coastal waters than previously thought, and that N
20 fixation occurs more widely than previously assumed. Influence of benthic macrofauna
21 on N cycling has received increased research attention in part due to the potential for
22 these organisms to mitigate external N enrichment. New research further supports
23 conclusions of the 2008 ISA, and **the body of evidence is sufficient to infer a causal
24 relationship between N deposition and the alteration of biogeochemistry in estuarine
25 and near-coastal marine systems.**

26 Since the 2008 ISA, a number of papers have identified links between nutrient
27 enrichment and acidification of coastal waters ([Appendix 7.2.4](#)). One of the initial studies
28 found that CO_2 production during decomposition of organic matter delivered to coastal
29 zones from rivers experiencing eutrophication has enhanced the acidification of coastal
30 subsurface waters in the Gulf of Mexico and the East China Sea ([Cai et al., 2011c](#)) and
31 additional studies provide evidence of acidification in estuaries due to this mechanism
32 ([Appendix 7.2.7.2](#)). Additional CO_2 in the water column is produced from respiration of
33 living algae and seagrasses. The CO_2 produced in eutrophic estuarine waters combines
34 with water molecules, producing carbonic acid, which makes the water more acidic.
35 Nutrient-enhanced coastal acidification tends to occur in locations where there is either
36 thermal or saline stratification. Modeling of coastal acidification via N enrichment and
37 atmospheric CO_2 dissolution suggests that the combined effects of these two pathways
38 are synergistic. **The body of evidence is sufficient to infer a likely causal relationship
39 between N deposition and increased nutrient-enhanced coastal acidification.**

1.7.1.1 Nitrogen Enrichment

1 Estuarine biogeochemistry is complicated because it directly controls more than just the
2 N cycle; the response to N loading resulting in eutrophication impacts the chemical
3 cycling of metals and DO ([Appendix 7.2.3](#)), redox conditions, pH ([Appendix 7.2.4](#)), and
4 ultimately energy transfer (e.g., food webs from microbes to humans). The response to N
5 loading is also tightly controlled by the availability of organic matter (i.e., C) and its
6 lability and reactivity. Excess nutrient inputs are occurring within the context of other
7 stressors such as climate change ([Appendix 7.2.6.12](#)) and rising atmospheric CO₂, which
8 further modify coastal biogeochemistry ([Doney, 2010](#)). As reported in the 2008 ISA,
9 estuaries are generally N limited, and have received sufficiently high levels of N input
10 from human activities (including deposition, agricultural runoff, and wastewater) to cause
11 eutrophication. Highly variable environments within estuaries are characterized by a
12 gradient of increasing salinity toward the ocean. As N moves downstream, some fraction
13 is taken up by phytoplankton or removed by microbial denitrification. Key processes that
14 influence N cycling include hypoxia, nitrification, denitrification, and decomposition.
15 Until recently, it was generally believed that NH₃ oxidation was accomplished only by
16 Proteobacteria in marine environments. New research discovered that some archaea can
17 also oxidize NH₃. These ammonia-oxidizing archaea are dominant in some estuaries,
18 while ammonia-oxidizing bacteria are more important in others.

19 In the complex environment of the freshwater-to-ocean continuum, there are many
20 chemical and biological indicators of eutrophic condition. One approach is to measure
21 total nutrient loading and concentrations; however, these data need to be interpreted in
22 the context of the physical and hydrological characteristics that determine ecosystem
23 response. Water quality measures such as pH and DO, along with key biological
24 indicators such as chlorophyll *a*, phytoplankton abundance, HABs, macroalgal
25 abundance, and submerged aquatic vegetation (SAV; rooted vascular plants that do not
26 emerge above the water), can all be used to assess responses to nutrient loading
27 ([Table 10-1](#)). Nitrogen removal from the estuary is also influenced by faunal as well as
28 microbial communities.

29 Organic particles in coastal regions sink to the sediment-water interface where they
30 accumulate and decompose. Decomposition of these organic particles transforms
31 nutrients and depletes O₂ in the water. Decreasing DO can create hypoxic (<2 mg/L of
32 dissolved O₂) or anoxic zones inimical to fish and other aerobic life forms. Oxygen
33 depletion largely occurs only in bottom waters under stratified conditions, not throughout
34 the entire water column. This can result in seasonal hypoxia in shallow coastal regions,
35 particularly those that receiving high inputs of nutrients from coastal rivers. Development
36 of hypoxia is increasingly a concern in estuaries across the U.S. ([Appendix 10.2.4](#)).

1 Since the 2008 ISA, N enrichment has been recognized as a potential contributing factor
2 to acidification of coastal waters ([Appendix 10.5](#)). Dissolution of atmospheric
3 anthropogenic CO₂ into the ocean has led to long-term decreases in pH. With increasing
4 N inputs to coastal waters, decomposition of excess organic matter associated with
5 eutrophication adds CO₂ to the water column ([Sunda and Cai, 2012](#); [Cai et al., 2011c](#);
6 [Howarth et al., 2011](#)). Models show that while the impact of each acidification pathway
7 (N enrichment or atmospheric CO₂ dissolution) may be moderate, the combined effect
8 may be much larger than would be expected from the additive effects of each pathway
9 ([Sunda and Cai, 2012](#); [Cai et al., 2011c](#)).

1.7.1.2 Models

10 Since the 2008 ISA, several new applications of existing models have quantified
11 eutrophication processes in estuaries and near-coastal marine ecosystems. These have
12 included studies that focused primarily on N cycling or hypoxia. Other models of
13 estuarine eutrophication focus on N load apportionment, or on relationships between N
14 loads and ecological endpoints. Since the 2008 ISA, SPARROW has been used to
15 estimate total N loads within watersheds to determine sources of N to streams and rivers;
16 it has also been applied at regional and national scales. Additional models and tools that
17 include the contribution of N directly from the atmosphere have been applied to U.S.
18 estuaries, including the Watershed N Loading Model (NLM) and the Watershed
19 Deposition Tool (WDT). The latter was developed by the U.S. EPA to map atmospheric
20 deposition estimates to watersheds using wet and dry deposition data from CMAQ
21 ([Schwede et al., 2009](#)). This tool links air and water quality modeling data for use in total
22 maximum daily load (TMDL) determinations and analysis of nonpoint-source impacts.
23 New model applications include studies that focused primarily on endpoints of N cycling,
24 hypoxia, and HABs. Models of coastal eutrophication are described in greater detail in
25 [Appendix 7.2.8](#).

1.7.1.3 National-Scale Sensitivity

26 Sensitivity of estuaries to biogeochemical changes associated with N enrichment varies
27 across the U.S. The biogeochemical sensitivity of estuaries and near coastal areas will be
28 discussed together with biological sensitivity to N enrichment in [Chapter 1.7.4](#).

1.7.2 Biological Effects of Nitrogen Enrichment

1 In the 2008 ISA, evidence was sufficient to infer a causal relationship between N
2 deposition and the alteration of species richness, community composition, and
3 biodiversity in estuarine ecosystems. The strongest evidence for a causal relationship was
4 from changes in biological indicators of nutrient enrichment [chlorophyll *a*, macroalgal
5 (seaweed) abundance, HABs, DO, and changes in SAV ([Table 10-1](#))]. Some indicators,
6 such as chlorophyll *a*, are directly linked to nutrient enrichment and provide evidence of
7 early ecosystem response; other indicators, such as low DO and decreases in SAV,
8 indicate more advanced eutrophication. Phytoplankton are the base of the coastal food
9 web and increases in primary producer biomass and altered community composition
10 associated with increased N can lead to a cascade of direct and indirect effects at higher
11 trophic levels. At the time of the 2008 ISA, N was recognized as the major cause of harm
12 to the majority of estuaries in the U.S. Since 2008, new paleontological studies,
13 observational studies, and experiments have further characterized the effects of N on
14 phytoplankton growth and community dynamics, macroinvertebrate response, and other
15 indices of biodiversity. For this ISA, new information is consistent with the 2008 ISA and
16 the causal determination has been updated to reflect more specific categories of effects to
17 include total primary production, altered growth and total algal community biomass. This
18 new research strengthens the evidence base and is consistent with the 2008 ISA
19 ([Chapter 1, Table 1-1](#)) that **the body of evidence is sufficient to infer a causal**
20 **relationship between N deposition and changes in biota including total primary**
21 **production, altered growth, total algal community biomass, species richness,**
22 **community composition, and biodiversity due to N enrichment in estuarine**
23 **environments.**

24 Since the 2008 ISA, additional evidence has shown that reduced forms of atmospheric N
25 play an increasingly important role in estuarine and coastal eutrophication and HAB
26 dynamics. New studies emphasize that N inputs interact with physical and hydrologic
27 factors to increase primary productivity and eutrophication in coastal areas.
28 Climate-related changes including temperature, precipitation, wind patterns, extreme
29 weather events, stronger estuary stratification, increased metabolism and organic
30 production, and sea-level rise are all expected to modify coastal habitats
31 ([Appendix 10.1.4.1](#)).

1.7.2.1 Primary Producers

32 Algae are the base of the coastal food web, and the 2008 ISA showed that changes in
33 chemical composition of N inputs can shift the algal community and cascade up the food

1 web. Chlorophyll *a* is broadly recognized indicator of phytoplankton biomass and is used
2 as a proxy for assessing effects of estuarine nutrient enrichment. It can signal an early
3 stage of water quality degradation related to nutrient loading and is incorporated into
4 water quality monitoring programs and national-scale assessments including U.S. EPA's
5 National Coastal Condition Assessment ([Appendix 7.2.7](#)). Phytoplankton sampling,
6 microcosms studies and sediment core analysis have shown changes in phytoplankton
7 community structure in estuaries with elevated N inputs ([Appendix 10.3](#)). These shifts at
8 the base of the food web to species that are not as readily grazed (e.g., cyanobacteria,
9 dinoflagellates) have a cascade of effects including poor trophic transfer and an increase
10 in unconsumed algal biomass, which could stimulate decomposition, O₂ consumption,
11 and the potential for hypoxia.

12 There is consistent and coherent evidence that the incidence of HAB outbreaks is
13 increasing in both freshwater and coastal areas, a problem that has been recognized for
14 several decades ([Appendix 10.2.2](#)). Of the 81 estuary systems for which data were
15 available for the National Estuarine Eutrophication Assessment (NEEA), 26 exhibited a
16 moderate or high symptom expression for nuisance or toxic algae ([Bricker et al., 2007](#)).
17 Since the 2008 ISA, HAB bloom conditions and effects of HAB toxins on wildlife have
18 been further characterized ([Appendix 10.2.2](#)). Release of toxins during HABs can be
19 harmful to fish and shellfish, and these toxins may be transferred to higher trophic levels.
20 The form of N affects phytoplankton growth and toxin production of some HAB species.
21 Increasing loads of NH₃⁺/NH₄⁺ have been linked to the expansion of HABs and altered
22 phytoplankton community dynamics ([Appendix 10.3.3](#)). Cyanobacteria, and many
23 chlorophytes and dinoflagellates may be better adapted to the use of NH₄⁺ while diatoms
24 generally thrive in oxidized forms of N such as NO₃⁻ ([Figure 10-7](#)).

25 Macroalgal (seaweed) growth is also stimulated by increased N inputs, which increase
26 the dominance of faster growing benthic or pelagic macroalgae to the exclusion of other
27 species ([Appendix 10.2.3](#)). Studies published since the 2008 ISA provide further
28 evidence that macroalgae respond to the form of N with some species showing greater
29 assimilation and growth rates with NH₄⁺ than with NO₃⁻. Increased abundance of
30 macroalgae, which block light, and increased epiphyte loads on the surface of SAV may
31 reduce the growth and biomass of SAV. SAV including the eelgrass *Zostera marina* are
32 important ecological communities found within some coastal bays and estuaries that are
33 sensitive to elevated nutrient loading and loss of this habitat can lead to a cascade of
34 ecological effects because many organisms are dependent upon seagrasses for cover,
35 breeding, and as nursery grounds. Recently, presence of seagrass beds was linked to
36 decreased bacterial pathogens of humans, fishes, and invertebrates in the water column
37 and lower incidence of disease in adjacent coral reefs ([Appendix 10.2.5](#)). The 2008 ISA
38 reported correlations between increased N loading and declines in SAV abundance and

1 newer studies have further characterized this relationship. In a survey of southern New
2 England estuaries, reduced eelgrass extent was observed at increased watershed N
3 loading. New studies have characterized the role of invertebrate mesograzers, such as
4 small crustaceans and gastropods, in controlling algal growth, potentially buffering
5 eutrophication effects on seagrass communities ([Appendix 10.3.7](#)). Macroalgae may not
6 be a good indicator of eutrophication in some upwelling-influenced estuaries in the
7 Pacific Northwest as an increase in macroalgal biomass in these systems does not appear
8 to be associated with temporal declines in eelgrass ([Appendix 10.2.3](#)).

1.7.2.2 Bacteria and Archaea

9 Ammonia-oxidizing prokaryotes carry out nitrification in estuarine waters.
10 Ammonia-oxidizing archaea are relatively recently described, and several studies since
11 the 2008 ISA have considered community responses of ammonia-oxidizing bacteria and
12 ammonia-oxidizing archaea. Community structure of ammonia-oxidizers is related to
13 nutrient inputs and affected by the form of available N ([Appendix 10.3.4](#)).

1.7.2.3 Invertebrates

14 The community of benthic organisms shifts toward shorter life spans and smaller body
15 size in coastal areas with severe seasonal hypoxia ([Appendix 10.2.4](#)). Reduced species
16 density and diversity in the northern Gulf of Mexico are linked to persistent hypoxic
17 events. The form of N present has been shown to affect molluscan taxonomic
18 assemblages ([Appendix 10.3.5](#)). Shifts in algal composition and productivity can affect
19 growth of shellfish that feed on phytoplankton. Shellfish contribute to N and C cycling
20 and can improve water quality, and recent research has explored the use of these
21 organisms for coastal N remediation ([Appendix 7.2.6.11](#)). Harvest of shellfish for human
22 consumption removes nutrients from estuaries.

23 N enrichment is one of several factors linked to increased disease susceptibility,
24 bleaching, and reduced calcification rate in corals ([Appendix 10.4.2](#)). Several studies
25 have isolated effects of N, which affects corals via pathways that are distinct from P. The
26 threatened status of staghorn coral (*Acropora cervicornis*) and elkhorn coral (*Acropora*
27 *palmata*) under the U.S. Endangered Species Act has been linked to indirect N pollution
28 effects, specifically low DO, algal blooms that alter habitat, and other non-nutrient
29 stressors ([Hernández et al., 2016](#)).

1.7.2.4 Fish

1 Fish biodiversity is altered by increased N inputs and resulting changes in biological and
2 chemical indicators ([Appendix 10.3.6](#)). Many fish are unable to persist at DO levels
3 below 2 mg/L ([Figure 10-4](#)). Recent studies in the southern Gulf of Saint Lawrence have
4 linked SAV loss to declines in fish biodiversity, although organisms did not change
5 positions within food webs. In laboratory conditions, turbidity associated with
6 eutrophication alters fish reproductive behaviors. Hypoxia has also recently been shown
7 to affect reproduction in fish. For example, hypoxia acts as an endocrine disruptor in
8 Atlantic croaker (*Micropogonias undulatus*; [Appendix 10.2.4](#)).

1.7.3 Biological Effects of Nutrient-Enhanced Coastal Acidification

9 Coastal acidification ([Chapter 1.7.1](#)), which can be exacerbated by elevated N input, is
10 projected to alter marine habitat, have a wide range of effects at the population and
11 community level, and impact food web processes. Newer studies show that organisms
12 that produce calcium carbonate shells are impacted by increasing acidification of ocean
13 waters ([Appendix 10.5](#)). Decreased concentration of carbonate ions (which organisms
14 such as calcareous plankton, oysters, clams, sea urchins, and coral take up to build shells)
15 are observed in acidic conditions. With increasing N inputs to coastal waters CO₂ in the
16 water column is produced from degradation of excess organic matter from changing land
17 use, as well as respiration of living algae and seagrasses, which in turn can make the
18 water more acidic. Documented declines of oyster production on the U.S. west coast are
19 linked to ocean acidification. Research on costressors associated with conditions of
20 coastal acidification and eutrophication suggest that interactions between elevated CO₂,
21 decreasing pH, and nutrient inputs are complex. **The body of evidence is suggestive of,
22 but not sufficient to infer, a causal relationship between N deposition and changes in
23 biota including altered physiology, species richness, community composition, and
24 biodiversity due to nutrient-enhanced coastal acidification.**

1.7.4 National-Scale Sensitivity and Critical Loads

25 The NEEA, the most recent comprehensive survey of eutrophic conditions in U.S.
26 estuaries conducted by the National Oceanic and Atmospheric Administration, defined
27 eutrophication susceptibility as the natural tendency of an estuary to retain or flush
28 nutrients ([Bricker et al., 2007](#)). In estuaries that have longer water residence times,
29 nutrients are more likely to lead to eutrophic conditions ([Appendix 10.1.4](#)). As reported
30 in the 2008 ISA and newer studies, nutrient loading accelerates hypoxia, which is more

1 likely in marine waters with limited water exchange, water column stratification, and
2 high production and settling of C to bottom waters. Other factors identified in the
3 2008 ISA that increase estuary sensitivity to eutrophication include human population,
4 agricultural production, and the size of the estuary relative to its drainage basin. The
5 NEEA reported that the most eutrophic estuaries in the U.S. occur in the mid-Atlantic
6 region, and the estuaries with the lowest degree of eutrophication are in the North
7 Atlantic ([Figure 10-2](#)). Estuaries identified in the 2008 ISA as susceptible to
8 eutrophication include the Chesapeake Bay, Pamlico Estuary in North Carolina, Long
9 Island Sound, as well as along the continental shelf adjacent to the Mississippi and the
10 Atchafalaya River discharges to the Gulf of Mexico. New research at the regional scale
11 includes long-term studies of several coastal systems on trends in coastal water quality
12 and chemistry. A 23-year study of the Chesapeake Bay concluded that water quality has
13 decreased and chlorophyll *a* levels have increased since 1986, in part due to long-term
14 climate trends (see [Appendix 10.2.5](#)).

15 Since the 2008 ISA, there is additional information on the extent and severity of
16 eutrophication and hypoxia in sensitive regions. Areas of eutrophication-related hypoxia
17 are found on the U.S. east and west coasts and the Gulf of Mexico ([Figure 10-5](#)). The
18 2008 ISA reported that the largest zone of hypoxic coastal water in the U.S. was the
19 northern Gulf of Mexico on the Louisiana-Texas continental shelf. In the summer of
20 2017, the hypoxic zone in the Gulf was the largest ever measured at 14,123 km²
21 (8,776 mi²) ([U.S. EPA, 2017e](#)). Atmospheric deposition to watersheds in the
22 Mississippi/Atchafalaya River Basin contributes approximately 16 to 26% of the total N
23 load to the Gulf of Mexico ([Appendix 10.2.4](#)). Long Island Sound also experiences
24 periods of anoxia. In other U.S. coastal systems, hypoxia incidence is increasing, but DO
25 impacts are relatively limited temporally and spatially. In the Pacific Northwest, coastal
26 upwelling can be a large source of nutrient loads and advection of upwelled water can
27 introduce hypoxic water into estuaries that is not related to anthropogenic sources.

28 The NEEA suggested that only a small fraction of the estuary systems evaluated reported
29 moderate to high SAV loss ([Bricker et al., 2007](#)), mostly in the mid-Atlantic region.
30 While seagrass coverage is improving in some estuaries, such as Tampa Bay (Tampa Bay
31 Case Study, [Appendix 16](#)), many estuaries continue to see declines in seagrass extent.
32 SAV is often at a competitive disadvantage under N enriched conditions due to the fast
33 growth of opportunistic macroalgae that preferentially take up NH₄⁺ and can block light
34 from seagrass beds.

35 There are thresholds of response identified for some biological and chemical indicators of
36 N enrichment in estuaries ([Appendix 10](#)). Chlorophyll *a* is an indicator of phytoplankton
37 biomass, and thus, a proxy for assessing estuarine nutrient enrichment. In general,

1 0–5 µg/L chlorophyll *a* is considered to be good condition, concentrations between 5 and
2 20 µg/L are classified as fair condition, and concentrations of >20 µg/L indicate poor
3 conditions ([Table 10-2](#)). A new response threshold of tidal-averaged total N
4 concentration of <0.34 mg/L has been identified for healthy eelgrass in Massachusetts
5 waters. Markedly decreased eelgrass coverage is observed at N loading rates
6 ≥100 kg N/ha/yr, and levels above 50 kg N/ha/yr are likely to impact SAV habitat extent
7 in shallow New England estuaries ([Table 10-4](#)). [Greaver et al. \(2011\)](#) identified the range
8 of 50–100 kg N/ha/yr total N loading as the empirical critical load for loss of eelgrass
9 based on [Latimer and Rego \(2010\)](#). In terms of DO, concentrations of 0 mg/L are anoxic,
10 0–2 are indicative of hypoxic conditions, and 2–5 mg/L are biologically stressful
11 conditions ([Figure 10-4](#)). Oxygen depletion largely occurs only in bottom waters under
12 stratified conditions, not throughout the entire water column.

13 The indicators of nutrient enrichment in coastal areas (chlorophyll *a*, HABs, macroalgal
14 abundance, DO, SAV, and benthic diversity) have been incorporated into indices of
15 coastal eutrophication. In the 2008 ISA, the Assessment of Estuarine Tropic Status
16 (ASSETS) categorical Eutrophication Condition index (ECI) developed for the NEEA
17 was used as an assessment framework for coastal U.S. estuaries ([Bricker et al., 2007](#)).
18 Additional indices of estuarine functioning that incorporate biological indicators have
19 since been developed both in the U.S. and internationally ([Appendix 10.2.6](#)).
20 Comparisons of these frameworks have identified robust methods to measure estuarine
21 response, such as incorporation of annual data, frequency of occurrence, spatial coverage,
22 secondary biological indicators, and a multicategory rating scale.

23 Since the 2008 ISA, N enrichment has been linked to coral bleaching and reduced
24 calcification rates ([Appendix 10.4.2](#)). Near-coastal coral reefs in the U.S. occur off south
25 Florida, Texas, Hawaii, and U.S. territories in the Caribbean and Pacific.

1.8 Wetland Ecosystem Nitrogen Enrichment and Acidification

26 New evidence, including new critical loads, supports and strengthens the causal findings
27 from the 2008 ISA regarding N enrichment effects in wetlands ([Chapter 1, Table 1-1](#)). In
28 freshwater and coastal wetland ecosystems, deposition of N and S do not tend to cause
29 acidification-related effects at levels currently common in the U.S. [([U.S. EPA, 2008a](#)), in
30 Annex B]. However, the 2008 ISA documented that wetlands can be sensitive to N
31 enrichment and eutrophication effects. Newer studies have characterized N effects on
32 biogeochemistry, physiology, biodiversity, national sensitivity, and critical loads for
33 freshwater and coastal wetlands; coastal wetlands are typically tolerant of higher N
34 loading than freshwater wetlands.

1.8.1 Wetland Biogeochemistry

1 In the 2008 ISA, evidence was sufficient to infer a causal relationship between N
2 deposition and the alteration of wetland biogeochemical cycling. Although sources and
3 rates of N inputs vary widely among wetlands, N deposition contributes substantially to
4 total loading in many wetlands. This additional N alters multiple aspects of
5 biogeochemistry, including C cycling, N cycling, and release of nutrients to
6 hydrologically connected surface waters. New research together with the information
7 included in the 2008 ISA shows that **the body of evidence is sufficient to infer a causal
8 relationship between N deposition and the alteration of biogeochemical cycling in
9 wetlands.**

10 The 2008 ISA reported that N enrichment altered N cycling in wetland ecosystems.
11 Chemical indicators of N deposition in wetlands include NO_3^- and NH_4^+ leaching, DON
12 leaching, N mineralization, denitrification rates, and N_2O emissions. A wetland can act as
13 a source, sink, or transformer of atmospherically deposited N, and these functions vary
14 with season and hydrological conditions. Vegetation type, physiography, local hydrology,
15 and climate all influence source/sink N dynamics in wetlands. A new synthesis of global
16 wetland data showed that wetland reactive N removal and water quality improvement is
17 proportional to reactive N load, and removal efficiency is 26% higher in nontidal than
18 tidal wetlands, while a new meta-analysis shows that N enrichment increases wetland
19 N_2O emissions by 207%. New studies have also evaluated the effects of N loading/N
20 addition on other endpoints related to N cycling in peat bog, riparian, mangrove, and salt
21 marsh wetlands (see [Appendix 11.3.1](#)). The endpoints evaluated include ecosystem N
22 retention, wetland export of N to surface waters, N fixation, N mineralization,
23 denitrification, emission of N_2O , and bacterial abundance, activity, and composition in
24 wetland soils. The results of North American studies are summarized in [Figure 11-2](#).
25 Across studies, N enrichment decreases the ability of wetlands to retain and store
26 nitrogen, which may diminish the wetland ecosystem service of improving water quality.

27 In the 2008 ISA, evidence from Canadian and European peatlands showed that N
28 deposition had negative effects on *Sphagnum* (moss) bulk density and mixed effects on
29 *Sphagnum* productivity depending on the history of deposition. There is new information
30 on how N deposition alters biogeochemical cycling of C in wetlands. Chemical indicators
31 of N deposition in wetlands include soil organic matter, total soil C or peat C, CO_2
32 emissions, and CH_4 emissions. Long-term C storage is an important ecosystem service of
33 wetlands for which measures of physical marsh stability can serve as a proxy, and
34 physical indicators of N deposition can include temperature, bulk density, physical
35 resistance, and soil water content. In addition, changes to plant growth rates and
36 productivity indicate altered C cycling in wetlands, and are summarized in [Chapter 1.8.2](#).

1 The literature evaluates the effects of N deposition, N loading, or experimental N
2 addition on C cycling in bogs, fens, riparian or intermittent marshes, freshwater tidal
3 marshes, mangroves, and salt marshes (see [Appendix 11.3.2](#)). Significant effects of N
4 loading upon biogeochemical cycling of C in North American wetlands (in which the N
5 addition was 500 kg N/ha/yr or lower) are summarized in [Figure 11-3](#). N enrichment
6 decreases wetland retention of C, as indicated by new studies and a new meta-analysis
7 that show that N enrichment increases methane production in salt marshes. New studies
8 of marshes along the Gulf Coast and East Coast find that N enrichment also decreases the
9 bulk density of salt marshes, making marshes less resilient to physical stresses from tidal
10 or storm flooding, and may accelerate coastal marsh loss.

1.8.2 Biological Effects of Wetland Nitrogen Enrichment/Eutrophication

11 In the 2008 ISA, evidence was sufficient to infer a causal relationship between N
12 deposition and the alteration of species richness, species composition, and biodiversity in
13 wetlands. New evidence is presented in the following sections regarding the effects of N
14 upon wetland plant physiology, architecture, demography, and biodiversity. **The body of
15 evidence is sufficient to infer a causal relationship between N deposition and the
16 alteration of growth and productivity, species physiology, species richness,
17 community composition, and biodiversity in wetlands.**

1.8.2.1 Growth, Productivity, and Physiology

18 In the 2008 ISA, evidence from Canadian and European bogs and fens showed that N
19 deposition had negative or mixed effects on *Sphagnum* (moss) productivity, depending on
20 history of deposition. In Canadian ombrotrophic peatlands experiencing deposition of
21 2.7–8.1 kg N/ha/yr, peat accumulation increased with N deposition, but accumulation
22 rates had slowed by 2004, indicating a degree of N saturation. Coastal wetlands
23 responded to N enrichment with increased primary production, shifting microbial and
24 plant communities and altering pore water chemistry, although many of the studies in
25 coastal wetlands used N enrichment levels more similar to those of wastewater than
26 atmospheric deposition. New research on N enrichment effects on growth and
27 productivity was conducted in ombrotrophic bogs, intermittent wetlands, freshwater tidal
28 marsh, mangroves, and coastal salt marshes (see [Appendix 11.4](#)). Ecological endpoints
29 evaluated to assess N loading effects on growth and productivity include plant
30 aboveground biomass and productivity, plant belowground biomass of roots and
31 rhizomes, and growth rates, and are summarized along with N effects on C cycling in
32 [Figure 11-3](#). The effects of N additions on plant physiology were not addressed in the

1 2008 ISA, but information regarding these effects is available for bogs and fens, riparian
2 wetlands, freshwater tidal marsh, mangroves, and salt marshes (see [Appendix 11.5](#)).
3 Ecological endpoints evaluated to assess N loading effects on plant physiology include
4 stoichiometry (i.e., nutrient concentrations and ratios of multiple nutrients in plant tissue),
5 nutrient acquisition efficiency (including insectivory rates in insectivorous plants),
6 nutrient use efficiency, and nutrient reabsorption efficiency, and are summarized in
7 [Figure 11-4](#).

8 In general, across types of wetlands, nitrogen loading increases aboveground growth and
9 productivity while decreasing or not affecting belowground growth and productivity. In
10 bogs and fens, N deposition decreases growth of state-listed *Sarracenia purpurea* (purple
11 pitcher plant), and N enrichment increases aboveground productivity of emergent sedges
12 more than of peat-building moss species. These changes cascade up to affect biodiversity
13 in bogs and fens (see below, [Chapter 1.8.2.2](#)). In freshwater and tidal marshes, N
14 enrichment increases aboveground productivity while decreasing belowground
15 productivity, and this shift from belowground to aboveground plant productivity may
16 account for changes in wetland C storage (see [Chapter 1.8.1](#)).

17 Changes to plant physiology and stoichiometry vary by species tolerance to N and N
18 acquisition strategies. In bogs, N enrichment typically causes increased plant tissue N
19 concentrations, decreased N use efficiency, and decreased N resorption efficiency during
20 senescence. After several years of exposure to high rates of N loading, bog plants may
21 experience leaf N saturation and limitation by other nutrients (e.g., P, K, and Ca,
22 indicated by increasing reabsorption efficiencies), resulting in leaf damage in sensitive
23 species. *S. purpurea* (purple pitcher plant) decreases its dependence upon insectivory for
24 nutrition at N deposition rates of 4.4 kg N/ha/yr. In freshwater marshes, N enrichment
25 also increases plant tissue N concentrations while increasing P limitation and altering
26 resorption efficiencies.

27 Plant architecture was not addressed in the 2008 ISA, and demography was addressed
28 only for bogs and fens. Aboveground, plant architecture includes branching patterns, as
29 well as the size, shape, and position of leaves and flower organs. New studies find N
30 enrichment affects plant architecture in a salt marsh, in mangroves, in freshwater tidal
31 marshes, and in a riparian wetland ([Appendix 11.6](#)). In terms of plant demography, the
32 2008 ISA found positive population growth rates for *S. purpurea* at 0 or 1.4 kg N/ha/yr,
33 but population losses at 14 kg N/ha/yr, and that N deposition above 6.8 kg N/ha/yr
34 increases population extinction risk of *S. purpurea*. New studies show that N addition has
35 species-specific effects upon reproduction of West Coast salt marsh plant species, and
36 increases mortality across the global distribution of mangrove species ([Appendix 11.7](#)).

1.8.2.2 Biodiversity

1 In the 2008 ISA, evidence was sufficient to infer a causal relationship between N
2 deposition and the alteration of species richness, species composition, and biodiversity in
3 wetlands. Notably, the 2008 ISA cited 4,200 native plant species in U.S. wetlands, 121 of
4 which are federally endangered. Given their relative area, wetlands provide habitat to a
5 disproportionately high number of rare plants. Many wetland species have adapted to N
6 limited conditions, including endangered species in the genera *Isoetes* (3 endangered
7 species) and *Sphagnum* (15 endangered species), as well as insectivorous plants such as
8 pitcher plants (*Sarracenia* spp.) and sundews (*Drosera rotundifolia*).

9 Coastal wetlands responded to N enrichment with increased primary production,
10 changing microbial and plant communities, and altered pore water chemistry, although
11 many of the studies available in 2008 used high N enrichment levels more similar to N
12 loading from wastewater than from atmospheric deposition. New research since 2008
13 including N deposition gradient studies, experimental N addition studies, and
14 observational studies that show that N enrichment altered biodiversity in bogs and fens,
15 intermittent wetlands, freshwater wetlands, freshwater tidal wetlands, and coastal salt
16 marshes (see [Appendix 11.8](#)).

17 New research from wetland ecosystems strengthens the 2008 causal statement. New
18 research confirms that, as in terrestrial systems, N addition can decrease the abundance
19 and richness of sensitive species while increasing the abundance and richness of tolerant
20 species. In bogs and fens, N enrichment decreases the survival of insectivorous plants and
21 the cover of mosses, while increasing the cover of shrub species. In freshwater marshes,
22 N enrichment changes plant community composition, increases the abundance of and
23 stresses caused by invasive plant species, promotes the harmful algal species that produce
24 the toxin microcystin, and increases mosquito larvae that are vectors for zoonotic
25 diseases (see [Figure 11-1](#)). In freshwater tidal and coastal marshes, N enrichment changes
26 plant community composition, increases cover of invasive plant species, increases
27 herbivory by invertebrates, and increases herbivory by the invasive mammal *Myocastor*
28 *coypus* (nutria).

1.8.2.3 National Sensitivity and Critical Loads for Wetlands.

29 Freshwater and coastal wetlands tend to have different sensitivity to added N. Broadly,
30 wetlands that receive a larger fraction of their total water budget in the form of
31 precipitation are more sensitive to the effects of N deposition. For example, bogs
32 (70–100% of hydrological input from rainfall) are more sensitive to N deposition than

1 fens (55–83% as rainfall), which are more sensitive than coastal wetlands (10–20% as
2 rainfall).

3 Since the 2008 ISA, a CL for U.S. coastal wetlands has been established. The CL is based
4 on several different ecological endpoints, including plant community composition,
5 microbial activity, and biogeochemistry (63–400 kg N/ha/yr). [Figure 11-6](#) shows a
6 comparison of the N CL for coastal wetlands with recent studies of ecological impacts of
7 N (at N levels of 100–250 kg N/ha/yr).

8 Since the 2008 ISA, two N critical loads (CLs) for U.S. freshwater wetlands have been
9 established. The CL for wetland C cycling, quantified as altered peat accumulation and
10 NPP, is between 2.7 and 13 kg N/ha/yr. The upper end of this critical load range is based
11 on measurements of wet deposition only (10 to 13 kg N/ha/yr), and therefore, does not
12 reflect total N loading. There is also a CL to protect biodiversity based on morphology
13 and population dynamics of the purple pitcher plant (*Sarracenia purpurea*) between
14 6.8–14 kg N/ha/yr. A more recent study across an N deposition gradient suggests that
15 purple pitcher plant populations experience negative effects of N deposition at rates lower
16 than this CL, but the more recent research has not yet been incorporated into the CL
17 framework. A comparison of freshwater wetland CLs to observed ecological impacts of
18 N from recent studies (4.4–500 kg N/ha/yr) is given in [Figure 11-7](#).

1.9 Freshwater and Wetland Ecosystem Sulfur Enrichment

19 New evidence from wetland and freshwater aquatic ecosystems strengthens and extends
20 the causal findings of the 2008 ISA regarding nonacidifying sulfur effects, and provides
21 the basis for a new causal determination ([Chapter 1, Table 1-1](#)). New research together
22 with the information included in the 2008 ISA shows that the evidence is sufficient to
23 infer a causal relationship between S deposition and the alteration of Hg methylation in
24 surface water, sediment, and soils in wetland and freshwater ecosystems. New evidence
25 is sufficient to infer a new causal relationship between S deposition and changes in biota
26 due to sulfide phytotoxicity, including alteration of growth and productivity, species
27 physiology, species richness, community composition, and biodiversity in wetland and
28 freshwater ecosystems.

29 SO_x deposition can have chemical and biological effects other than acidification,
30 particularly in flooded wetland soils and aquatic ecosystems. The 2008 ISA described
31 qualitative relationships between sulfate deposition and a number of ecological
32 endpoints, including altered S cycling, sulfide phytotoxicity, internal eutrophication of
33 aquatic systems, altered methane emissions, increased mercury (Hg) methylation, and
34 increased Hg loading in animals, particularly fish. [Table 12-11](#) summarizes chemical

1 concentrations that alter ecological endpoints and the quantitative relationships
2 describing effects of sulfate deposition. Recent research supports these relationships
3 between S deposition and ecological endpoints and provides the basis for SO_x deposition
4 levels, water column sulfate concentrations, and water column sulfide concentrations
5 protective of plants and animals.

1.9.1 Biogeochemistry

6 SO_x deposition alters biogeochemical processes via S enrichment including S cycling
7 (see [Appendix 12.2.1](#)), P cycling (see [Appendix 12.2.4](#)), C cycling (see
8 [Appendix 12.2.5](#)), and Hg cycling (see [Appendix 12.3](#)). The primary chemical indicator
9 for nonacidifying or enrichment effects of S in wetland and aquatic ecosystems is surface
10 water sulfate concentration, as it is for acidifying effects. The 2008 ISA reported that
11 chemical reduction of sulfate was an important indicator of SO_x effects on water
12 chemistry, as the process generates ANC. There are no new studies on ANC generation
13 through sulfate reduction, although microbial sulfate reduction remains an active area of
14 research. In aquatic ecosystems for which atmospheric and terrestrial S inputs are similar
15 in magnitude to rates of microbial sulfate reduction, the products of microbial sulfate
16 transformation may be more reliable indicators of S enrichment effects than surface water
17 sulfate concentrations. These chemical indicators include methylmercury (MeHg),
18 sulfide, and phosphate.

19 MeHg is the most persistent and toxic form of Hg in the natural environment, and is
20 measured in surface water or aquatic sediments (MeHg concentration or the percentage of
21 MeHg in total Hg) to predict its effects upon biota. Several new studies demonstrate
22 significant positive relationships between surface water SO₄²⁻ concentrations and water
23 or sediment MeHg concentrations (see [Appendix 12.3.5](#)). Another product of sulfate
24 reduction, sulfide (measured as surface water or sediment pore water S²⁻ concentrations)
25 is also a water quality indicator of deposition effects upon biota. In freshwater
26 ecosystems with iron-rich sediments, sulfide may react with iron bound to phosphates in
27 the sediment to release phosphate into the water column, increasing primary productivity;
28 new research documents this process, referred to as internal eutrophication
29 ([Appendix 12.2.4](#)).

30 In terms of S enrichment effects upon carbon cycling, the 2008 ISA documented the
31 suppression of methane emissions in wetland soils by sulfate addition in several studies
32 and noted that 15 kg S/ha/yr suppressed methane emissions. Recent research has
33 confirmed that S enrichment increases the abundance or metabolic activity of
34 sulfate-reducing prokaryotes (SRPs), which under some conditions compete with

1 methanogens and suppress their activity, in turn suppressing methane emissions
2 ([Appendix 12.2.4](#)). However, there are no new studies documenting S deposition effects
3 upon methane emissions in U.S. ecosystems.

1.9.2 Biological Effects of Sulfur Enrichment

4 Nonacidifying S effects upon biota include plant toxicity, changes in plant growth and
5 biodiversity, and increased Hg concentrations in biota. The toxicological effects of Hg
6 accumulation in animals were documented in the 2008 ISA and newer studies.

1.9.2.1 Sulfur Nutrient and Toxicity to Plants

7 Plants and other organisms require S as an essential nutrient. The deposition of S can
8 affect plant protein synthesis by affecting S availability for S containing amino acids,
9 which in turn will affect N uptake. The 2008 ISA documented the effects of sulfate
10 toxicity on plant development and reproduction at very high S loads. There is no new
11 evidence of S deposition effects upon plant S nutrition or sulfate toxicity. The product of
12 microbial sulfate reduction, sulfide, is an important plant toxin, and the 2008 ISA
13 documented sulfide phytotoxicity in European systems. Together with new research
14 showing sulfide phytotoxicity in North American wetlands, **the body of evidence is**
15 **sufficient to infer a causal relationship between S deposition and changes in biota**
16 **due to sulfide phytotoxicity including alteration of growth and productivity, species**
17 **physiology, species richness, community composition, and biodiversity in wetland**
18 **and freshwater ecosystems.**

19 The 2008 ISA showed that sulfide toxicity decreased biomass of wetland plants and
20 aquatic macrophytes in mesocosms under aquatic S concentrations higher than current
21 U.S. concentrations. In Europe, research showed that a threshold value of <48 mg
22 $\text{SO}_4^{2-}/\text{L}$ in surface water would protect the sensitive aquatic species *Stratiotes aloides* and
23 *Potamogeton acutifolius* (not native to CONUS), as well as to protect *Potamogeton*
24 *zosteriformis* and *Utricularia vulgaris*, which are both native and widely distributed in
25 CONUS. New research has demonstrated sulfide phytotoxicity effects at current ambient
26 sulfide concentrations in multiple ecosystems within the U.S. ([Appendix 12.2.3](#)). Sulfide
27 decreased total plant cover and cover of dominant species in a New York fen, and
28 decreased the growth rate of *Cladium jamaicense* (sawgrass), a keystone species in the
29 Florida Everglades. *Zizania palustris* (wild rice) is an economically and culturally
30 important species sensitive to sulfide, and the Minnesota Pollution Control Agency has
31 developed a model for this species that calculates protective levels of water SO_4^{2-}

1 concentrations, given iron and DOC concentrations in water bodies. A recent review
2 identifies sulfide thresholds between 0.3–29.5 mg S²⁻/L for altered growth, productivity,
3 physiology, or mortality of 16 freshwater wetland emergent plant and aquatic submerged
4 macrophyte species native to North America (see [Table 12-2](#)).

1.9.2.2 Sulfur Effects on Mercury Methylation

5 In the 2008 ISA, evidence was sufficient to infer a causal relationship between S
6 deposition and increased methylation of Hg, in aquatic environments where the value of
7 other factors is within adequate range for methylation. In the 2008 ISA, sulfur-reducing
8 bacteria (SRB) were identified as the organisms responsible for Hg methylation. New
9 evidence shows the ability to methylate Hg is more broadly distributed phylogenetically,
10 including both bacteria and archaea, which is why this document refers to
11 sulfate-reducing mercury methylators as SRPs rather than SRB ([Appendix 12.3.2](#)). In the
12 2008 ISA, wetland and lake-bottom sediments were identified as habitat for mercury
13 methylating SRPs. Recent research documents microbial mercury methylation in lakes, in
14 wetland sediments and moss, within periphyton, in marine ecosystems, and within
15 disturbed terrestrial forest soils ([Appendix 12.3.2](#) and [Appendix 12.3.3](#)). Microbial
16 mercury methylation responsive to SO_x deposition occurs in freshwater lakes, freshwater
17 wetlands, freshwater reservoirs, and freshwater agricultural areas ([Appendix 12.3.4](#)).
18 Between the 2008 ISA and new research, **the body of evidence is sufficient to infer a**
19 **causal relationship between S deposition and the alteration of Hg methylation in**
20 **surface water, sediment, and soils in wetland and freshwater ecosystems.**

21 Hg methylation is determined in part by surface water sulfate, as many strains of SRPs
22 possess the recently identified gene pair *hgcAB*, and pair their metabolism of C with both
23 dissimilatory sulfate reduction and mercury methylation (see [Appendix 12.3.2](#) and
24 [Figure 12-5](#)). Microbial methylation rates are determined by other environmental
25 requirements of SRPs, including seasonality and temperature, pH, organic matter in water
26 and sediments, iron, nitrate, and salinity ([Appendix 12.3.3](#)). New research demonstrates
27 that Hg methylation occurs at ambient sulfate concentrations within U.S. water bodies.
28 Multiple lines of evidence support a relationship between sulfate surface water
29 concentrations and MeHg concentration or production in various freshwater systems.
30 Linear relationships between sulfate concentrations and MeHg concentrations were
31 observed in sediments of the South River, VA; across peat bogs in Minnesota and
32 Ontario; and across prairie pothole lakes in Saskatchewan ([Figure 12-17](#)). In addition to
33 the studies of lake and wetland sediments reviewed in the 2008 ISA, studies employing
34 lab incubations show that sulfate increases Hg methylation in samples from Adirondack
35 peat bogs, from South River, VA sediments, from periphyton growing in North American

1 lakes and wetlands, and from leaf packs in Minnesota river water ([Appendix 12.3.3.1](#)).
2 Experimental addition of S to field mesocosms or whole ecosystems has shown that S
3 enrichment as wet S deposition increases MeHg in water, sediment, or biota, in Little
4 Rock Lake, WI; Bog Lake Fen, MN; the Experimental Lakes Area, Ontario; and the bog
5 experiment at Degerö Stormyr, Sweden ([Appendix 12.3.4.1](#)). In observational studies of
6 S and Hg deposition, fish Hg concentrations decline with temporal declines in SO_x
7 deposition in Isle Royale (a Class I area), fish Hg concentrations correlate positively with
8 Hg and S deposition across Texas ecoregions, and a 12-year study found fish Hg in
9 Voyageurs National Park (a Class I area) declined in lakes with decreasing S deposition
10 only when lake DOC remained constant ([Appendix 12.3.5.1](#)). New research is consistent
11 and coherent with the research presented in the ISA in demonstrating that sulfur
12 enrichment from SO_x deposition stimulates mercury methylation in North American
13 ecosystems. Current research suggests that mercury methylation generally peaks between
14 10 and 100 mg SO₄²⁻/L in surface water, and quantitative relationships between S and Hg
15 such as target values or thresholds are reported in [Table 12-12](#).

1.9.2.3 Sulfur, Mercury, and Animal Species

16 Mercury is a developmental, neurological, endocrine, and reproductive toxin across
17 animal species. The 2008 ISA documented Hg accumulation in fish, songbirds, four turtle
18 species, insectivorous passerine birds, and the common loon (*Gavia immer*). Recent
19 research also documented Hg accumulation in insectivore songbirds, bats, and fish in
20 agricultural wetlands. The 2008 ISA reported that 23 states had issued fish advisories by
21 2007 in response to the U.S. EPA's fish tissue criterion of 0.3 µg MeHg/g fish (0.3 ppm),
22 set to protect human health. The 2008 ISA reported on the negative impacts of Hg on the
23 development, morphology, survival, or reproduction in the following fish species:
24 walleye (*Stizostedion vitreum*), grayling (*Thymallus thymallus*), mummichog (*Fundulus*
25 *heteroclitus*), rainbow trout (*Oncorhynchus mykiss*), fathead minnows (*Pimephales*
26 *promelas*), and zebrafish (*Danio rerio*). However, a recent report on Hg in streams of the
27 U.S. by the USGS summarizes current research indicating that birds, fish, and fish-eating
28 wildlife experience negative effects of Hg at lower concentrations than the 0.3 ppm
29 criterion set to protect human health on the basis of fish consumption.

30 The 2008 ISA documented a link between decreased S deposition and decreased fish
31 MeHg concentrations. Recent research in Voyageurs National Park (a Class I Area)
32 supports this finding. There is also supporting evidence from fish surveys of Texas
33 reservoirs across regions with different S deposition loads, and from an S addition
34 experiment in a peat bog in the Marcell Experimental Forest in northern Minnesota,
35 where increased S loading increased Hg concentrations in larval *Culex* spp. (mosquitoes),

1 which are an important food source for both aquatic and terrestrial species
2 ([Appendix 12.4](#) and [Figure 12-18](#)). In addition to the studies that consider S deposition,
3 there are recent studies that consider sulfate concentrations in water in relation to fish Hg
4 concentrations in six lakes in South Dakota, and in the marshes of the Everglades
5 ([Appendix 12.4](#)). In the freshwater marshes of the Everglades, recent work indicates a
6 concentration of 1 mg/L sulfate to keep water MeHg low ([Appendix 12.3.4.3](#)), which is
7 also a sulfate concentration that will protect fish from elevated Hg burdens in that system
8 ([Figure 12-14](#)).

1.9.3 National-Scale Sensitivity and Critical Loads

9 The 2008 ISA identified ecosystems in the Northeast as particularly sensitive to Hg
10 methylation in response to S deposition, as many watersheds in this region have abundant
11 wetlands and freshwater water bodies with high DOC and low pH. The U.S. EPA
12 national stream surveys found that MeHg in predator fish exceeded the Hg criterion in a
13 quarter of stream miles and half the lakes surveyed. Fish MeHg levels were highest in
14 streams in watersheds with considerable wetland area, and surveys showed highest fish
15 MeHg concentrations in the southeastern U.S., suggesting that ecosystems sensitive to
16 SO_x deposition effects upon Hg methylation extend beyond the Northeast ([Figure 12-15](#)).
17 Recent studies confirm that Hg methylation is more widespread than was documented at
18 the time of the 2008 ISA. New research conducted in agricultural wetlands in California
19 suggests Hg methylation in these systems may provide a route to animal and human Hg
20 exposure through food, specifically MeHg concentrations in rice seeds.

21 There are no CLs for S to prevent sulfide phytotoxicity or Hg methylation, although there
22 are sulfate and sulfide water quality values that represent protective levels against toxic
23 effects of sulfide and Hg to biota (see [Table 12-12](#)). There are European CLs for Hg
24 concentrations in soil and fish tissue targeted to protect human health, drinking water
25 quality, and terrestrial soils, but these CLs are not framed in terms of SO_x, Hg, or PM
26 deposition (see [Appendix 12.6](#)).

1.10 Ecological Effects of Particulate Matter other than N and S Deposition

27 Since publication of the 2009 PM ISA, new literature builds upon the existing knowledge
28 of ecological effects associated with PM components other than those associated with N
29 and S deposition, especially metals and organics. In some instances, new techniques have
30 enabled further characterization of the mechanisms of PM on soil processes, vegetation,

1 and effects on fauna. New studies provide additional evidence for community-level
2 responses to PM deposition, especially in soil microbial communities. However,
3 uncertainties remain due to the difficulty in quantifying relationships between ambient
4 concentrations of PM and ecosystem response. Overall, **the body of evidence is**
5 **sufficient to infer a likely causal relationship between deposition of PM and a**
6 **variety of effects on individual organisms and ecosystems**, based on information from
7 the previous review and new findings in this review.

8 PM deposition comprises a heterogeneous mixture of particles differing in origin, size,
9 and chemical composition. Exposure to a given concentration of PM may, depending on
10 the mix of deposited particles, lead to a variety of toxic responses and ecosystem effects.
11 Effects of PM on ecological receptors can be both chemical and physical ([U.S. EPA,](#)
12 [2009a, 2004](#)). As described in the 2009 *Integrated Science Assessment for Particulate*
13 *Matter* (2009 PM ISA), particulates that elicit direct and indirect effects on ecological
14 receptors vary in terms of size, origin, and chemical composition. Particle composition is
15 attributed to ecological outcomes to a greater extent than particle size ([Grantz et al.,](#)
16 [2003](#)). PM associated metals and organics are linked to responses in biota; however, the
17 heterogeneous nature of PM composition and distribution coupled with variability
18 inherent in natural environments confound assessment of the ecological effects of
19 particulates. Although most effects are from chemical composition of PM, there are some
20 effects of particle size generally limited to flux of solar radiation and soiling of leaves by
21 large coarse particles in areas near industrial facilities.

22 In general, new studies on PM deposition to vegetation support findings in previous PM
23 reviews on altered photosynthesis, transpiration, and reduced growth. Additional
24 characterization of PM effects at the leaf surface since the 2009 PM ISA has led to a
25 greater understanding of PM foliar uptake. Alterations in leaf fatty acid composition are
26 associated with metals transferred to plant tissues from PM deposition on foliar surfaces
27 ([Appendix 15.4.2](#)).

28 An important characteristic of fine particles (0.1 to 1.0 μm) is their ability to affect the
29 flux of solar radiation passing through the atmosphere, which can be considered in both
30 its direct and diffuse components. A newly available research method links changes in
31 expression of proteins involved in photosynthesis to changes in radiation associated with
32 aerosols and PM. Although this method has not been widely applied, it may represent an
33 important way to study mechanistic changes to photosynthesis in response to more
34 diffuse radiation resulting from PM in the air column ([Appendix 15.2](#)).

35 Several studies published since the 2009 PM ISA show PM chemical constituent effects
36 on soil physical properties and nutrient cycling. Previous findings in the PM ISA of
37 changes to microbial respiration and biomass are further supported by new studies.

1 Microbial community responses to PM vary in tolerance to heavy metals and organics
2 ([Appendix 15.5.3](#)).

3 In fauna, results from ecotoxicity assays with PM extracts using bacteria, rotifers,
4 nematodes, zebrafish, and earthworms support findings in the 2009 PM ISA that toxicity
5 is not related to the total mass of PM in the extract, but to the chemical components of the
6 PM. In nematodes exposed to PM from air filters, the insulin-signaling pathway was
7 identified as a possible molecular target. Use of wildlife as PM biomonitors has been
8 expanded to new taxa since the last PM review. Several studies in invertebrates and birds
9 report physiological responses to air pollutants, including PM ([Appendix 15.6](#)).

10 For ecosystem level effects, a gradient of response with increasing distance from PM
11 source was reported in the 2009 PM ISA. Newly available studies from long-term
12 ecological monitoring sites provide limited evidence for recovery in areas such as those
13 around former smelters due to the continued presence of metals in soils after operations
14 ceased. A novel experimental microecosystem using microbial communities living in
15 terrestrial mosses indicates that PM deposition alters responses of primary producers,
16 decomposers, and predators ([Appendix 15.3](#)).

1.11 Recovery of Ecosystems from Nitrogen (N) and Sulfur (S) Deposition in the U.S.

17 Evidence from across the U.S. of ecosystem recovery from N nutrient enrichment and
18 acidification corresponding to long-term trends in N and S emissions is variable. Most
19 studies of recovery focus on ecosystem acidification recovery due to decreases in S
20 emissions and deposition. Overall N emissions and deposition have been increasing or
21 relatively steady; consequently, there has been little reported on N enrichment recovery.

1.11.1 Overarching Concepts of Ecological Recovery from Acidification

22 Both chemical and biological indicators are used to assess the degree of ecological
23 degradation associated with environmental stressors and document responses in
24 ecosystems where improved conditions allow for recovery. Recovery can be documented
25 by measurement of indicators and projected/modeled recovery trajectories.

26 For acidification caused by N and S deposition, chemical recovery of aquatic and
27 terrestrial ecosystems are characterized by trends in water quality indicators (NO_3^- ,
28 SO_4^{2-} , pH, ANC, inorganic monomeric Al, MeHg) towards inferred preindustrial values
29 or, in the case of inorganic Al and MeHg, below water quality threshold values protective

1 of biota and human health. Preindustrial conditions varied across the U.S. in response to
2 variation in climate, geology, and biological communities, and preindustrial chemical
3 indicator values are currently inferred from models, paleolimnology samples, or historical
4 samples. When evaluating ecosystem recovery to acidification, it is important to note that
5 different chemical pools within the soil may recover at different rates with the same
6 decreases in declining atmospheric deposition at different rates. For example, soil
7 solution Ca:Al ratio or SO_4^{2-} or NO_3^- respond more quickly than will total N. Indicators
8 of slowly recovering pools (such as the percentage of base saturation in the soil or soil C
9 to N ratio) will have long response times with regard to changes in atmospheric
10 deposition. An indicator such as acid-neutralizing capacity (ANC), which is influenced
11 by both fast (solution) and slow (soil) pools, has an intermediate response time. Chemical
12 indicators such as ANC or pH may not necessarily follow a recovery path that mirrors the
13 reverse of the acidification path due to dynamic relationships among ANC, pH, DOC,
14 and inorganic Al; depletion of soil base cation pools; and/or pH-dependent S adsorption
15 on soils. In addition, the ANC level that reflects recovery of pH or Al_i may differ between
16 the acidification and recovery phases ([Hesthagen et al., 2008](#)).

17 Biological recovery may follow chemical recovery of such water and soil quality
18 constituents; however, there may be a lag of decades between the onset of chemical
19 recovery and biological recovery [([U.S. EPA, 2008a](#)); [Appendix 8](#)]. As observed in some
20 of the early studies on formerly acidified systems, the biological recovery trajectory may
21 exhibit hysteresis, where a system does not follow the same path from acidification to
22 recovery ([Frost et al., 2006](#)). Complete biological recovery would entail a return to the
23 same species make-up, richness, and abundance as existed in the ecosystem in question
24 prior to the advent of human-caused acidic deposition (around the Year 1860 in North
25 American ecosystems). In a practical sense, complete biological recovery is probably not
26 attainable at most acidified locations within a reasonable management time frame
27 (perhaps 100 years) because soil reserves of base cations at many locations have been
28 depleted in response to many decades of acidic deposition and because other stressors, in
29 addition to acidic deposition, have also altered ecosystem structure and/or function or
30 will do so in the coming decades. Such stressors include changes in climate, land use, and
31 other perturbations. More commonly, only partial biological recovery may be possible.
32 Ecosystems deemed to be on a recovery trajectory are those found to be moving towards
33 a mix of species presence and abundance that approximates the undisturbed state. There
34 is substantial evidence that recovery rates from acidification differ between taxonomic
35 groups (e.g., rotifers vs. crustaceans) ([Frost et al., 2006](#); [Malley and Chang, 1994](#)). In
36 general, recovery in freshwater ecosystems is characterized by populations of plankton
37 and benthic invertebrates prior to the recovery of fish populations, although most
38 biological communities studied to date have not returned to preacidification conditions,
39 even after recovery of chemical parameters.

1.11.2 Acidification Recovery in the U.S.

1 Long-term monitoring has been very important in tracking the ecological response to N
2 and acidifying deposition ([Appendix 7](#) and [Appendix 4.4](#)). Experimental liming studies
3 have also provided some evidence for biological recovery, although these types of studies
4 are limited in the U.S. ([Appendix 4.3.4](#) and [Appendix 8.4.6](#)). The historical focus on
5 aquatic acidification has resulted in more data to evaluate recovery in aquatic than
6 terrestrial ecosystems ([Appendix 7.1.3](#)). Fewer studies have tracked the potential
7 recovery of terrestrial ecosystems; however, since the early 1990s, evidence has grown,
8 which indicates that soils in some areas are beginning to recover, yet most sensitive
9 regions continue to acidify in response to deposition ([Appendix 4.6.1](#)). In areas where N
10 and S deposition has decreased, chemical recovery must first create physical and
11 chemical conditions favorable for growth, survival, and reproduction in order for
12 biological recovery to occur.

13 The northeastern U.S. and southern Appalachians are two regions of the U.S. where a
14 large body of research has evaluated recovery. In the Northeast, evidence for chemical
15 recovery is primarily from soils ([Appendix 4.6.1](#)) and freshwater lakes and streams
16 ([Appendix 7.1.5.1](#)). In regards to biological recovery ([Appendix 8.4](#)), newer studies have
17 documented some evidence for zooplankton recovery and the successful reintroduction of
18 brook trout in previously acidified Adirondack water bodies or recolonization of
19 previously acidic lakes from refugia ([Appendix 8.6.6](#)). In addition to decreased
20 acidification, a few studies report declines in methylmercury concentrations in biota or
21 water in response to decreasing S, which is suggestive of ecosystem recovery
22 ([Appendix 12.5](#)).

23 In contrast to the northeastern U.S., there is little evidence for recovery in the southern
24 Appalachian Mountain region ([Appendix 4.6.1](#) and [Appendix 16.3](#)). This area is
25 characterized by an abundance of low-ANC streams situated on acidic, highly weathered
26 soils. Streams in this region are strongly affected by SO_4^{2-} adsorption on soils, and
27 long-term monitoring studies suggest that soil base cation depletion has prevented
28 chemical recovery ([Appendix 7.1.5.1.4](#)). Biogeochemistry modeling scenarios suggest
29 that even with large decreases in SO_4^{2-} deposition, it may take decades for soil base
30 cation levels to recover in this region.

31 New studies continue to support findings in the 2008 ISA that biological response to
32 water chemistry recovery varies among taxa and among water bodies, and that most
33 biological communities studied have not returned to preacidification conditions, even
34 after recovery of chemical parameters ([Appendix 8.4](#)). Since the 2008 ISA, research has
35 described the DOC of many lakes and streams has risen, with the source of the DOC
36 likely from the soils in the adjacent terrestrial watershed ([Chapter 1, Table 1-2](#);

1 [Appendix 4.3.9](#) and [Appendix 7.1.2.9](#)). The mechanism causing the observed increase in
2 DOC is unclear, and may be due to a combination of soil recovery from acidification,
3 changes in climate (e.g., temperature and precipitation), and N deposition, among other
4 mechanisms. DOC interacts like a weak acid; therefore, DOC content may affect pH and
5 ANC levels and constrain the extent of recovery from acidification. At the same time, the
6 acidic properties of DOC make it a host for binding trace metals such as toxic inorganic
7 Al (for additional discussion on inorganic Al and DOM see [Appendix 4.3.5](#)) and
8 decreases the toxicity of dissolved Al to aquatic organisms. Overall, current research
9 indicates DOC increases are inconsistent across surface waters in the U.S. with large
10 increases in DOC with acidification recovery in some locations while other recovering
11 sites have not shown increasing trends in DOC.

1.11.3 Nitrogen (N) Driven Nutrient Enrichment Recovery in the U.S.

12 In most freshwater systems sensitive to nutrient effects of atmospheric deposition of N,
13 there is no evidence for biological recovery although decreases in NO_3^- concentrations
14 consistent with declines in N deposition have been reported in some regions of the U.S.,
15 notably the Appalachian, Adirondack, and Rocky Mountains ([Appendix 7.1.5](#)). Some
16 estuaries have shown improvements in biological indicators, such as increases in the
17 extent of SAV, in response to decreases in N inputs from atmospheric deposition and in
18 wastewater and agricultural runoff. For an example, see the Tampa Bay case study
19 ([Appendix 16](#)). In other coastal areas of the U.S., biological indicators of nutrient
20 enrichment have remained relatively unchanged or declined. In the well-studied
21 Chesapeake Bay watershed where extensive restoration efforts have been implemented,
22 water quality and measures of ecological condition have shown little improvement during
23 a 23-year period ([Williams et al., 2010](#)). The one exception to the pattern of no
24 improvement in water quality was an observed increase in the amount of SAV
25 ([Appendix 10.2.5](#)).

1.12 Climate Modification of Ecosystem Response to Nitrogen (N) and Sulfur (S) Addition

26 Nitrogen and S loading occurs in many ecosystems concurrently experiencing multiple
27 stressors, including human-driven climate change. Climate change effects on U.S.
28 ecosystems were recently summarized in the U.S. National Climate Assessment
29 ([Galloway et al., 2014](#); [Groffman et al., 2014](#)). Each appendix of the ISA evaluating N
30 enrichment or acidification includes a section on how climate modifies the ecosystem
31 response. Additionally, to serve as a foundation for the discussion, text in [Appendix 13](#) is

1 excerpted from [Greaver et al. \(2016\)](#), a current review of how climate (e.g., temperature
2 and precipitation) modifies ecosystem response to N that focuses on empirical
3 observations.

4 Anthropogenic emissions of greenhouse gases are likely to cause a global-average
5 temperature increase of 1.5 to 4.0°C and a significant shift in the amount and distribution
6 of precipitation by the end of the 21st century ([Collins et al., 2014](#)). Recent work has
7 focused on the effects of anthropogenic N on the Earth’s radiative forcing ([Pinder et al.,
8 2012](#)) and how temperature and precipitation alter ecological responses to N exposure
9 ([Greaver et al., 2016](#)). Most work is conducted on the effects of climate and N or
10 acidifying deposition (N + S); relatively little work is conducted on how climate modifies
11 ecosystem response to S.

12 Climate effects on ecosystems is a rapidly expanding field; however, for some processes,
13 we are beginning to understand how temperature and precipitation may interact to alter
14 ecosystem response to N and S addition. Although, for many biogeochemical pools and
15 processes data is insufficient to quantify either the direction or magnitude of how climate
16 may alter ecosystem response with certainty.

1.13 Key Scientific Uncertainties

17 Evaluation of uncertainty is an important part of ecosystem assessment. Uncertainty
18 refers to the absence of information and is a way to describe how certain we are in
19 scientific knowledge. As described by [Curry and Webster \(2011\)](#), the nature of
20 uncertainty can be expressed by the distinction between ontic uncertainty and epistemic
21 uncertainty. Ontic uncertainty is associated with inherent variability or randomness, and
22 is an irreducible form of uncertainty. Epistemic uncertainty is associated with
23 imperfections of knowledge, which may be reduced by further research and empirical
24 investigation. [Walker et al. \(2003\)](#) [as summarized in [Curry and Webster \(2011\)](#)]
25 characterized uncertainty as a progression from deterministic understanding to total
26 ignorance:

27 “**Statistical uncertainty** is the aspect of uncertainty that is described in
28 statistical terms. An example of statistical uncertainty is measurement
29 uncertainty, which can be due to sampling error or inaccuracy or
30 imprecision in measurements.

31 **Scenario uncertainty** implies that it is not possible to formulate the
32 probability of occurrence of one particular outcome. A scenario is a
33 plausible but unverifiable description of how the system and/or its

1 driving forces may develop over time. Scenarios may be regarded as a
2 range of discrete possibilities with no a priori allocation of likelihood.

3 **Recognized ignorance** refers to fundamental uncertainty in the
4 mechanisms being studied and a weak scientific basis for developing
5 scenarios. Reducible ignorance may be resolved by conducting further
6 research, whereas irreducible ignorance implies that research cannot
7 improve knowledge.”

8 The understanding and reporting of uncertainty is not consistent across scientific
9 disciplines, and uncertainty may be quantified by various methods. [Csavina et al. \(2017\)](#)
10 provided an overview of terminology and definitions of 41 different terms used to
11 describe uncertainty. Here we provide a brief summary of some of the key methods that
12 may be used to evaluate the uncertainty of the relationship between NO_x, SO_x, and PM
13 pollutants and ecological effects. Quantified estimates of uncertainty vary according and
14 number of decision points ([Chapter 1.13.2.3](#)) including the method used and the input
15 parameters under consideration; therefore, the analyses and discussion of quantified
16 uncertainty values will occur in the Risk and Exposure Assessment as scoped in the 2017
17 IRP ([U.S. EPA, 2017b](#)).

1.13.1 Atmospheric Science

18 Estimating atmospheric deposition involves quantification of emissions, atmospheric
19 concentrations, and deposition fluxes of the various species that make up atmospheric
20 SO_x, NO_y, and NH_x. This is accomplished with environmental measurements, model
21 predictions, or hybrid approaches that combine measurements and modeling methods.
22 There are a wide range of uncertainties across the environmental measurements and
23 model parameters used to estimate atmospheric deposition fluxes. The largest
24 uncertainties are those for dry deposition and ammonia emissions, whether measured or
25 modeled. The smallest uncertainties are associated with ambient concentration
26 measurements and continuously monitored stationary emissions like electric power
27 plants.

1.13.1.1 Emissions Uncertainty

28 Quantitative uncertainty estimates are not documented in the NEI, but uncertainties are
29 often evaluated through separate efforts by comparing inventory predictions with
30 measured long-term trends, statistical source apportionment methods, inverse chemical
31 transport modeling, and comparison with satellite data ([Appendix 2.2.2](#)). SO₂ and NO_x

1 emission uncertainties for electric power generating units, the major source of SO₂ and an
2 important source of NO_x, are in the 10–15% range because emissions are usually
3 continuously monitored ([Appendix 2.2.3](#)). NO_x emission uncertainties for mobile
4 sources, the largest source of NO_x, arise from differences in engine type, size, age, and
5 maintenance, as well as fuel composition and emission control equipment.
6 Over-estimation of NO_x emissions from mobile sources was proposed as an explanation
7 for modeled NO_x concentration bias in several studies. However, mixed results have
8 been observed across several studies when modeled concentrations were compared to
9 measurements. Estimates of NO_x emissions uncertainties are in the 10–20% range for
10 on-road gasoline and diesel vehicles, and up to 30% for off-road vehicles like ships,
11 airplanes, and locomotives ([Appendix 2.2.3](#)). In contrast, total NH₃ emissions
12 uncertainties appear to be greater, underestimated by as much as a factor of two or more
13 according to several recent studies ([Appendix 2.2.3](#)). The predominant sources, livestock
14 operations and fertilizer application, exhibit large temporal and regional variability due to
15 differences in climate conditions and farming practices. As a result, detailed models are
16 required for estimating NH₃ emissions ([Appendix 2.2.2](#)), but data on local environmental
17 conditions and farming practices necessary for good model performance are often not
18 available. Large discrepancies between modeled and measured N concentrations and
19 deposition rates have been attributed to uncertainties in ammonia emissions
20 ([Appendix 2.2.3](#)).

1.13.1.2 Atmospheric Measurement Uncertainty

21 Uncertainties in concentration and deposition measurements from network-based
22 measurements are generally under 20%, and surface concentration uncertainties from
23 satellite-based measurements typically somewhat higher. Concentration and deposition
24 data are derived from several specialized national monitoring networks, including the
25 national SO₂ monitoring network, the NCore network for multipollutant concentration
26 monitoring including NO_y, the Ammonia Monitoring Network, CASTNet for estimating
27 dry deposition, and the National Trends Network for wet deposition ([Appendix 2.4.1](#)).
28 Uncertainties are estimated from reports of precision in data quality reports where
29 available, and otherwise from network data quality objectives.

30 For air concentration measurements used for estimating dry deposition, CASTNet,
31 measured precision was 2–5% for sulfate, 5–13% for nitrate, and 2–6% for ammonium in
32 2016 ([Appendix 2.4.5](#)). Additional uncertainty is associated with for estimating dry
33 deposition from NTN concentration data. Uncertainties of 30% for SO₂ and 40% for
34 HNO₃ have been reported using a simple inferential approach ([Clarke et al., 1997](#)).
35 However, single site determinations are of limited use because of dry deposition fluxes

1 are determined by a number of factors and can vary considerably over small spatial
2 scales. In most recent efforts, dry and total deposition on a regional or national scale is
3 usually modeled with CTMs ([Chapter 1.13.1.3](#)).

4 Precipitation concentration measurement precision and estimated wet deposition
5 precision in the National Trends Network were less than 7% for sulfate and nitrate and
6 less than 20% for ammonium. Ammonia air concentration measurement methods used in
7 AMoN evaluated a precision of 10% ([Appendix 2.4.6](#)). Minimum performance
8 specifications for SO₂ monitoring from the national SO₂ monitoring network include a
9 precision of 2.0% ([Appendix 2.4.4](#)). Data quality objectives for NO_y in the NCore
10 network include a precision of 15% ([Appendix 2.4.2](#)). Uncertainty in satellite-based
11 measurements depend on vertical profile, cloud fraction, cloud pressure, surface
12 reflectivity, and extent of aerosol scattering. Estimates of 20% for NO₂ ([Appendix 2.4.2](#))
13 and 10–45% for SO₂ ([Appendix 2.4.4](#)) have been reported for cloud free conditions.

1.13.1.3 Atmospheric Modeling Uncertainty

14 The Community Multiscale Air Quality modeling system is probably the most widely
15 used model in the U.S. for estimating atmospheric deposition. In a recent CMAQ
16 evaluation, atmospheric nitrate concentrations were overestimated by 22 to 26%, sulfur
17 dioxide concentrations were overestimated by 39 to 47%, and sulfate concentrations were
18 underestimated by 9 to 17%, as annual averages over a range of 4 years compared to
19 surface-based measurements ([Appendix 2.5.3](#)). Mixed results have been observed in
20 several recent comparisons of CMAQ wet deposition estimates to network-based
21 measurements, with average differences in modeled results and measurements ranging
22 from 15% or less to 99% for nitrate, sulfate, and 15% or less to 60% for ammonium
23 ([Appendix 2.5.3](#)). Modeling methods for estimating dry and total deposition are still
24 under development, and uncertainties have not been extensively evaluated or quantified.
25 Recent sensitivity analysis results found less than 5% differences in total deposition
26 estimates because of compensation of competing model processes, but extensive
27 comparison of model results and measurements are not available ([Appendix 2.5.3](#)).

28 In addition to measurable uncertainties associated with measurement precision or
29 comparisons between models and measurements, there are also structural uncertainties
30 due to incomplete understanding of the underlying science related to atmospheric
31 deposition that are not possible to quantify. The main structural uncertainties associated
32 with deposition estimates are canopy effects of NO_x (including both bidirectional gas
33 exchange and canopy reactions), bidirectional exchange of NH₃ with biota and soils, and

1 processes determining transference ratios that relate average concentration to deposition
2 ([Appendix 2.5](#)).

1.13.2 Ecological Effects

3 Evaluation of ecological effects caused by acidification or eutrophication involves a suite
4 of parameters and dose-response functions, both empirical and modeled. The quantitative
5 uncertainty of empirically observed variables in ecology is determined by the use of
6 statistics. A suite of mathematical statistical models are available to describe the
7 variability among empirical observations and the strength of a cause and ecological effect
8 relationship, the appropriate method to apply depends on the experimental design.
9 Statistics for empirical data include calculation of probability, distributions, standard
10 deviation, variance, *t*-tests, ANOVA, linear regression, spatial statistics, Bayesian
11 analysis, and multivariate analysis, among others. In general, ecological endpoints
12 determined by empirical studies to be affected by deposition were reported in the ISA if
13 they were statistically significant; this means the magnitude of effect was larger than the
14 estimated uncertainty.

15 Models of chemical and ecological processes, including biogeochemistry, provide
16 representations of biological and geochemical interactions through mathematical
17 expressions. The models used to characterize aquatic and terrestrial biogeochemistry
18 response to N and S deposition can be complex, including many interacting variables.
19 Model results are often compared to empirically collected data to confirm the model.
20 Each of the input variables used in a biogeochemical model entails uncertainty. Model
21 uncertainty is governed, in part, by how close the model predictions are to actual
22 observations. Uncertainty in modeled results may arise from limitations in input data or
23 from limitations in model assumptions. Statistical inference methodologies enable
24 uncertainty analysis and determine the strength of the relation between a given uncertain
25 input and the output (i.e., sensitivity analysis). For biogeochemistry models these
26 methods include first-order sensitivity index, Monte Carlo technique, extended Fourier
27 amplitude sensitivity test, Morris one-factor-at-a-time, and Bayesian analysis.

1.13.2.1 Empirical Critical Loads

28 Empirical N CLs for terrestrial and aquatic ecosystems reported in this ISA have been
29 estimated using empirical data sets. The exact effects threshold may be determined using
30 expert judgement. For example, if three levels of N addition are applied to a study site
31 (10, 20, and 30 kg N/ha/yr) and an effect is noticed at 20 kg N/ha/yr, then the CL is

1 estimated at <20 kg N/ha/yr. Another approach would be to fit a mathematical function to
2 the observations, and a scientific judgement made to identify the level of deposition
3 and/or N addition, or threshold, at which the ecological effect is considered to occur and
4 which is likely to be biologically adverse.

5 There are some challenges associated with developing CLs that can result in uncertainty.
6 First, because biological responses are often continuous, there can be a lack of an obvious
7 cut off between adverse and nonadverse effects. As a result, individual author groups
8 have selected different response thresholds. For example, N CLs for lichens have been
9 calculated for (1) deposition values associated with thallus N concentrations above the
10 97% distribution quantile observed for clean sites ([Fenn et al., 2008](#)), (2) community
11 composition shifts from oligotroph to eutroph dominance ([Fenn et al., 2008](#)), (3) low
12 probability of detecting regionally distributed sensitive species ([Root et al., 2015](#); [Geiser
13 et al., 2010](#)), or (4) extirpation of oligotrophs ([Fenn et al., 2008](#)). Secondly, clean site data
14 can be lacking in some ecoregions. For instance, few empirical data are available for sites
15 in the eastern U.S. with deposition rates <4 kg N/ha/yr. This makes it difficult to quantify
16 physiological or community compositional that may have occurred in this region at
17 deposition rates of 1–4 kg N/ha/yr.

18 The [Pardo et al. \(2011a\)](#) study provided a compilation of terrestrial and aquatic N CLs
19 reported since the 2008 ISA. Uncertainty in derivation of empirical CLs for N input as
20 presented by [Pardo et al. \(2011a\)](#) arises in estimation of the ambient (and perhaps
21 historical) deposition loads and in estimation of the biological effects caused by those
22 deposition levels. According to [Pardo et al. \(2011a\)](#), sources of uncertainty in N
23 deposition estimates for N CLs at the Ecoregion Level 1 scale include: “(1) the difficulty
24 of quantifying dry deposition of nitrogenous gases and particles to complex surfaces;
25 (2) sparse data, particularly for arid, highly heterogeneous terrain (e.g., mountains); and
26 (3) sites with high snowfall or high cloud water/fog deposition, where N deposition tends
27 to be underestimated.” Examples of high uncertainty include high-elevation sites in the
28 Rockies and Sierra Nevada mountains, due in part to highly uncertain estimates of dry
29 deposition ([Appendix 2](#)). For sensitive receptors such as phytoplankton shifts in high
30 altitude lakes, N deposition model bias may be close to, or exceed, predicted CL values
31 ([Williams et al., 2017a](#)).

32 Physical, chemical, and ecological variability across lakes affect their response to N
33 deposition and contribute to uncertainty of CL estimates ([Appendix 9.1.1.2](#)). A review by
34 [Bowman et al. \(2014\)](#) noted that current N CLs for sensitive alpine systems may not be
35 protective under future climate scenarios of warmer summer temperatures and a shorter
36 duration of snow cover.

1 Between the publication of [Pardo et al. \(2011a\)](#) and the cutoff date for literature in this
2 ISA (May 2017), some additional aquatic and terrestrial N CLs have been published
3 ([Appendix 4](#); [Appendix 6.5](#)). [Simkin et al. \(2016\)](#) was not based on field addition or N
4 gradient of deposition studies, instead the methods were a spatial analysis of plant
5 diversity using a large data set of over 15,000 forest, shrubland, and herbaceous sites
6 across the U.S. Atmospheric N deposition varied nearly 20-fold across the site gradient.
7 They found that N deposition was negatively correlated with plant species richness at
8 many locations, but positively correlated at others. In one large empirical data set used to
9 describe N CLs for U.S. grassland biodiversity, [Simkin et al. \(2016\)](#) estimated the
10 uncertainty surrounding the mean CL estimates. For open canopy ecosystems, for
11 example, they estimated a mean of 8.7 kg N ha/yr and provided 95% confidence
12 intervals, which can be used as estimates of uncertainty, of 6.4 to 11.3 kg N ha/yr. For
13 closed canopy systems, the mean of 13.4 kg N ha/yr was surrounded by a 95%
14 confidence interval of 6.8 to 22.2 kg N ha/yr.

15 The majority of studies that evaluate terrestrial N CLs for N enrichment effects are based
16 on observed response of a biological receptor to N deposition (or N addition as a proxy
17 for deposition), without a known soil chemistry threshold that causes the biological
18 effect. In contrast, critical loads for acidification are typically based on the deposition
19 amount that causes a value of a soil chemical indicator which is known to cause adverse
20 biological effect. The link between soil chemical indicator and biological effect is based
21 on empirical evidence ([Appendix 5](#)). The relationship between deposition and the
22 biogeochemistry that causes effects on soil chemistry is typically modeled ([Appendix 4](#),
23 [Chapter 1.13.2](#)).

1.13.2.2 Modeled Critical Loads

1.13.2.2.1 Terrestrial and Aquatic Acidification: Biogeochemistry

24 A variety of process models have been used to estimate past and future resource
25 conditions under scenarios of acidification/recovery responses and critical and target
26 loads, both aquatic and terrestrial. Models include simple approaches such as the simple
27 mass-balance equation (SMBE), and dynamic models, such as PnET-BGC and ForSAFE,
28 MAGIC, VSD, and VSD+ ([Appendix 4.5](#)). Critical loads for terrestrial and aquatic
29 acidification are calculated by the model to determine the amount of deposition that alters
30 soil or water chemistry to a threshold value known to have detrimental effects on a
31 biological receptor.

1 Of the several well-established models of terrestrial biogeochemistry used to evaluate soil
2 acidification ([Appendix 4.5](#)), each relies heavily on input or simulated values for base
3 cation weathering (BCw) rate, one of the most influential yet difficult to estimate
4 parameters in the calculation of critical acid loads of N and S deposition for protection
5 against terrestrial acidification ([Appendix 4.5.1.1](#)). Obtaining accurate estimates of
6 weathering rates is difficult because weathering is a process that occurs over very long
7 periods of time, and estimates on an ecosystem's ability to buffer acid deposition rely on
8 accurate estimates of weathering. Various approaches can be used to estimate BCw,
9 including the empirical soil clay approach, the PROFILE model (e.g., [Phelan et al.,](#)
10 [2014](#)), the F-factor approach ([U.S. EPA, 2009c](#)), and calibration of a dynamic model such
11 as MAGIC (e.g., [McDonnell et al., 2014b](#); [Povak et al., 2014](#)). There are new studies on
12 estimating BCw, including evaluation of uncertainty ([Whitfield, 2018](#); [Futter et al.,](#)
13 [2012](#)). When applying PROFILE to upland forests in the U.S., [Whitfield \(2018\)](#) found
14 the greatest uncertainty in BCw estimate was due to the particle size class-based method
15 used to estimate the total specific surface area upon which weathering reactions can take
16 place.

17 The uncertainty of forest soil CLs for acidification in U.S. calculated using simple
18 mass-balance equations (SMBE) was investigated by [Li and McNulty \(2007\)](#). The results
19 included a quantification of how the 17 of the model's parameters contributed to the
20 uncertainty and indicated that uncertainty in the CLs came primarily from components of
21 base cation weathering and acid-neutralizing capacity, whereas the most critical
22 parameters were BCw, base rate, soil depth, and soil temperature. The authors concluded
23 that improvements in estimates of these factors are crucial to reducing uncertainty and
24 successfully scaling up SMBE for national assessments (see [Appendix 4.6](#)).

25 Several dynamic models are commonly used to model terrestrial soil acidification
26 ([Appendix 4.5](#)). [Tominaga et al. \(2009\)](#) conducted a Monte Carlo multiple-model
27 evaluation of the dynamic models MAGIC, SAFE, and VSD and found that given the
28 same deposition scenario, the three models (without calibration) simulate changes in soil
29 and soil solution chemistry differently, but the basic patterns were similar. The authors
30 also found the greatest differences in model outputs were attributed to the cation
31 exchange submodel. [Bonten et al. \(2015\)](#) compared how well the common types of
32 dynamic models used to evaluate terrestrial soils (VSD, MAGIC, ForSAFE, and
33 SMARTml). quantified several variables including soil S, soil pH, soil ANC, BC, base
34 saturation, and Al ([Appendix 4.5.3](#)).

35 Uncertainty analysis of a dynamic model (VSD) used for CL based on soil chemistry
36 chemical limits showed that the main drivers of uncertainty were largely dependent on
37 the chemical criterion selected [[Appendix 5.5.3.3](#); ([Reinds and de Vries, 2010](#))]. For

1 example, base cation weathering, deposition, and the parameters describing the H-Al
2 equilibrium in the soil solution were the main sources of uncertainty in the estimates of
3 maximum critical loads for S (CL_{max}[S]) based on the Al:Bc criterion of 1.0, and
4 uncertainty in CL_{max}(S) based on ANC was completely determined by base cation
5 inputs. The denitrification fraction was the most important source of uncertainty for the
6 maximum critical loads of N (CL_{max}[N]). Calibration of VSD reduced the levels of
7 uncertainty for all critical loads and criteria.

8 [Fakhraei et al. \(2017b\)](#) reviewed sensitivity and uncertainty analysis techniques
9 (e.g., first-order sensitivity index, Monte Carlo technique, extended Fourier amplitude
10 sensitivity test, Morris one-factor-at-a-time, and Bayesian analysis) in the context of a
11 biogeochemistry model. The authors apply these techniques to determine the uncertainty
12 and sensitivity of the PnET-BGC model calculation of TMDLs of acidifying deposition
13 that occur in high-elevation, acid-impaired streams in GSMNP ([Fakhraei et al., 2017a](#)).
14 Sensitivity analyses showed that modeled estimates of maximum allowable acidifying
15 deposition loads were most sensitive to uncertainty in model input parameters of air
16 temperature, precipitation quantity, and rate of calcium weathering. Importantly, as more
17 uncertainty was incorporated into model input parameters (± 5 to ± 10 to $\pm 20\%$
18 uncertainty), estimates of allowable deposition loads to protect aquatic ecosystem
19 recovery decreased in magnitude ([Fakhraei et al., 2017a](#)).

1.13.2.2.2 Biogeochemistry and Plant Biodiversity Linked Modeling

20 Plant biodiversity models, such as VEG and PROPS, have been coupled to dynamic
21 biogeochemical models, such as ForSAFE and VSD+ ([Mcdonnell et al., 2018b](#);
22 [Mcdonnell et al., 2018a](#); [Phelan et al., 2016](#)). ForSAFE-Veg is an older and more broadly
23 applied model than VSD + PROPS. There are some key differences between Veg and
24 PROPS. Plant species in the VEG component of ForSAFE-VEG are defined by
25 mathematical equations based on expert opinion regarding such parameters as plant needs
26 for moisture, sunlight, and N supply to represent unobservable fundamental niches. In the
27 PROPS statistical relationships based on empirical data are used to characterize plant
28 species, which is likely more approximate of real world niches influenced by competition
29 among species. These model chains are subject to the same constraints and uncertainties
30 as the biogeochemical models on their own, plus those of the plant response modules.

1.13.2.2.3 Aquatic Eutrophication Modeling

31 Many of the models that estimate N loads to the coastal zone from the landscape and
32 freshwater inflow have been compared, and there is a good deal of knowledge about their

1 limitations and uncertainties ([McCrackin et al., 2013](#); [Alexander et al., 2008](#)). In a 2000
2 National Research Council review, it was determined that these models are
3 hydrodynamically complex and tend to be specific to particular sites. Thus, they are
4 difficult to apply broadly ([NRC, 2000](#)).

5 This SPARROW model application used only wet deposition as the measure of N
6 deposition. A large amount of N from nonpoint source urban influences (this is most
7 likely primarily the dry deposition of exhaust N gases) often approximately doubles the
8 importance of N deposition as an N source to higher order river systems ([Howarth,
9 2008a, b](#)).

1.13.2.3 Key Considerations

10 The choice of model for CL estimation, or for scenario projection, depends largely on the
11 availability of time, data, and resources. Major decisions inherent in the modeling efforts
12 include:

- 13 • Empirical observation or application of a model
- 14 • Steady state or dynamic model
- 15 • Statistical or process-based model
- 16 • Protection against acidification or nutrient N enrichment
- 17 • Site-specific, regional, or national spatial scale
- 18 • Resources to be protected (i.e., stream, lake, soil, vegetation, aquatic biota)
- 19 • Chemical indicator(s) of adverse effects (e.g., water ANC, water NO₃⁻, soil BS)
- 20 • Critical level(s) for selected indicator(s)
- 21 • Time frame of evaluation (i.e., ambient, 2050, long-term steady state)

22 Each of these decision points introduces additional uncertainties, data needs, and
23 potential assessment errors. [U.S. EPA \(2008a\)](#) summarized CL research and monitoring
24 needs identified by [U.S. EPA \(2006b\)](#) at the time of the previous (2009) U.S. EPA Risk
25 and Exposure Assessment.

1.14 Ecosystem Services

26 For acidification, the ecosystem service literature since the 2008 ISA includes studies that
27 better characterize ecosystem service valuation by pairing biogeochemical modeling and
28 benefit transfer equations informed by willingness-to-pay surveys, especially for the
29 Adirondacks and Shenandoah regions ([Appendix 14](#)). Aside from valuation, the total

1 number of ecosystem services affected by N and S deposition is better quantified by the
2 new studies that use the final ecosystem goods and services classification system
3 (FEG-CS). However, for many regions and specific services, poorly characterized
4 dose-response between deposition, ecological effect, and services are the greatest
5 challenge in developing specific data on the economic benefits of emission reductions
6 ([NAPAP, 2011](#)).

7 In the 2008 ISA there were no publications that specifically evaluated the effects of N
8 deposition on ecosystem services associated with N driven eutrophication. Since the 2008
9 ISA, several comprehensive studies have been published on the ecosystems services
10 related to N pollution in the U.S. ([Appendix 14](#)). These include an evaluation of services
11 affected by multiple N inputs (including N deposition) to the Chesapeake, a synthesis of
12 the cost-benefits on N loading across the nation, and analysis of the amount of N that
13 leaked out of its application causing effects on adjacent ecosystems and ecosystem
14 services. In their work (this work specifically identified the costs of the atmospheric
15 portion of total N loading), the estimate of the total number of ecosystem services
16 affected by N is better quantified by the new studies that use FEG-CS ([Bell et al., 2017](#);
17 [Clark et al., 2017](#); [Irvine et al., 2017](#); [O'Dea et al., 2017](#); [Rhodes et al., 2017](#)). In these
18 analyses, critical load exceedances for N related air pollution were used as a model
19 stressor from which a total of 1,104 unique chains linking stressor to beneficiary were
20 identified.

21 The conclusions considering the full body of literature are that (1) there is evidence that
22 N and S emissions/deposition have a range of effects on U.S. ecosystem services and
23 their social value; (2) there are some economic studies that demonstrate such effects in
24 broad terms; however, it remains methodologically difficult to derive economic costs and
25 benefits associated with specific regulatory decisions/standards; and (3) thousands of
26 causal relationships are now documented between N and S air pollution and changes in
27 Final Ecosystem Goods and Services.

APPENDIX 1. INTRODUCTION TO APPENDICES

1 The appendices and [Chapter 1](#) serve different purposes in this ISA. [Chapter 1](#) is meant to
2 summarize the key messages derived from assessment of the policy relevant science of
3 NO_y, SO_x and PM in this review of the secondary National Ambient Air Quality
4 Standards. It provides a general introduction to the purpose, process, development, and
5 organization of the ISA as well as highlights connections, concepts, and changes based
6 on new evidence and causality. In addition, [Chapter 1](#) provides a discussion of
7 uncertainty and a synthesis of information on the recovery of ecosystems from N and S
8 deposition.

9 While the purpose of [Chapter 1](#) is to synthesize, integrate, and provide key messages, the
10 purpose of the appendices is to provide a more detailed description of the state of science
11 for specific topic areas. [Appendix 1](#) is an introduction to the purpose and organization of
12 [Appendix 2–Appendix 16](#). [Appendix 2](#) characterizes the sources, atmospheric processes,
13 and the trends in ambient concentrations and deposition of NO_y, SO_x, and PM.
14 [Appendix 3](#) describes the direct effects of NO_y and SO_x gases on plants and lichens.
15 [Appendix 4–Appendix 6](#) describe the effects of N and S deposition on biogeochemistry
16 and the biological effects of acidification and N enrichment in terrestrial environments.
17 [Appendix 7](#) describes the effects of N and S deposition on aquatic biogeochemistry.
18 [Appendix 8–Appendix 10](#) characterize the biological effects of freshwater acidification,
19 freshwater N enrichment, and N enrichment in estuaries and near-coastal systems.
20 [Appendix 11](#) describes the effects of N deposition on wetlands, and [Appendix 12](#)
21 characterizes the ecological effects of S as a nutrient. [Appendix 13](#) presents information
22 on climate modification of ecosystem response to N and S, while [Appendix 14](#) discusses
23 ecosystem services. [Appendix 15](#) is a review of the ecological effects of forms of PM, not
24 related to N or S deposition. Finally, [Appendix 16](#) presents case studies for six locations
25 in the U.S. (southern California, northeastern U.S., Rocky Mountain National Park,
26 southeastern Appalachia, Tampa Bay, and the Adirondacks) where data are sufficient to
27 well characterize the ecological effects of N and S deposition. These sites would
28 therefore make good candidates to better assess risk and exposure by exploring linkages
29 across various effects and ecosystems-types in a specific location.location.

APPENDIX 2. SOURCE TO DEPOSITION

2.1. Introduction

1 In this appendix, emphasis is placed on those species subject to atmospheric processes
2 relevant for review of the air quality criteria and associated welfare-based secondary
3 National Ambient Air Quality Standards (NAAQS) for oxides of nitrogen, oxides of
4 sulfur, and/or particulate matter (PM). As such, this appendix largely focuses on
5 examining the fundamental and applied science of atmospheric processes relevant to
6 assessing environmental exposures and effects associated with atmospheric deposition of
7 nitrogen (N) and sulfur (S) species, including those present in PM.²⁵ Together this
8 information serves as a prologue to the detailed descriptions of the evidence of ecological
9 effects from oxidized and reduced N and oxidized S, including those present in PM, that
10 follow in later appendices.

11 Recent advances in research on N and S emissions sources, atmospheric transformation
12 and transport, measurement and modeling techniques, atmospheric loadings, and
13 deposition processes relevant to this review of the NAAQS are evaluated in this
14 appendix. N and S species of interest are generally classified into three groups: oxidized
15 nitrogen, reduced nitrogen, and oxidized sulfur. While NO₂ and SO₂ are the most well
16 known as air pollutants, research on the entire range of oxides of nitrogen and sulfur is
17 considered for review of the air quality criteria. Reduced nitrogen is also discussed
18 because it strongly influences the atmospheric deposition of NO_y and SO_x as well as the
19 chemistry of PM formation. Oxidized nitrogen, reduced nitrogen, and oxidized sulfur all
20 have particulate forms (NO₃⁻, NH₄⁺, SO₄²⁻), which together account for a large fraction
21 of PM mass ([U.S. EPA, 2009a](#)), as well as gas-phase components that act as major
22 precursors to PM. Thus, a consideration of the combined effects of oxides of nitrogen,
23 oxides of sulfur, and PM requires an understanding of the atmospheric processes
24 involving oxidized nitrogen, reduced nitrogen, and oxidized sulfur.

25 Oxidized nitrogen species considered here range from nitric oxide (NO) and nitrogen
26 dioxide (NO₂), collectively referred to as NO_x, to higher order organic and inorganic
27 oxidation products, collectively referred to as NO_z (e.g., pNO₃, HNO₃, HONO, PAN,
28 other organic nitrates). NO_z is especially relevant when considering nutrient addition to
29 ecosystems and the acidification of surface waters. NO_x and NO_z together are referred to

²⁵ Since ecological effects of PM are governed mainly by PM composition, the most relevant PM species (nitrate and sulfate) are also species that are derived from sulfur and nitrogen oxide precursors, and there is a high degree of overlap in the discussion of the impacts of NO_y and SO_x, and the impacts of PM_{2.5}. The PM ISA ([U.S. EPA, 2009a](#)) provides more extensive information about the atmospheric processes for total PM mass.

1 as NO_Y (i.e., $\text{NO}_X + \text{NO}_Z = \text{NO}_Y$). Nitrous oxide (N_2O) is an oxide of nitrogen, but it is
2 not included as a component of NO_Y . N_2O contributes to stratospheric ozone depletion
3 and climate forcing [AR5; (IPCC, 2013)], but it contributes little to N deposition, and is
4 not included in this appendix.

5 Reduced nitrogen species are NH_3 and NH_4^+ as well as reduced organic nitrogen
6 compounds. NH_3 and NH_4^+ together are referred to as NH_X (i.e., $\text{NH}_3 + \text{NH}_4^+ = \text{NH}_X$).
7 Reduced nitrogen contributes to acidification and N enrichment, and it also has a key role
8 in neutralizing acidity in cloud, fog, and rain water as well as aqueous aerosol particles
9 formed from atmospheric oxidation of SO_2 and NO_X . Additionally, NH_3 is a precursor for
10 atmospheric particulate matter, reacting with gas-phase nitric acid (HNO_3) to form
11 ammonium nitrate (NH_4NO_3), a major component of N deposition in many areas of the
12 U.S. For this assessment, NO_Y and NH_X are grouped together as total reactive nitrogen,
13 N_r (i.e., $\text{NO}_Y + \text{NH}_X = \text{N}_r$). N_r does not include nitrous oxide and reduced organic
14 nitrogen compounds. However, to the extent it is available, information on the sources,
15 abundances, and fate of reduced organic nitrogen is included in the sections that follow.

16 Gaseous oxides of sulfur (SO_X) is defined to include sulfur monoxide (SO), sulfur
17 dioxide (SO_2), sulfur trioxide (SO_3), and disulfur monoxide (S_2O). Of these only SO_2 is
18 present in the lower troposphere at concentrations relevant for environmental
19 considerations. However, SO_2 interacts with particles and cloud drops and is oxidized to
20 sulfate. SO_2 and sulfate (SO_4^{2-}) account for much of the acidification of surface water in
21 the U.S. and together these make up total oxides of sulfur discussed in this appendix
22 (SO_X).

23 Particulate matter (PM) impacts discussed in this document are also mainly focused on N
24 and S containing species, which together usually make up most of the fine PM mass in
25 many areas of the U.S. PM is usually classified into two size fractions which differ in
26 their physical and chemical characteristics, atmospheric behavior, and health and
27 environmental effects. These are $\text{PM}_{2.5}$, particles smaller than 2.5 μm in diameter, and
28 $\text{PM}_{10-2.5}$, particles with diameter between 2.5 and 10 μm . Ecological impacts of PM
29 depend largely on its composition (U.S. EPA, 2009a, 2004). Together $\text{PM}_{2.5}$ and $\text{PM}_{10-2.5}$
30 make up PM_{10} . PM contains numerous individual components representing a wide range
31 of chemical and physical properties. However, in most areas of the U.S. $\text{PM}_{2.5}$ mass is
32 composed almost entirely of sulfate, nitrate, and organic materials. In contrast, $\text{PM}_{10-2.5}$ is
33 composed of crustal material similar in composition to soil in the area where the $\text{PM}_{10-2.5}$
34 is found, as well as sea salt in coastal areas. There is little discussion of $\text{PM}_{10-2.5}$ effects in
35 this document because in most rural and remote areas $\text{PM}_{10-2.5}$ is largely due to natural
36 sources like soil and sea salt.

1 There are several other reasons for focusing on the sulfate and nitrate fraction of PM_{2.5}
2 mass in this document in addition to the observation that they often account for most
3 PM_{2.5} mass. Together they also usually account for an even greater fraction of PM_{2.5} in
4 rural and remote areas that make up most of the U.S. land mass over which effects in this
5 document are relevant. While organic matter can also account for a large fraction of
6 PM_{2.5}, it is composed of a wide variety of individual compounds that cannot be identified
7 at a molecular level, making it difficult to assess ecological impacts. Also, there is little
8 information on organic PM impacts, except for individual compounds that make minor
9 contributions to mass. As a result, the main contributors to PM_{2.5} mass for which
10 ecological impacts can be readily assessed are limited to sulfate and nitrate, which are
11 also components of total oxides of sulfur and oxides of nitrogen, respectively. Since
12 ecological effects of PM are governed mainly by PM composition, the most relevant PM
13 species (nitrate and sulfate) are also species that are derived from sulfur and nitrogen
14 oxide precursors, and there is a high degree of overlap in the discussion of the impacts of
15 NO_y and SO_x, and the impacts of PM_{2.5}.

16 In addition to nitrogen (N) and sulfur (S) and their transformation products, other PM
17 components such as trace metals and organics are deposited to ecosystems and may
18 subsequently impact biota. Evidence for effects of PM on ecological receptors include
19 direct effects of airborne PM on radiative flux and both direct and indirect effects of
20 deposited particles. Direct effects include alteration of leaf processes from deposition of
21 PM (“dust”) to vegetative surfaces ([U.S. EPA, 2009a](#)). Indirect effects encompass
22 physiological responses associated with uptake of PM components and alterations to
23 ecosystem structure and function (see [Appendix 15](#)).

24 Much of the discussion in sections dealing with chemistry, measurement, and deposition
25 (both wet and dry) focus on sulfuric acid (H₂SO₄) and HNO₃, which have been long
26 established as the major species contributing to acid rain. Other N and S species that
27 either hydrolyze to form acids are also included, along with organic acids, to the extent
28 that they contribute substantively to acidification of terrestrial (see [Appendix 5](#)) and
29 aquatic environments (see [Appendix 8](#)) and/or N enrichment (see [Appendix 6](#),
30 [Appendix 9](#), [Appendix 10](#), and [Appendix 11](#)).

31 Major sources of the precursors (NO_x, SO₂) to the formation of HNO₃ and H₂SO₄ include
32 on- and off-highway vehicles and electricity-generating units (EGUs). SO₂ is oxidized to
33 H₂SO₄ either in the gas phase or cloud water by several well-known mechanisms. NO₂ is
34 oxidized to HNO₃, which can either deposit as HNO₃ or interact with NH₃ to form
35 particulate NH₄NO₃. NH₄NO₃ can exhibit semivolatile behavior that can substantially
36 alter the distance over which NH₃ and HNO₃ can travel. Reduced organic nitrogen
37 species, which could have large agricultural sources, can constitute a substantial fraction

1 of N delivered to ecosystems by precipitation. In areas where the rainwater pH is greater
2 than about 4.5, pH is not exclusively controlled by N and S species, as organic acids such
3 as formic, acetic, and oxalic acids can be major contributors to the acidity of rainwater.

4 A wide variety of N containing compounds, consisting of oxidized and reduced organic
5 and inorganic species contribute to wet and dry deposition. In general, deposition of
6 reduced (organic + inorganic) N exceeds that of oxidized N across the continental U.S.
7 (CONUS). Nationwide, deposition of N species occurs mainly by dry deposition of
8 HNO₃ and NH₃. The pattern is more complex for S in that for large areas, mainly in the
9 central U.S., wet deposition tends to dominate over dry deposition. Dry deposition of
10 particulate SO₄²⁻ is a minor source of S to the surface, largely due to the low deposition
11 velocities of fine-mode particles.

12 Precipitation chemistry has been monitored at a large number of sites across the U.S. for
13 several decades as part of the National Acid Deposition Program (NADP).
14 Concentrations of inorganic gas and particulate phase N and S species have been
15 monitored across the U.S. since 1990 by the Clean Air Status and Trends Network
16 (CASTNET). These concentrations are then used to infer dry deposition (i.e., the transfer
17 of gaseous and particulate pollutants from the atmosphere to the surface by impaction
18 through turbulent motions and gravitational settling). Estimates of dry deposition over the
19 CONUS are inferred by atmospheric models. Starting in 2007, monitoring of NH₃ was
20 initiated at a subset of CASTNET sites. Cloud deposition, which can account for the bulk
21 of deposition at high elevations in mountainous areas, is monitored at two locations on a
22 regular basis, but has been the subject of shorter term field studies in various locations in
23 the U.S.

24 Although the pH of rainwater has increased noticeably across the U.S., coincident with
25 notable decreases in the wet deposition of nitrate and sulfate since 1990, there are still
26 widespread areas, mainly in the eastern U.S., affected by acid precipitation. Deposition of
27 total nitrogen has not reflected the continuing decrease in NO_x emissions, largely because
28 emissions and concentrations of NH₃ have increased in many areas. Large areas, at least
29 one-third of the continental U.S. (CONUS), are estimated to receive at least 10 kg/ha/yr
30 wet + dry deposition of reactive nitrogen species. This estimate is likely too low because
31 reduced organic nitrogen species are not measured by the routine monitoring networks or
32 considered in air quality models such as U.S. EPA's Community Multiscale Air Quality
33 (CMAQ) modeling system.

34 Three of the four major contributors to inorganic N deposition are included in the
35 definitions of either oxides of nitrogen or particulate matter: HNO₃ is an oxide of
36 nitrogen, NH₄⁺ is a PM component, particulate NO₃⁻ is both a PM component and an
37 oxide of nitrogen. The fourth major contributor, NH₃, is neither an oxide of nitrogen nor a

1 component of particulate matter. In a recent comparison, the contribution of NH₃ to total
2 inorganic N deposition ranged from 19% in locations in the Northwest U.S. to 63% in
3 locations in the Southwest U.S., and was generally higher in summer than in winter ([Li et
4 al., 2016d](#)). In general, the majority of inorganic N deposition was accounted for by
5 oxides of nitrogen and particulate matter in the Northwest, Northeast, Southeast, and
6 Rocky Mountains, but the contribution of oxides of nitrogen and particulate matter was
7 roughly equivalent to contributions from NH₃ in the Upper Midwest, Florida, and smaller
8 in the Southwest ([Li et al., 2016d](#)). However, since NH₃ is a PM precursor, it can also be
9 definitively stated that inorganic N deposition is entirely accounted for by oxides of
10 nitrogen, PM components, and PM precursors.

11 Since the *2008 Integrated Science Assessment for Oxides of Nitrogen and*
12 *Sulfur—Ecological Criteria* (hereafter referred to as the 2008 ISA) ([U.S. EPA, 2008a](#)),
13 there have been a number of new developments. These apply to methods, such as
14 data-model fusion to integrate information for deposition across the U.S.; the use of
15 chemistry-transport models linking deposition to ambient air quality; the expansion of
16 CASTNET monitoring to include NH₃ and NO_y at selected sites and intercomparisons of
17 monitoring methods with research grade instruments; and advances being made in
18 satellite-based measurements in conjunction with chemistry-transport model simulations
19 of tropospheric NO₂, SO₂, and NH₃ that will allow mapping of dry deposition over
20 remote areas with spatial resolution of ~10 km × 10 km. These new developments are
21 described in the following sections of this appendix. [Appendix 2.2](#) considers sources and
22 emissions of N, S, and PM to the atmosphere. [Appendix 2.3](#) summarizes the atmospheric
23 chemical transformations of N and S compounds and formation of PM that occur during
24 transport from sources to deposition to the surface. [Appendix 2.4](#) describes measurement
25 of relevant atmospheric species, including national monitoring networks and methods.
26 [Appendix 2.5](#) discusses the use of chemical transport models to estimate deposition.
27 [Appendix 2.6](#) shows the geographic distributions of atmospheric concentrations and
28 deposition of N, S, and PM.

2.2. Sources of Nitrogen and Sulfur Compounds and Particulate Matter to the Atmosphere

29 This section describes advances in our understanding of NO_x, NH₃, and SO₂ emissions.
30 [Appendix 2.2.1](#) describes annual national emissions of each species based mainly on the
31 2014 National Emissions Inventory (NEI). [Appendix 2.2.2](#) describes methods of
32 estimating emissions. Methods for major sources of SO₂ and NO_x are reliable and have
33 remained largely the same since the last review. The same is true to an extent for direct
34 PM emissions. However, there have been fundamental changes in methods for estimating

1 NH₃ emissions, and these are described in some detail. [Appendix 2.2.3](#) describes
2 emission uncertainties, including recent comparisons between NEI data and alternative
3 methods of estimating emissions. Geographic distributions of emissions are presented in
4 [Appendix 2.5](#), where they can be more directly compared with concentration and
5 deposition data.

2.2.1. National Emissions by Source

6 N and S containing compounds contributing to deposition can be either primary
7 (i.e., directly emitted from sources) or secondary (i.e., produced from atmospheric
8 reactions involving precursor species directly emitted from sources). Major primary
9 species include NO_x, SO₂, NH₃, and reduced organic nitrogen (RON).

10 [Table 2-1](#) shows nationwide emissions of NO_x, SO₂, and NH₃ by source category
11 compiled from the 2014 National Emissions Inventory (NEI) and other sources.
12 Emissions estimates are not available for RON. For the most part, NO_x, SO₂, and NH₃
13 are each emitted by different sources. NO_x emissions come from several important
14 sources. Highway vehicles are the largest source category of NO_x emissions nationwide,
15 but off-highway vehicles, EGU's, other stationary fuel combustion, industrial processes,
16 fires, and biogenic emissions from soil are all substantial contributors to total NO_x
17 emissions. Lightning is not included in the NEI, but can also contribute substantially to
18 total NO_x emissions. Although lightning is shown as a relatively modest source of NO_x,
19 most production by lightning occurs during the summer and is highest in the
20 south-central and southwestern U.S. ([Zhang et al., 2012a](#)).

21 NH₃ originates mainly from agriculture, which accounts for ~80% of its emissions
22 nationwide. Agriculturally related sources consist of livestock, including confined animal
23 feeding operations, and soils after addition of N containing fertilizers. Fertilizer
24 application occurs mainly during spring and summer. In addition to NH₃, reduced organic
25 compounds such as urea and a wide range of proteins and other biological components
26 are also emitted as the result of agricultural activity. [Xing et al. \(2013\)](#) observed that in
27 contrast to SO₂, NO_x, and other pollutants, total national emissions of NH₃ increased
28 from 1990 to 2010. The authors attributed this to agricultural emissions, including
29 livestock, which they also identified as the dominant source of NH₃ emissions in the
30 continental U.S. However, regionally the relative importance of agricultural and vehicle
31 emissions is likely to be variable. The deposition of reduced nitrogen can be three times
32 higher near roads ([Bettez et al., 2013](#)), and motor vehicles can be a substantial contributor
33 to total NH₃ emissions in urban areas ([Baum et al., 2001](#)).

Table 2-1 Emissions of NO_x (nitric oxide + nitrogen dioxide), sulfur dioxide, and ammonia by source category for 2014 (Teragrams^a N, S/yr).

	NO _x	SO ₂	NH ₃
Highway vehicles	1	0	0.08
Off-highway	0.7	0.05	<0.01
Utilities (fuel combustion)	0.5	2	0.02
Other stationary (fuel combustion)	0.5	0.4	0.06
Industrial and other processes	0.4	0.3	0.08
Agriculture	0	0	2
Fires: wild, prescribed and agricultural	0.5	0.09	0.2
Biogenic	0.3	-- ^b	0.08 ^c
Total	4.0	2.3	2.3

N = nitrogen; NH₃ = ammonia; NO_x = the sum of nitric oxide and nitrogen dioxide; S = sulfur; SO₂ = sulfur dioxide; yr = year.

^a1 Teragram = 1 × 10⁹ kg.

^bNot applicable.

^c[Bouwman et al. \(1997\)](#).

Source: <https://www.epa.gov/air-emissions-inventories/air-pollutant-emissions-trends-data> update except as noted.

1 SO₂ emissions are dominated by stationary sources burning fossil fuels, particularly
 2 EGUs, which contribute about 70% of total nationwide SO₂ emissions. SO₂ emissions
 3 densities in most counties east of the Mississippi River are larger than in most counties in
 4 the West (see [Appendix 2.6.5](#)).

5 Emissions of NO_x and SO₂ have decreased appreciably in recent years. National
 6 emissions of NO_x have decreased by 48%, and national SO₂ emissions between 2002 and
 7 2014 decreased by 68% ([OAQPS-Emissions Inventory and Analysis Group, 2016](#)).
 8 Further details of declining emissions for these species can be found in the ISA's for
 9 health effects for NO_x and SO₂ ([U.S. EPA, 2008b, c](#)). In contrast, nationwide primary
 10 PM_{2.5} and PM₁₀ emissions estimates have changed little between the 2002 NEI ([U.S.](#)
 11 [EPA, 2009a](#)) and the 2014 NEI, with national PM_{2.5} emissions estimates decreasing from
 12 5.4 to 5.3 MMT, and PM₁₀ emissions estimates decreasing from 19.9 to 17.0 MMT.

13 Not included in [Table 2-1](#) are primary emissions of PM_{2.5} and PM₁₀. Nationwide PM₁₀
 14 emissions according to the 2014 NEI totaled 17.0 MMT. This is somewhat higher than
 15 the SO₂, NO_x and NH₃ emissions in [Table 2-1](#), but 85% of these were from dust and

1 fires, dominated by soil and organic matter. By comparison, total nationwide PM_{2.5}
2 primary emissions totaled 5.3 MMT based on the 2014 NEI. This is comparable to the
3 totals for NO_x, SO₂ in [Table 2-1](#) when it is considered that emissions in [Table 2-1](#) are
4 given in terms of mass of N and S and does not include oxygen, while PM_{2.5} emissions
5 are based on total mass. However, primary PM_{2.5} emissions are also dominated by dust
6 (i.e., agricultural dust and road dust) and fires (i.e., wildfires, prescribed fires, and
7 agricultural fires), which together account for two-thirds of total nationwide PM_{2.5}
8 primary emissions. PM_{2.5} from these source categories are mainly crustal material (dust)
9 and organic matter (fires).

10 As described in [Appendix 2.1](#), in rural and remote areas secondary PM_{2.5} formed from
11 NO_x and SO₂ account for a greater fraction of PM_{2.5} than primary PM_{2.5}. The fraction of
12 PM_{2.5} accounted for by NO₃⁻ and SO₄²⁻ formed from SO₂ and NO_x in various U.S.
13 locations is discussed in [Appendix 2.3](#). The NO_x, SO₂, and NH_x emissions listed in
14 [Table 2-1](#) cannot be used to quantitatively estimate the amount of secondary PM formed
15 because the precursors are not completely converted to PM. However, they provide not
16 only an estimate of emissions that lead to total NO_y and SO_x, but also provide an
17 estimate of the emissions that can be used in conjunction with atmospheric models to
18 estimate PM_{2.5} concentrations (See [Appendix 2.5](#)). The emissions estimated in [Table 2-1](#)
19 are ultimately responsible for the majority of PM_{2.5} in many areas, and of the fraction of
20 PM mass (i.e., SO₄²⁻, NO₃⁻, NH₄⁺) for which ecosystem impacts are best understood.

2.2.2. Methods of Estimating Emissions

21 The source categories used in [Table 2-1](#) represent groups of similar NEI source sectors.
22 Highway Vehicles comprise all on-road vehicles, including light-duty as well as
23 heavy-duty vehicles, both gasoline and diesel powered. Off-Highway vehicles and
24 engines include aircraft, commercial marine vessels, locomotives, and nonroad
25 equipment. Utilities (Fuel Combustion), also identified as electric power generating units
26 (EGUs), are mostly coal burning, but some facilities burn natural gas and other fuels.
27 Other Stationary (Fuel Combustion) includes commercial/institutional, industrial, and
28 residential combustion of biomass, coal, natural gas, oil, and other fuels. Industrial and
29 Other Processes include a variety of different industries, including chemical
30 manufacturing, cement manufacturing, and oil and gas production. The other processes
31 included in this category include gasoline stations and terminals, commercial cooking,
32 road and construction dust, solvent use, and waste disposal. Agriculture includes both
33 fertilizer application and livestock waste emissions. Fires include wildfires, prescribed
34 fires, and agricultural field burning. The biogenic category includes emissions from

1 vegetation and soil. Both nitrifying and denitrifying organisms in the soil can produce
2 NO_x, mainly in the form of NO.

3 Emissions data for each source category listed in [Table 2-1](#) are from the 2014 National
4 Emissions Inventory (NEI), Version 1. The NEI is a national compilation of criteria air
5 pollutant and hazardous air pollutant emissions. The process of estimating emissions is
6 explained for each source in a detailed technical support document for the inventory
7 ([U.S. EPA, 2016b](#)). The NEI is maintained to support the NAAQS, and the Clean Air Act
8 requires states to submit emissions to the U.S. EPA as part of their State Implementation
9 Plans (SIPs). The Air Emissions Reporting Rule (AERR) requires agencies to report all
10 sources of emissions, except fires and biogenic sources. Reporting of open fire sources,
11 such as wildfires, is encouraged, but not required. Data in the NEI come from a variety of
12 sources. The emission values are predominantly from state, local, and tribal agencies and
13 are used wherever they are available, unless there are gaps or problems with submitted
14 data. U.S. EPA quality assures and augments the data provided by states to assist with
15 data completeness using separate augmentation procedures for each source as described
16 in detail in a technical support document to fill in gaps for sources and/or pollutants that
17 are often not reported by state, local, and tribal agencies. The intent is to create the most
18 complete inventory for use in air quality modeling, national rule assessments,
19 international reporting, and other reports. QA procedures and acceptance criteria are
20 detailed in the NEI technical support document ([U.S. EPA, 2016b](#)).

21 For nonpoint sources, U.S. EPA provides tools that state, local, and tribal agency staff
22 can use to generate emission estimates. For the 2014 NEI, the U.S. EPA developed
23 emission estimates for many nonpoint sectors in collaboration with a consortium of
24 inventory developers from various state agencies regional planning organizations called
25 the Nonpoint Method Advisory (NOMAD) Committee. More detailed NOMAD
26 subcommittees were established to collaborate on methods and emission factors for key
27 nonpoint source categories/sectors, including oil and gas exploration and production,
28 residential wood combustion, agricultural NH₃ sources (including fertilizer and
29 livestock), and industrial and commercial/institutional fuel combustion, among other
30 sources. The U.S. EPA also generates emission estimates as stand-alone data sets
31 covering biogenics, agricultural livestock, fertilizer application, nonroad mobile sources,
32 rail emissions, and commercial marine vessel ports and in-transit (underway) sources.
33 U.S. EPA data sets for sources and pollutants are used only for sources not provided by
34 state, local, and tribal data. Tools and methods for estimating emissions from a given
35 source, including EGU's, agricultural livestock, fertilizer application, mobile sources,
36 agricultural and wildland fires (wildfires + prescribed fires), and wood combustion, were
37 described in the 2014 NEI technical support document ([U.S. EPA, 2016b](#)).

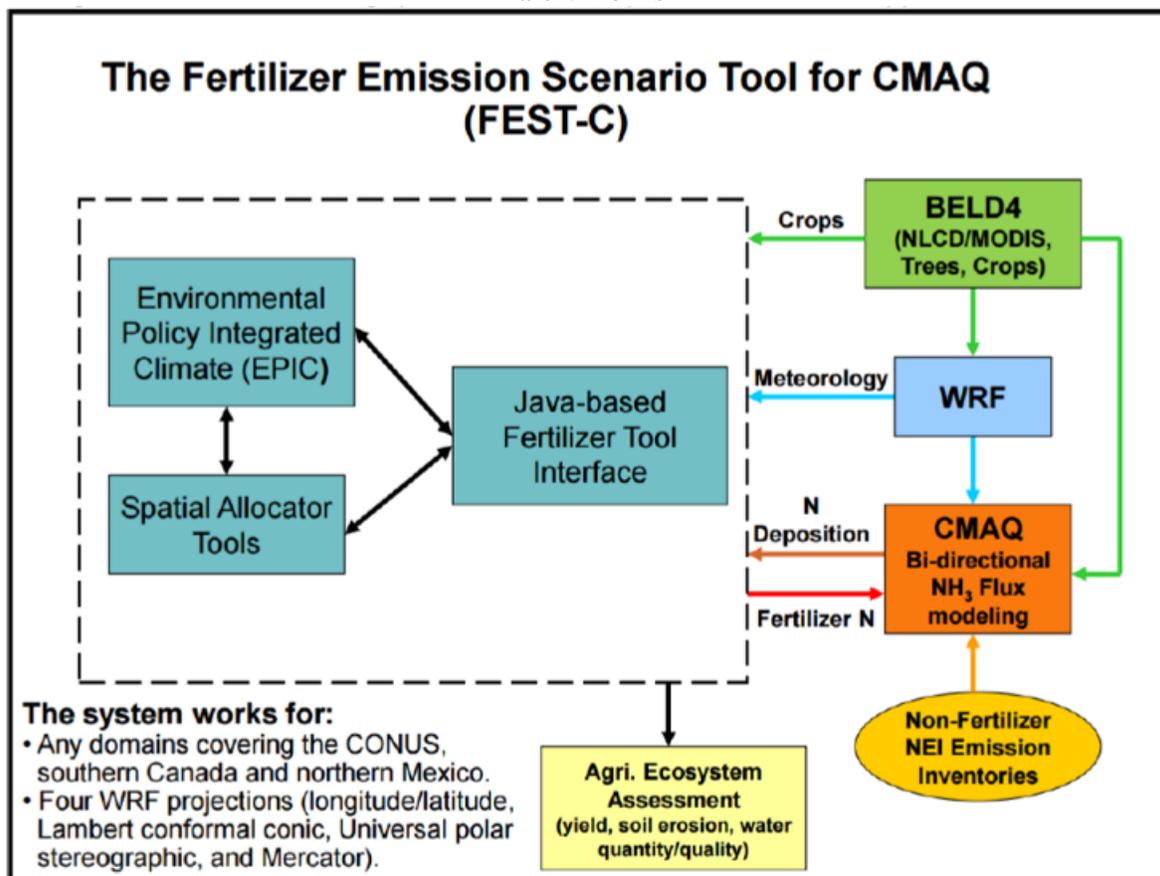

1 The 2014 NEI technical support document provides considerable detail on emission
2 factors and emission estimation methods by source used to generate the data in [Table 2-1](#)
3 ([U.S. EPA, 2016b](#)). Methods for estimating PM_{2.5} and PM₁₀ emissions from dust and fire,
4 the two largest national sources, are derived from experimental emission factors along
5 with source specific information (e.g., crop type and tilling frequency for agricultural
6 dust, vehicle weight and miles traveled for unpaved road dust) using source specific
7 equations available in the NEI technical support document. These methods are largely
8 well-established, although they have been updated to accommodate satellite data and
9 emissions modeling improvements, particularly in the case of fire emissions.

10 Methods for estimating emissions from electric power generating units and mobile
11 sources, the largest sources of SO₂ and NO_x, are also well established, and emissions
12 from these sources are decreasing. In contrast, ammonia emissions in the U.S. are
13 increasing ([Butler et al., 2016](#)), and significant uncertainties in the magnitude as well as
14 spatial and temporal variability of NH₃ emissions estimates were reported in the 2008
15 ISA ([U.S. EPA, 2008a](#)). Two new methods for estimating ammonia emissions from
16 fertilizer applications and livestock waste are highly relevant to understanding NH_x
17 sources and deposition are provided here as examples, but a similar level of detail is
18 given in the NEI technical support document for other sources of NH₃, SO₂, and NO_x,
19 and a thorough reading of that document is necessary for a full description of emissions
20 estimation methods used to construct [Table 2-1](#) ([U.S. EPA, 2016b](#)).

21 Soil and fertilizer emissions are treated differently in the NEI for NH₃ and NO_x. For NH₃,
22 fertilizer application is recognized as a major source for which emissions are specifically
23 estimated, and emissions from fertilizer application are estimated only for NH₃. The
24 approach to calculating emissions from fertilizer application in the 2014 NEI is a
25 completely new methodology to estimate ammonia (NH₃) emissions from agricultural
26 soils. The approach to estimate 2014 fertilizer emissions consists of these steps: (1) run
27 the Fertilizer Emissions Scenario Tool for CMAQ FEST-C (v1.2)
28 (<https://www.cmascenter.org/fest-c/>) and the bidirectional version of CMAQ (v5.0.2)
29 (<https://www.cmascenter.org/>) to produce Year 2011 nitrate (NO₃), ammonium (NH₄⁺,
30 including urea), and organic (manure) nitrogen (N) fertilizer usage estimates, and gaseous
31 ammonia NH₃ emission estimates respectively; (2) calculate county-level emission
32 factors for 2011 as the ratio of bidirectional CMAQ NH₃ fertilizer emissions to FEST-C
33 total N fertilizer application; (3) run FEST-C to produce Year 2014 NO₃, NH₄⁺ (including
34 Urea), and organic (manure) nitrogen fertilizer usage estimates; and (4) multiply
35 county-level 2014 FEST-C total fertilizer estimates by the 2011 emission factors to
36 estimate 2014 NH₃ emissions. FEST-C reads land use data from the Biogenic Emissions
37 Land Use Dataset (BELD) Version 4, meteorological variables from the Weather
38 Research and Forecasting (WRF v3.7.1) model (<http://www.wrf-model.org/index.php>)

1 and nitrogen deposition data from a previous or historical average CMAQ simulation.
 2 The Environmental Policy Integrated Climate (EPIC) modeling system
 3 (<http://epicapex.tamu.edu/>) provides information regarding fertilizer timing, composition,
 4 application method, and amount. [Figure 2-1](#) provides a comprehensive flowchart of the
 5 complete EPIC/FEST-C/WRF modeling system.

areNEI emis

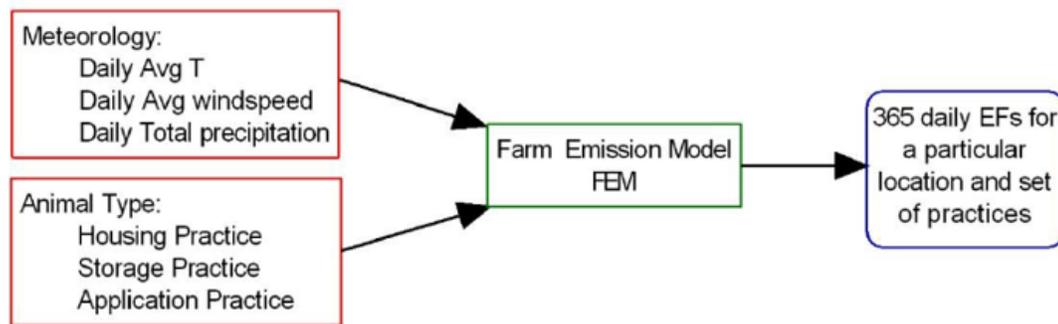

Source: [U.S. EPA \(2016b\)](#).

Figure 2-1 Modeling system used to compute 2014 Fertilizer Application Emissions.

6 Fertilizer application can also lead to NO_x emissions, but it does not dominate soil
 7 emissions of NO. Biogenic emissions of NO are computed based on 2014 meteorology
 8 data from the Weather Research and Forecasting (WRF) model version 3.8 (WRFv3.8)
 9 and using the Biogenic Emission Inventory System, Version 3.61 (BEIS3.61) model,
 10 based on land use and vegetation data ([U.S. EPA, 2016b](#)). The contribution of fertilizers

1 to soil NO_x emissions is not estimated in the NEI, but it has been estimated as 10%
2 globally ([Hudman et al., 2012](#)). Biogenic emissions of NH₃ are not estimated in the NEI,
3 but aside from fertilizer application it is a minor contributor, as shown in [Table 2-1](#).
4 Further details on estimating biogenic NO_x emissions are given in the NEI Technical
5 Support Document ([U.S. EPA, 2016b](#)).

6 Livestock waste is another important source of ammonia in the U.S. In the 2014 NEI, the
7 U.S. EPA has updated the methodology for ammonia emissions from the
8 housing/grazing, storage and application of manure from beef cattle, dairy cattle, swine,
9 broiler chicken, and layer chicken production. Cows, swine, and chickens account for
10 95% of national NH₃ emissions from livestock waste in 2014. The approach to estimate
11 2014 livestock NH₃ emissions from these animals consists of these general steps:
12 (1) estimate 2014 county-level animal populations using 2012 and 2014 USDA
13 agricultural census data; (2) use a model developed by Carnegie-Mellon University
14 ([Mcquilling and Adams, 2015](#); [Pinder et al., 2004a](#); [Pinder et al., 2004b](#)) to produce daily
15 resolved, climate-level emission factors for a particular distribution of management
16 practices for each county and animal type, as expressed as emissions/animal; and
17 (3) multiply the county animal populations by the daily emission factor for each county
18 and animal type to estimate emissions per day and sum daily emissions across the entire
19 year for each county and SCC to produce annual emissions for use in the NEI. The model
20 inputs and outputs are shown in [Figure 2-2](#).

Source: [U.S. EPA \(2016b\)](#).

Figure 2-2 Process to produce specific location and practice specific daily emission factors for livestock waste.

1 Similar details are given for estimating emissions for major sources of NO_x and SO₂ in
2 the NEI technical support document ([U.S. EPA, 2016b](#)), including EGU's, on-road
3 mobile sources, marine vessels, locomotives, other nonroad sources, airports, rail yards,
4 landfills, agricultural and wildland fires, wood combustion, other fuel residential and
5 industrial fuel combustion, charcoal grilling, waste disposal, vegetation and soil, and
6 other sources. Air emissions data from the 2014 Toxic Release Inventory (TRI) were also
7 used in the 2014 NEI to supplement point source NH₃ emissions provided to the U.S.
8 EPA by state, local, and tribal agencies. The TRI is a U.S. EPA database containing data
9 on disposal or other releases including air emissions of over 650 toxic chemicals from
10 approximately 21,000 facilities. Data are submitted annually by U.S. facilities that meet
11 TRI reporting criteria.

2.2.3. Evaluation and Uncertainty

12 As described in the 2008 ISA ([U.S. EPA, 2008a](#)), emissions from different sources in the
13 NEI are estimated with a wide range of methods that include direct measurements,
14 indirect measurements, model predictions, and assumptions. Because there are unknown,
15 incomplete, and variable emission rates, as well as unknown sources that are not
16 represented, the NEI reflects an on-going process of updating increasing or declining
17 emissions, improving estimation methods, and filling data gaps as measurements become
18 available or understanding of emissions changes. Often, steps are taken to reduce errors
19 in estimation as they are discovered, resulting in improved estimates as uncertainties are
20 found. For example, the estimate of [Gilliland et al. \(2003\)](#) that annual NEI NH₃ was 37%
21 higher than estimates based on modeled NH₄⁺ deposition led to the development of lower
22 emission factors for nondairy cows and swine ([U.S. EPA, 2008a](#)). Because of these
23 unknowns and limitations, quantitative uncertainty estimates based on probability density
24 functions or other statistical methods are not provided with NEI data. Instead, emission
25 factors receive a rating based on the reliability of methods used for determining the
26 emission factor. The rating is based on both the number of representative sources and the
27 characteristics of the data used to determine the emission factor, but it does not imply
28 statistical error bounds or confidence intervals for the emission factor ([U.S. EPA, 1996](#)).

29 As an alternative, uncertainties are often evaluated through separate efforts using a
30 variety of techniques. These techniques include comparing inventory predictions with
31 measured long-term trends, comparing emission estimates derived from principle
32 component analysis or other statistical methods, comparing emissions estimated by
33 inverse modeling of chemical transport models, and comparison with satellite data ([U.S.
34 EPA, 2008a](#)). The distinction between the inventory compilations like the NEI and
35 alternative satellite- and model-based methods of estimating emissions is generally

1 described in terms of bottom-up and top-down estimates. The entries in emissions
2 inventories are obtained using a bottom-up approach, in which entries are based on
3 emissions factors, activity rates, and control device efficiency for various source types.
4 This contrasts to a top-down approach in which measurements of pollutant concentrations
5 from satellites, aircraft, or surface monitors are used to constrain a priori estimates of
6 emissions using a chemistry-transport model (CTM).

7 Because of this variety of top-down approaches and the number of separate studies
8 resulting in a wide range of estimated uncertainties, there is no single estimate of
9 uncertainty that applies to either total emissions or emissions from individual sources in
10 [Table 2-1](#). However, reports from numerous publications on emissions inventory
11 evaluation have resulted in a wide range of uncertainty estimates for application to NEI
12 data, and these were summarized in the 2008 ISA ([U.S. EPA, 2008a](#)). Across all sources,
13 total NO_x emissions estimates from satellite data ranged from “highly consistent” with
14 NEI estimates ([Martin et al., 2006](#)) to 68% higher than NEI estimates ([Jaegle et al.,](#)
15 [2005](#)). Fewer estimates of individual source emissions were evaluated, with NO_x
16 emissions both higher and lower than estimates using other methods.

17 Some recent work has shown summertime over-prediction of model NO_x estimates using
18 recent U.S. EPA inventories (e.g., 2008 and 2011) when compared against monitored
19 ambient concentrations ([Canty et al., 2015](#); [Anderson et al., 2014a](#)). [Appel et al. \(2017\)](#)
20 found in their simulations that NO_x model over-estimates in summer were greatly
21 diminished or reversed in other seasons. [Anderson et al. \(2014a\)](#) and [Travis et al. \(2016\)](#)
22 concluded that emissions of NO_x from mobile sources are being overestimated and are
23 the source of this bias. Studies over Texas ([Souri et al., 2016](#); [Tang et al., 2015](#))
24 suggested a smaller or no bias in on road NO_x emissions compared to [Anderson et al.](#)
25 [\(2014a\)](#) and [Travis et al. \(2016\)](#), and suggested that both high and low biases in other
26 NO_x source categories (e.g., area sources, point sources, soil NO) impact
27 model/measurement discrepancies. [Marr et al. \(2013\)](#) used near-road measurements to
28 also conclude that mobile source NO_x emissions in U.S. EPA’s 2008 NEI agreed well
29 with measurements (i.e., within 3%). The cause of discrepancies between measured and
30 modeled concentrations are difficult to diagnose because the emission modeling process
31 and associated photochemical modeling is complex. Researchers are continuing to
32 investigate this question.

33 There can be higher uncertainties for specific sources. For example, about 60% of the
34 total NO_x emitted by soils nationwide is estimated to occur in the central Corn Belt of the
35 U.S. Spatial and temporal variability in soil NO_x emissions can lead to uncertainty in
36 emissions estimates. Soil emissions occur mainly during summer and across the entire
37 country, including areas where anthropogenic emissions are low. Emission rates depend

1 primarily on fertilization amount, soil temperature, and moisture. Models of NO_x
2 emissions from soils (e.g., [Hudman et al., 2012](#)) include these dependencies, but most
3 measurements on which they are based are made at temperatures <30°C. However, in
4 agricultural areas subjected to very high temperatures (>40°C) like the Imperial Valley,
5 CA, emissions factors for NO following fertilizer application ranged from 1.8 to 6.6%, as
6 compared to estimates of typically ~1 to 2% ([Oikawa et al., 2015](#)). [Oikawa et al. \(2015\)](#)
7 also suggest that in many areas of the Southwest, the NEI overestimates anthropogenic
8 emissions at the expense of soil emissions and that these soil emissions have a noticeable
9 effect on ozone formation. [Travis et al. \(2016\)](#) estimate that combustion accounts for
10 68% of NO_x emissions in the Southeast in summer, with the remainder from soils. These
11 results indicate that soil emissions need to be better understood. Estimating emissions
12 from highway vehicles can also be challenging because there is a wide variation in
13 emissions between different vehicles.

14 Activity rates and uncertainties for NH₃ are difficult to quantify, and estimates have yet
15 to be made for reduced organic nitrogen. NH₃ emission estimates are generally more
16 uncertain than NO_x and SO₂ emission estimates because of the variety of agricultural
17 practices used, re-emission after deposition, and the dispersed nature of agricultural
18 processes, as well as the complex influences of meteorology on processes controlling
19 transformation and removal of nitrogen species on spatial and temporal emission patterns.
20 As described in [Appendix 2.5.2](#), NO₂ and NH₃ can be both emitted from and deposited to
21 soils, water, or vegetation depending on their atmospheric concentrations and
22 characteristics of the underlying surface.

23 Mixed results were reported in evaluating the total NH₃ emissions estimates in the 2008
24 ISA ([U.S. EPA, 2008a](#)). However, as described above, there have been major changes in
25 estimation methods for the most important ammonia sources since that report, and more
26 recently [Paulot et al. \(2014\)](#) showed that a range of published bottom-up and top-down
27 estimates of annual total U.S. ammonia emissions agreed within 10%. The NEI national
28 estimate of 2.3 Tg NH₃ from [Table 2-1](#) was within 20% of the average across all
29 estimates of 2.8 ± 0.2 Tg NH₃ reported by [Paulot et al. \(2014\)](#). However, in the same
30 comparison there was a divergence in the timing of the seasonal maximum, and
31 agreement varied considerably temporally and spatially ([Paulot et al., 2014](#)).

32 Most SO₂ emissions originate from point sources having well-known locations and
33 identifiable fuel streams. Uncertainties in annual emissions were estimated to range from
34 4 to 9% for SO₂ and slightly larger for NO_x from the same point sources identified in the
35 1985 NAPAP inventories for the U.S. ([Placet et al., 1990](#)).

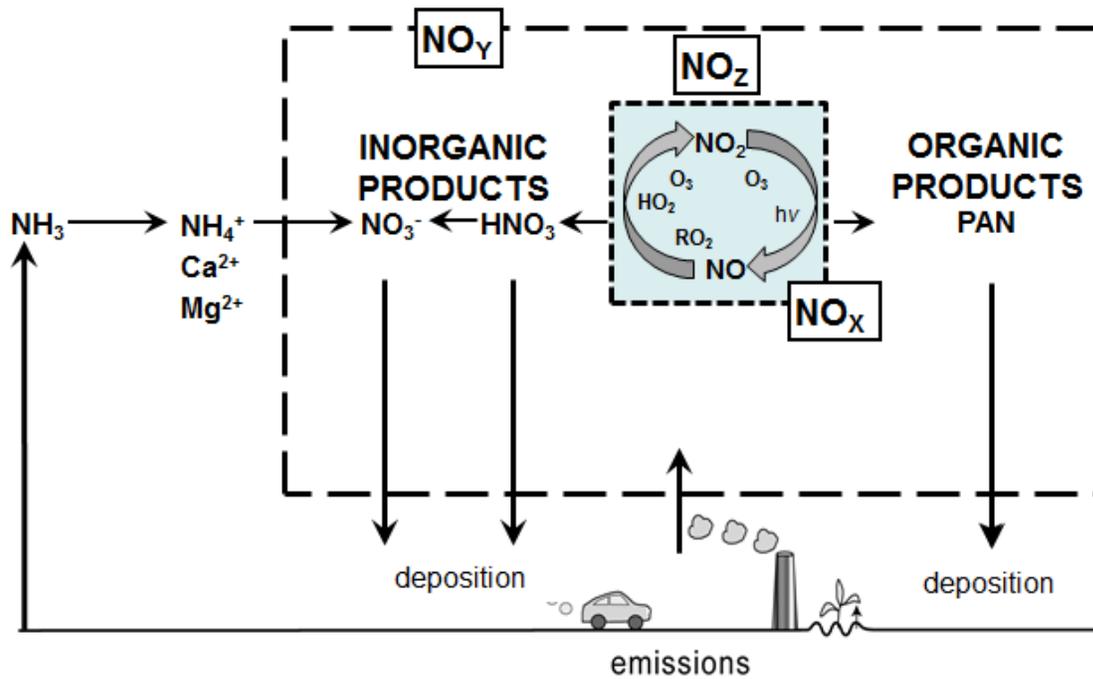

2.3. Atmospheric Chemistry of Nitrogen and Sulfur Species and Particulate Matter (PM)

1 The atmospheric chemistry of N and S species relevant for the production of ecosystem
2 nutrients and acidic species was extensively reviewed in the 2008 ISA ([U.S. EPA,
3 2008a](#)). The main findings from that review and key findings from more recent studies
4 and reviews are included here. [Appendix 2.3.1](#) describes atmospheric NO_x chemistry and
5 the formation of HNO₃. [Appendix 2.3.2](#) describes atmospheric sulfur oxide chemistry and
6 the formation of H₂SO₄. [Appendix 2.3.3](#) reviews the role of ammonia as the most
7 important atmospheric base for neutralizing atmospheric nitric and sulfuric acids and
8 forming PM. The chemistry of all of these species largely controls the extent of acid
9 deposition as well as the fraction of nitrogen in particulate matter, which in turn
10 determines deposition rate and transport distance. The remaining sections review
11 atmospheric organic sulfur and nitrogen compounds ([Appendix 2.3.4](#)), atmospheric
12 organic acids ([Appendix 2.3.5](#)), and formation of PM_{2.5} ([Appendix 2.3.6](#)).

2.3.1. Nitrogen Oxides

13 NO_x (NO + NO₂) is the precursor for oxidized nitrogen species that contribute to acidic
14 deposition. More specific details on the chemistry and transformation of NO_x can be
15 found in the *2016 ISA for Oxides of Nitrogen—Health Criteria* ([U.S. EPA, 2016f](#)) and
16 for SO_x in the *2008 ISA for Sulfur Oxides* ([U.S. EPA, 2008c](#)). Hence, those topics are
17 only briefly recounted here with special reference to the secondary NO_x and SO_x
18 NAAQS. Oxidized nitrogen species (NO_y) are introduced into the atmosphere as NO_x,
19 mainly from fossil fuel combustion as described in [Appendix 2.2](#). [Figure 2-3](#) summarizes
20 the atmospheric reactions of NO_x, showing rapid inter-conversion of NO and NO₂ in
21 sunlight, with slower formation of more oxidized organic and inorganic products (NO_z).

22 A large number of oxidized nitrogen species in the atmosphere are formed from the
23 oxidation of NO and NO₂ (shown in the inner box). These include nitrate radicals (NO₃),
24 nitrous acid (HONO), nitric acid (HNO₃), dinitrogen pentoxide (N₂O₅), nitryl chloride
25 (ClNO₂), peroxyxynitric acid (HNO₄), peroxyacetyl nitrate (PAN) and its homologues
26 (PANs), other organic nitrates, such as isoprene- and monoterpene-derived nitrates, and
27 particulate nitrate (pNO₃⁻). These species (and NH₃) are characterized by large
28 differences in their solubilities ([Table 2-2](#)), which determine their ability to be taken up
29 by cloud droplets, airborne particles, and moist surfaces.

Ca^{2+} = calcium ion; HNO_3 = nitric acid; HO_2 = hydroperoxy radicals; $h\nu$ = solar photon; Mg^{2+} = magnesium; NH_3 = ammonia; NH_4^+ = ammonium; NO = nitric oxide; NO_2 = nitrogen dioxide; NO_3^- = nitrate ion; NO_x = the sum of NO and NO_2 ; NO_z = oxidation products of NO_x ; NO_y = NO_x + NO_z ; O_3 = ozone; PAN = peroxyacetyl nitrate; RO_2 = organic peroxy radicals.

Note: The inner shaded box contains NO_x (NO + NO_2). The outer box contains other species (NO_z) formed from reactions of NO_x . All species shown in the outer and inner boxes are collectively referred to as NO_y by the atmospheric sciences community.

Figure 2-3 Schematic diagram showing pathways for reactive nitrogen species in ambient air.

Table 2-2 Henry's law coefficients for selected reactive nitrogen species at 25°C in water.

Compound	Coefficient (mol/kg/bar)
HNO ₃	2.6 × 10 ⁶
HONO	49
NO	0.0019
NO ₂	0.012
PAN	4.1
NH ₃	61

1 bar = 10⁵ Pa; C = Celsius; HNO₃ = nitric acid; HONO = nitrous acid; NH₃ = ammonia; NO = nitric oxide; NO₂ = nitrogen dioxide; PAN = peroxyacetyl nitrate.

Source: adapted from [Sutton et al. \(2011\)](#).

1 Reactions producing more oxidized forms of nitrogen (NO_z) involve mainly O₃, OH, and
 2 organic radicals with NO and NO₂. The reaction of NO₂ with OH leads directly to HNO₃:

Equation 2-1

3 The reaction of NO₂ with O₃ produces nitrate radical (NO₃), which reacts further to form
 4 dinitrogen pentoxide (N₂O₅), and ultimately also produces HNO₃:

Equation 2-2

Equation 2-3

Equation 2-4

5 The relative importance of these two paths for producing HNO₃ is strongly location and
 6 seasonally dependent, with the first path dominating when OH radicals are abundant
 7 (during the day) and the second during the night and under cold conditions. [Warneck](#)
 8 [\(1999\)](#) estimated that most HNO₃ is formed in the sunlit portions of clouds by the
 9 reaction of NO₂ with OH, with much smaller amounts from the pathway involving N₂O₅
 10 hydrolysis. Because it is highly soluble, HNO₃ is taken up by particles or cloud droplets
 11 to form NO₃⁻ and is also deposited onto moist surfaces, such as on vegetation. HNO₃ also

1 recycles back to NO₂ in the gas phase by photolysis and reaction with OH radicals, but on
2 timescales longer than that for uptake by cloud droplets, particles, and the surface.
3 Whereas photolysis of HNO₃ is slow ($\tau \sim 10^6$ s) in the gas phase, it can be two orders of
4 magnitude faster on moist surfaces ([Ye et al., 2016](#)), releasing NO₂ and/or HONO back to
5 the atmosphere.

6 NO₂ reacts with organic peroxy radicals to form organic nitrates such as peroxyacetyl
7 nitrate (PAN) and its homologues as shown on the right side of [Figure 2-3](#); other RO₂NO₂
8 compounds are much less stable than PANs. NO and NO₃ radicals also react with organic
9 radicals produced by the oxidation of isoprene and monoterpenes to form a wide range of
10 organic nitrates. Considering the troposphere as a whole, most of the mass of NO_z shown
11 in [Figure 2-3](#) is in the form of PAN and HNO₃. However, organic nitrates such as
12 isoprene- and monoterpene-derived nitrates increase in importance in the planetary
13 boundary layer (PBL), and are likely to be dominant in vegetated areas ([Kim et al.,](#)
14 [2015a](#); [Min et al., 2014](#)).

15 In forested areas, the initial step in the production of isoprene nitrates (INs) is most often
16 the reaction of isoprene with OH radicals to produce isoprene peroxy radicals. These can
17 react with HO₂ radicals, other RO₂ radicals, or isomerize to produce a variety of organic
18 compounds. They can also react with NO to produce multifunctional organic nitrates.
19 Lifetimes on the order of one to a few hours can be estimated for these first generation
20 INs based on their reactions with OH radicals and O₃ ([Lockwood et al., 2010](#); [Paulot et](#)
21 [al., 2009](#)). The reaction products can further react with NO (after internal rearrangement)
22 to form secondary organic nitrates such as ethanal nitrate, methacrolein nitrate,
23 propanone nitrate, and methyl vinyl ketone nitrate. The second-generation organic
24 nitrates are more stable than the first-generation INs because they lack a double carbon
25 (C = C) bond. Obviously, the relative importance of pathways forming nitrates or other
26 products depends on the ambient concentrations of NO and other oxides of nitrogen for
27 which many key experimental details are still lacking. During the SEAC⁴RS
28 measurement campaign, which took place in the summer of 2013 in the southeastern
29 U.S., [Travis et al. \(2016\)](#) found that these two pathways were of comparable importance.

30 In addition to oxidation initiated by OH radicals, isoprene is also oxidized by NO₃
31 radicals. [Rollins et al. \(2009\)](#) determined a yield of first-generation carbonyl nitrates of
32 70% based on experiments in large reaction chambers. These first-generation nitrates can
33 further react with NO, leading to the production of second-generation organic (alkyl)
34 nitrates. [Mao et al. \(2013\)](#) estimated that the global mean lifetime is ~5 days for these
35 second-generation organic nitrates. [Mao et al. \(2013\)](#) also suggested that the export of
36 INs and other organic nitrates followed by their decomposition is potentially a larger
37 source of NO_x to the boundary layer of the western North Atlantic Ocean than the export

1 of PANs. Some INs are low enough in volatility that they can partition to the particle
2 phase [e.g., (Rollins et al., 2009)]. Once in the particle phase, the INs hydrolyze to form
3 HNO₃ and an alcohol, with a rate constant that correlates strongly with the acidity of the
4 particles (Rindelaub et al., 2015; Jacobs et al., 2014).

5 In addition to considering the chemistry of isoprene-derived nitrates during SEAC⁴RS,
6 Fisher et al. (2016) considered the formation of organic nitrates derived from the
7 oxidation of monoterpenes with either one or two double bonds. Their modeling results
8 suggest that isoprene- and monoterpene-derived nitrates account for 25 to 50% and ~10%
9 of total organic nitrates and that production of isoprene- and monoterpene-derived
10 nitrates account for ~20% of the net loss of NO_x emitted in the Southeast during summer.
11 Fisher et al. (2016) also noted that production of organic nitrates involving biogenic
12 VOCs is the dominant NO_x sink only in areas where elevated levels of biogenic VOCs
13 coincide with low NO_x levels (otherwise the major sink would be formation of HNO₃).
14 As a result, these processes will represent only a minor pathway for NO_x loss. In any
15 event, as with isoprene-derived nitrates, monoterpene-derived nitrates are also mainly
16 taken up by particles with formation of HNO₃. Uptake by particles was estimated by
17 Fisher et al. (2016) to account for ~60% of the removal of gas-phase organic nitrates,
18 with ~20% recycled back to NO_x and another 15% deposited to the surface.

2.3.2. Sulfur Oxides

19 SO₂ is the only gas phase form of SO_x (SO₂ + SO₄²⁻) emitted in the tropospheric
20 boundary layer at concentrations of concern for environmental exposures (U.S. EPA,
21 2008c). It reacts in both the gas phase and in aqueous solution in clouds and particles to
22 form SO₄²⁻. As described in the 2008 ISA (U.S. EPA, 2008a), the steps involved in
23 aqueous-phase oxidation of SO₂ begins with dissolution of SO₂ following Jacobson
24 (2002):

Equation 2-5

25 and is followed by formation and dissociation of H₂SO₃:

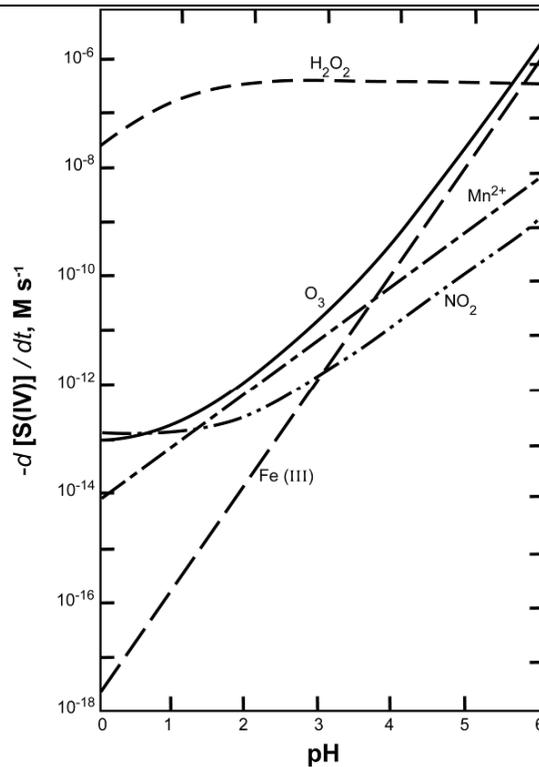

Equation 2-6

26 Dissolved SO₂ thus rapidly partitions into four forms with the same oxidation state, with
27 their relative concentrations dependent on pH:

Equation 2-7

1 S(IV) is then oxidized to SO_4^{2-} in cloud water primarily by either H_2O_2 , O_3 , and O_2 in the
 2 presence of dissolved Fe(III). Reaction with H_2O_2 is most important at pH less than about
 3 5.3, and reaction with either dissolved O_3 or with O_2 catalyzed by Fe(III) becomes most
 4 important at pH greater than about 5.3, as shown in [Figure 2-4 \(Seinfeld and Pandis,](#)
 5 [1998\)](#).

aq = aqueous; Fe(III) = iron (oxidation number III); H_2O_2 = hydrogen peroxide; Mn(II) = manganese (oxidation number II); NO_2 = nitrogen dioxide; O_3 = ozone; S(IV) = sulfur (oxidation number IV); SO_2 = sulfur dioxide.
 Concentrations assumed are: $[SO_2(g)] = 5$ ppb; $[NO_2(g)] = 1$ ppb; $[H_2O_2(g)] = 1$ ppb; $[O_3(g)] = 50$ ppb; $[Fe(III)(aq)] = 0.3 \mu M$; $[Mn(II)(aq)] = 0.03 \mu M$.
 Source: [Seinfeld and Pandis \(1998\)](#).

Figure 2-4 Rate of conversion of sulfur (IV) to sulfur (VI) by different oxidation paths as a function of pH.

6 The remaining SO_2 is oxidized to H_2SO_4 in the gas phase with a characteristic timescale
 7 of ~10 days [based on $OH = 10^6/cm^3$ and rate coefficient = $1.3 \times 10^{-12}/cm^3/molec/s$;
 8 ([Sander et al., 2011](#))] following a multistep process:

Equation 2-8

Equation 2-9

1 and/or by

Equation 2-10

2 where sCI is a stabilized Criegee intermediate ([Berndt et al., 2012](#); [Mauldin et al., 2012](#);
3 [Welz et al., 2012](#)) and products refer to other organic radicals. Criegee radicals are
4 produced by the reaction of alkenes with O₃ during both night and day. The relative
5 importance of the OH and sCI pathways depends in large measure on the local
6 concentration of alkenes, in particular biogenic alkenes. [Welz et al. \(2012\)](#) also raised the
7 possibility that Criegee radicals might be important for the oxidation of NO₂ to form
8 nitrate radicals. SO₃ produced by either path further reacts to form gas-phase H₂SO₄ via

Equation 2-11

9 Because H₂SO₄ is extremely soluble, it is removed rapidly by transfer to the aqueous
10 phase of particles and cloud droplets.

2.3.3. Acid Neutralization by Ammonia

11 As the most common soluble base in the atmosphere, NH₃ plays a key role in neutralizing
12 the acidity in ambient particles and in cloud, fog, and rainwater resulting from dissolution
13 of H₂SO₄ and HNO₃, and the weak acidity due to organic acids. The atmospheric lifetime
14 of NH₃ with respect to oxidation by OH radicals is ~2 months [based on
15 OH = 10⁶ molec/cm³ and rate coefficient = 1.6 × 10⁻¹³/cm³/molec/s; ([Sander et al.,
16 2011](#))]. As a result, uptake by cloud droplets, particles, and the surface is favored over
17 reaction with OH radicals. [Xu and Penner \(2012\)](#) estimate a globally averaged lifetime
18 for NH₃ of ~11 hours as a result of these processes, implying strong spatial and temporal
19 variability of NH₃ concentrations.

20 Sulfuric acid can be partly or totally neutralized by NH₃. [Seinfeld and Pandis \(1998\)](#)
21 define two regimes: (1) ammonia poor [TA] <2 [TS] and (2) ammonia rich [TA] >2 [TS],
22 where TA and TS refer to total ammonia, ammonium and sulfate concentrations in gas,
23 aqueous, and solid forms. In the first regime, there is partial neutralization; sulfate is in
24 the form of (NH₄)HSO₄, the vapor pressure of NH₃ is very low, equilibrium favors

1 formation of ammonium sulfate over ammonium nitrate, any nitrate is driven to the gas
2 phase, and ammonium nitrate levels are low (or even zero). In the second regime, sulfate
3 is in the form of $(\text{NH}_4)_2\text{SO}_4$, and any NH_3 left over could react with HNO_3 to form
4 NH_4NO_3 . However, this conceptual model neglects interactions with organic compounds.
5 Analysis of data by [Kim et al. \(2015a\)](#) from the SEAC⁴RS field study and the Chemical
6 Speciation Network (CSN) during August–September of 2013 indicates that the extent of
7 neutralization of sulfuric acid and acidic sulfate by ammonium was incomplete in the
8 Southeast despite an excess of atmospheric NH_3 . [Kim et al. \(2015a\)](#) suggested that uptake
9 of NH_3 is inhibited by organic compounds in particles. This suggestion is in accord with
10 laboratory studies of [Liggio et al. \(2011\)](#) who found that organic compounds, especially
11 terpenes and *n*-alkanes on particle surfaces are effective in inhibiting NH_3 uptake by
12 particles.

13 NH_4NO_3 is in thermodynamic equilibrium with gas-phase NH_3 and HNO_3 . The
14 equilibrium constant is extremely sensitive to variations in relative humidity and
15 temperature such that it varies over several orders of magnitude depending on
16 atmospheric conditions, but in general, lower temperature and higher relative humidity
17 (e.g., during winter) shifts the equilibrium towards condensed phase NH_4NO_3 . The effects
18 on phase partitioning are pronounced because of the large variation in the equilibrium
19 constant, K , ($\sim 10\text{--}10^3$ ppb²) between summer and winter conditions in many locations.
20 Also, as noted by [Malm et al. \(2016\)](#), NH_4NO_3 can volatilize and reform multiple times
21 during transport away from sources of NH_3 and HNO_3 . Because the atmospheric lifetimes
22 of NH_3 , HNO_3 , and NH_4NO_3 differ substantially from each other, local conditions of
23 temperature and relative humidity, by implication, control how far these species can
24 travel.

25 Although the above considerations apply to particles in general, it should be remembered
26 that the mass of airborne particles is present in two distinct size fractions, each with its
27 own characteristic composition [see [U.S. EPA \(2009a\)](#)]. These differences determine the
28 size fraction in which pNO_3^- will be found. Because SO_4^{2-} is found mainly in the fine
29 particle mode these considerations tend to apply more to the atmospheric fine mode.
30 Displacement of HCl (and other hydrohalic acids) from marine aerosol (found typically
31 in the coarse mode) by gas-phase HNO_3 has long been known to occur, resulting in
32 particulate nitrate (pNO_3^-) being associated with sodium in the coarse mode in many
33 coastal areas. [Brimblecombe and Clegg \(1988\)](#) provided a detailed evaluation of the
34 thermodynamic data and a discussion of this process. [Wolff \(1984\)](#) found that
35 coarse-mode pNO_3^- is formed by adsorption of HNO_3 on basic soil particles (i.e., those
36 containing Ca^{2+} and Mg^{2+}). These distinctions between the behavior of pNO_3^- in the fine
37 and coarse modes are important as deposition rates for these two size modes can differ

1 appreciably and there can be large differences in the ratio of fine to coarse pNO_3^- as
2 shown in [Appendix 2.5.2.1](#).

3 The composition of rainwater and of particles is strongly affected by pH. As described
4 above, pH determines the distribution of S(IV) species in cloud water, rainwater and the
5 aqueous phase of particles. This in turn impacts their oxidation processes
6 ([Appendix 2.3.2](#)), the solubility of trace metals, and the partitioning of weak acids among
7 other factors. As the most abundant base in the atmosphere, NH_3 has a strong influence
8 on pH of cloud water. However, the role of NH_3 as a base is limited to atmospheric
9 processes. Once deposited in soil, oxidation of NH_3 and NH_4^+ to NO_3^- (during
10 nitrification) produces an amount of H^+ equivalent to HNO_3 deposition [[Scheffe et al.](#)
11 ([2014](#)) and references therein].

2.3.4. Organic Nitrogen and Sulfur

12 In addition to deposition of NO_y and NH_x , the deposition of other nitrogen compounds,
13 in particular dissolved organic nitrogen (DON) also occurs. Proteins, amino acids, urea,
14 amines, and other DON compounds can contribute to acidification in soils and be an
15 important source of nutrients to terrestrial and aquatic environments ([Jickells et al., 2013](#);
16 [Cape et al., 2011](#); [Cornell, 2011b](#); [Sutton et al., 2011](#)). The content of organic nitrogen in
17 particles and rainwater can be characterized in two ways. First, it can be calculated as the
18 difference between total N as measured by total elemental analysis [see e.g., [Bronk et al.](#)
19 ([2000](#))] minus NO_3^- and NH_4^+ . In the second way, the content of organic nitrogen in
20 particles and rainwater can be characterized by measuring the concentrations of
21 individual species. However, the number of species constituting DON at a particular
22 location can be quite large. For example, [Altieri et al. \(2009a\)](#) detected several thousand
23 organic N containing species in precipitation samples collected in New Jersey and found
24 the overall composition was consistent with oligomerization of amino acids; in most
25 compounds, N was in reduced form.

26 [Cornell \(2011a\)](#) estimated based on measurements reported in 58 published studies that
27 organic N constitutes 35% of total N in rainwater in North America. [Jickells et al. \(2013\)](#)
28 estimated based on data from a number of measurement sites ($n = 115$ globally), that
29 average DON in rainwater contributes ~25% of the flux of total nitrogen. They also
30 reasoned that because it is correlated with total nitrogen in rainwater ($R^2 = 0.57$), which
31 has a large anthropogenic component, DON might also have a large anthropogenic
32 component. Further description of DON measured at sites in the CONUS are deferred to
33 [Appendix 2.6.2](#).

1 A large number of organosulfates (R-O-SO₃H) have been detected in rainwater samples
2 ([Altieri et al., 2009b](#)). However, their abundances could not be determined. [Tolocka and](#)
3 [Turpin \(2012\)](#) estimated that organic sulfates could contribute up to 5 to 10% of organic
4 mass on average to particle mass based on measurements taken at 12 sites across the U.S.
5 [Liao et al. \(2015\)](#) found that organic sulfates accounted a few percent of particulate
6 sulfate, mainly from the two most abundant forms, isoprene epoxydiol sulfate and
7 glycolic acid sulfate. Organic sulfates such as these have high acid dissociation constants
8 and are expected to act as singly charged species.

9 Phytoplankton emit copious amounts of dimethyl sulfide, which can be oxidized to sulfur
10 dioxide and to methanesulfonic acid. The SO₂ that is formed can then be a source of
11 H₂SO₄ in coastal areas.

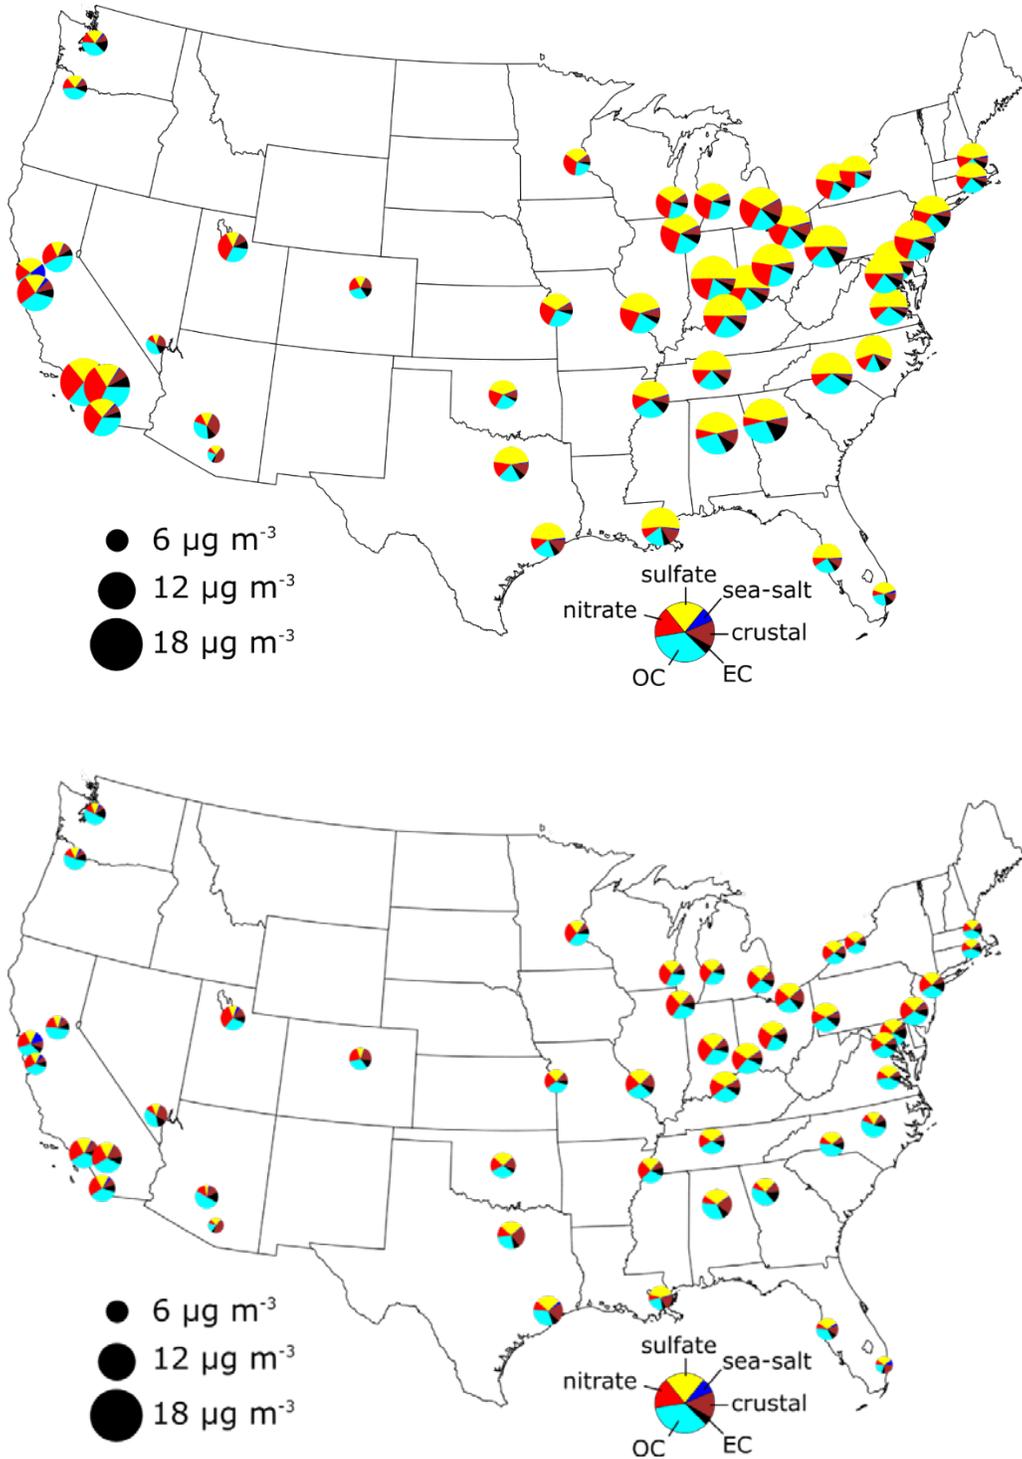

2.3.5. Organic Acids

12 The effects of deposition of acidic sulfur and nitrogen should be considered in the context
13 of a more complete description of the composition of rainwater, including organic acids.
14 However, organic acids are not routinely measured by monitoring networks because they
15 are unstable with respect to microbial degradation following collection. As a result, data
16 for organic acids in rainwater are sparse. Formic and acetic acids are typically the most
17 abundant organic acids found in rainwater in the U.S. ([Willey et al., 2011](#); [Avery et al.,](#)
18 [2006](#); [Talbot et al., 1990](#)). They are largely secondary in origin (i.e., produced in the
19 atmosphere by the photochemical oxidation of biogenic and anthropogenic
20 hydrocarbons). [Paulot et al. \(2011\)](#) suggested that isoprene oxidation is the largest global
21 source of formic and acetic acids. These acids are also produced by the oxidation of
22 ethane and propylene emitted in automobile exhaust. Their abundances in rainwater and
23 their effects on pH are not negligible. For example, [Willey et al. \(2011\)](#) found that formic
24 acid (pK_a = 3.75) and acetic acid (pK_a = 4.76) were the major organic acids present and
25 contributed ~22 and 5%, respectively, of free acidity (mean pH = 4.65) in rainwater
26 samples collected at Wilmington, NC in 2008. In addition, other organic acids
27 (e.g., oxalic acid, lactic acid) have been found to be present at much lower levels at this
28 site ([Avery et al., 2006](#)). [Vet et al. \(2014\)](#) noted that organic acids should be monitored in
29 areas where the concentration of H⁺ is <5 µeq/L (or pH ≥ 5.3). As will be seen in
30 [Appendix 2.6](#), this condition is met in areas like the Northwest where concentrations of
31 NO₃⁻ and SO₄²⁻ in rainwater are low. Even in areas where the effects of organic acid
32 neutralization by NH₄⁺ might be small, the vapor pressures of some organic acids
33 (e.g., oxalic acid) would be reduced by orders of magnitude, resulting in increased uptake
34 of the organic acid from the gas phase and growth of particles ([Ortiz-Montalvo et al.,](#)
35 [2014](#); [Paciga et al., 2014](#)).

2.3.6. Particulate Matter (PM)

1 The chemistry of NO_x and SO₂ described in [Appendix 2.3.1](#) and [Appendix 2.3.2](#), and the
2 neutralization reactions of NH₃ described in [Appendix 2.3.3](#) are relevant not only to
3 understanding the distribution of NO_y and SO_x species, but also in explaining a large
4 fraction of PM_{2.5} in most of the U.S. [Figure 2-5](#) shows PM_{2.5} composition in numerous
5 U.S. locations. In all locations SO₄²⁻ and NO₃⁻ account for a substantial fraction, and in
6 many cases the majority, of PM_{2.5}. In general, SO₄²⁻ accounts for an increasing fraction of
7 PM_{2.5} moving east or south, and NO₃⁻ for a greater fraction moving west or north.
8 [Figure 2-5](#) also shows that PM_{2.5} concentrations are lower and SO₄²⁻ accounts for a much
9 greater fraction of PM_{2.5} mass in 2003–2005 than in 2013–2015. This reflects the steep
10 decline in SO₂ emissions over this period ([Appendix 2.2.1](#)) and demonstrates that it has
11 greatly impacted PM_{2.5} composition and concentration in the U.S.

12 The decrease in SO₄²⁻ contribution is so large that in many locations where SO₄²⁻ was the
13 greatest contributor to PM_{2.5} mass in 2003–2005, organic carbon was more abundant in
14 2013–2015. However, as described in [Appendix 2.1](#), organic matter does not contribute
15 as much to acidification or nutrient enrichment as SO₄²⁻ and NO₃⁻, and SO₄²⁻ and NO₃⁻
16 still account for the majority of PM_{2.5} mass in many locations. The remaining mass of
17 PM_{2.5} is composed of elemental carbon, sea salt (mostly Na and Cl), and crustal material
18 (Si and Al are most abundant elements). Monitoring methods are described and spatial
19 and temporal trends for PM_{2.5} species are further developed in the 2009 PM ISA ([U.S.](#)
20 [EPA, 2009a](#)). There is much less information on PM₁₀ or PM_{10-2.5} composition because of
21 the lack of routine monitoring on the scale that has been implemented for PM_{2.5} species.

Source: EPA 2016 analysis of Air Quality System network data 2003-2005.

Figure 2-5 Contributions of organic carbon (OC), elemental carbon (EC), sulfate, nitrate, sea salt, and crustal components to $\text{PM}_{2.5}$ at selected sites (A) 2003–2005 (B) 2013–2015.

2.4. Concentration and Deposition Measurements

1 An extensive review of techniques for measuring NO_x, NO_z, NO_y, NH_x, and SO_x
2 appeared in the 2008 ISA ([U.S. EPA, 2008a](#)). Updates to techniques for measuring NO_x,
3 NO_y, and SO_x species can be found in the latest ISA for Oxides of Nitrogen ([U.S. EPA,](#)
4 [2016f](#)), Sulfur Oxides ([U.S. EPA, 2008c](#)), and PM, including PM_{2.5}, PM₁₀, and PM_{10-2.5}
5 ([U.S. EPA, 2009a](#)) Health Effects, to which the reader is referred for details. In the
6 following sections, measurements of NO_x, SO₂, and PM in national networks are only
7 briefly discussed and the measurement of species most relevant to acid and nutrient
8 deposition and measurement methods for wet and dry deposition are the main focus.
9 [Appendix 2.4.1](#) explains the roles of various national and regional monitoring networks
10 in place to support the NAAQS or to collect data used for estimating acid and nutrient
11 deposition. [Appendix 2.4.2](#), [Appendix 2.4.3](#), and [Appendix 2.4.4](#) describe methods used
12 to measure gas-phase oxides of nitrogen, reduced nitrogen, and sulfur oxides that are not
13 based on filter collection. Each of these sections is divided into separate discussions of
14 the methods used in monitoring networks, remote sensing methods, and recent advances
15 in research methods and other methods that are effective for intensive field studies but
16 impractical for routine monitoring. Satellite-based remote sensing methods are useful
17 because network coverage is often sparse and satellite-based measurements are becoming
18 a more widely used alternative to ground-based measurements. [Appendix 2.4.5](#) describes
19 filter-based methods used in CASTNET and other networks for mainly particulate
20 species, but also for some gases, including HNO₃ and SO₂. [Appendix 2.4.6](#) describes wet
21 and dry deposition measurement and recent advances.

2.4.1. Monitoring Networks

22 Federal Reference Methods (FRMs) have been established and national monitoring
23 networks put in place for NO₂ as the indicator of oxides of nitrogen, SO₂ as the indicator
24 of sulfur oxides, and PM_{2.5} and PM₁₀ as indicators for PM. These methods and networks
25 are described in detail in recent *Integrated Science Assessments for Health Effects of*
26 *Oxides of Nitrogen* ([U.S. EPA, 2016f](#)), *Sulfur Oxides* ([U.S. EPA, 2008c](#)), and *Particulate*
27 *Matter* ([U.S. EPA, 2009a](#)). However, in general the large fractions of N and S deposition
28 accounted for by species other than NO₂ and SO₂ make measurements of these indicator
29 species alone inadequate for estimating deposition amounts of total oxides of nitrogen
30 and total sulfur oxides. Similarly, it has long been established that wet deposition of S is
31 usually dominated by SO₄²⁻ rather than SO₂ ([Dana, 1980](#)). In this respect, PM_{2.5}
32 monitoring is potentially useful because it efficiently collects the range of PM species
33 involved in acidification and N deposition. However, variability of SO₄²⁻ and NO₃⁻ as a

1 fraction of total PM_{2.5} presents a challenge for relating PM_{2.5} mass to these effects. An
2 additional challenge is the estimate of deposition from PM_{2.5} concentrations, because of
3 the strong dependence of deposition flux on particle size (see [Appendix 2.5.2](#)) and
4 general unavailability of size distribution measurements.

5 In principle, a multipurpose, multipollutant monitoring network could efficiently meet the
6 needs of estimating N and S deposition and air monitoring for ecosystem protection,
7 while at the same time addressing other national air monitoring priorities. Such a network
8 could include measurements of other N and S species besides NO₂ and SO₂ as well as
9 other species that are otherwise not routinely monitored to better understand a variety of
10 air pollution processes. This is the overall concept behind the National Core Network
11 (NCore), a newly developed multipollutant monitoring network, and measurements of
12 NO_y and NH₃ were included as NCore monitoring in part because of their relevance to
13 atmospheric deposition ([Scheffe et al., 2009](#)). NCore has been operating since January 1,
14 2011 and has 80 monitoring sites designed for measuring multiple pollutants ([Weinstock,
15 2012](#)). The network provides a core of sites that measure SO₂, NO₂, NO_y, and PM
16 components including ammonium, nitrate, and sulfate, but with sparser coverage than the
17 FRM networks for SO₂ or NO_x. Because NO_y is measured rather than NO_x, and because
18 of collocated SO₂ and SO₄²⁻ measurements, ambient concentrations of both NO_y and SO_x
19 can be determined from NCore data, so that these data can be used to estimate total
20 deposition of oxides of nitrogen and sulfur. However, because of the wide range of
21 deposition velocities for different species, NO_y measurements alone are not sufficient for
22 estimating deposition and species concentrations are also necessary. A further
23 disadvantage is that most NCore sites are located in urban areas.

24 Instead of using NCore or the national NO₂, SO₂, and PM monitoring networks, national
25 scale N and S deposition have relied on monitoring networks specifically designed for
26 estimating deposition. [Table 2-3](#) lists monitoring networks that have been used for recent
27 estimates of atmospheric N and S deposition for the National Acid Deposition Program
28 ([Schwede and Lear, 2014a](#)).

Table 2-3 Summary of monitoring networks used by [Schwede and Lear \(2014a\)](#).

Network	Chemical Species	Period of Record	Website
CASTNET	Concentration: HNO ₃ , SO ₂ , pSO ₄ ^{2-a} , pNO ₃ ^{-a} , pNH ₄ ^{+a}	2000–2012	http://epa.gov/castnet/javaweb/index.html
AMoN	Concentration: NH ₃	2008–2012	http://nadp.sws.uiuc.edu/AMon/
SEARCH	Concentration: HNO ₃ , SO ₂ , NH ₃	2005–2011	http://www.atmospheric-research.com/studies/SEARCH/
NTN	Wet deposition: SO ₄ ²⁻ , NO ₃ ⁻ , NH ₄ ⁺	2000–2012	http://nadp.sws.uiuc.edu/NTN/

^apSO₄²⁻ is particulate sulfate concentration, pNO₃⁻ is particulate nitrate concentration, pNH₄⁺ is particulate ammonium concentration.

Note: summary of data from monitoring networks used in the methodology.

Source: [Schwede and Lear \(2014a\)](#).

1 Wet deposition is estimated as the product of pollutant concentration in precipitation and
2 precipitation depth (e.g., in rain or snow). Concentration in precipitation is currently
3 measured as a weekly average by the National Atmospheric Deposition Program/National
4 Trends Network (NADP/NTN) across a national network of 250 sites using a standard
5 precipitation collector described in the 2008 ISA ([U.S. EPA, 2008a](#)). The NADP
6 precipitation network was initiated in 1978 to collect data on amounts, trends, and
7 distributions of acids, nutrients, and cations in precipitation. It expanded to meet the
8 needs of the National Acid Precipitation Assessment Program established in 1981 to
9 understand causes and effects of acid precipitation. The NTN is the only network
10 providing a long-term record of precipitation chemistry across the U.S. Sites are mainly
11 located away from urban areas and pollution sources. An automated collector ensures that
12 the sample is exposed only during precipitation (wet-only sampling). Species measured
13 are free acidity (H⁺ as pH), conductance, calcium (Ca²⁺), magnesium (Mg²⁺), sodium
14 (Na⁺), potassium (K⁺), sulfate (SO₄²⁻), nitrate (NO₃⁻), chloride (Cl⁻), and ammonium
15 (NH₄⁺). Relatively high confidence has been assigned to wet deposition estimates because
16 of established capabilities for measuring relevant chemical components in precipitation
17 samples ([U.S. EPA, 2011a](#)). The Atmospheric Integrated Research Monitoring Network
18 (AIRMoN) started in 1992 and measures the same species as the NTN, but on a daily
19 rather than weekly basis.

20 In contrast, direct measurements of dry deposition flux are rare and difficult, and dry
21 deposition fluxes of gases and particles are estimated from concentration measurements
22 by an inferential technique described in the 2008 ISA ([U.S. EPA, 2008a](#)). In the

1 inferential model approach, the deposition of a pollutant is accomplished by introducing a
2 resistance component to account for the individual chemical and biological processes that
3 control pollutant adsorption and capture at natural surfaces ([Hicks et al., 1987](#)).

4 Concentrations are measured in the Clean Air Status and Trends Network (CASTNET),
5 which was established under the 1991 Clean Air Act Amendments to assess trends in
6 acidic deposition. CASTNET is a long-term environmental monitoring network with
7 95 sites located throughout the U.S. and Canada, managed and operated by the U.S. EPA
8 in cooperation with other federal, state, and local partners (www.epa.gov/castnet)
9 including six Native American tribes. CASTNET is the only network in the U.S. that
10 provides a consistent, long-term data record of acidic dry deposition fluxes. It
11 complements the NTN, and nearly all CASTNET sites are collocated with or near an
12 NTN site. Together, these two monitoring programs are designed to provide data
13 necessary to estimate long-term temporal and spatial trends in total deposition (dry and
14 wet) as well as ecosystem health. Species measured in CASTNET include: O₃, SO₂,
15 HNO₃ in the gas phase and SO₄²⁻, NO₃⁻, NH₄⁺, Ca²⁺, Mg²⁺, K⁺, Na⁺, and Cl⁻ in particles.

16 While CASTNET data are more useful for estimating dry deposition than data from FRM
17 networks, monitors are generally sparse and deposition is only determined for discrete
18 locations. Also, not all of the species that contribute to total sulfur and nitrogen
19 deposition are measured in CASTNET ([Schwede et al., 2011](#)). Despite these
20 disadvantages, CASTNET data still be very useful if used in combination with modeled
21 data ([Schwede et al., 2011](#)). NH₃ is not measured in CASTNET, but the National
22 Atmospheric Deposition Program (NADP) deployed a separate NH₃ monitoring network
23 (AMoN) using Radiello[®] passive samplers starting in the fall of 2007 at 16 sites;
24 currently there are more than 60 active AMoN sites, two-thirds of which are located at
25 CASTNET sites.

26 A limitation of dry deposition derived from CASTNET and other dry deposition
27 networks is that results cannot be spatially interpolated because of the complexity of the
28 deposition field ([Schwede and Lear, 2014a](#); [Baumgardner et al., 2002](#)). Combined with
29 the sparse coverage of the network, this complexity restricts the capability of routine
30 monitoring networks to provide data on dry deposition. To some extent, this limitation
31 can be addressed by considering data from other networks.

32 The remaining network in [Table 2-3](#) is the Southeastern Aerosol Research and
33 Characterization network (SEARCH), which is a highly instrumented network of four
34 urban and four rural stations in Alabama, Florida, Georgia, and Mississippi ([Hansen et
35 al., 2003](#)). The four rural SEARCH sites have been used for dry deposition estimates.
36 SEARCH began as a public-private collaboration in early 1998 and has continued

1 operation with several objectives, including understanding processes governing PM_{2.5} and
2 copollutants emissions, transport, and deposition in the southeastern U.S.

3 One additional network that has been identified as potentially suitable for use in future
4 deposition estimates ([Schwede et al., 2011](#)) is the Interagency Monitoring of Protected
5 Visual Environments (IMPROVE) network. The IMPROVE network consists of more
6 than 100 monitoring sites in national parks and other remote locations and is primarily
7 focused on visibility impairment, but has also provided a reliable, long-term record of
8 particulate mass and species components. Several other monitoring networks are operated
9 either by the U.S. EPA or jointly with other federal agencies; species measured and other
10 details for networks making measurements relevant for deposition are shown in [Naess](#)
11 [\(2016\)](#). Even if concentration data from other networks are combined with CASTNET
12 data, large areas of the U.S. are still relatively far away from, or in a different
13 environment than, the nearest monitor.

14 Another deficiency of both the NTN and CASTNET is that not all species that contribute
15 to total sulfur and nitrogen deposition are measured. Reliable measurements of NO_Y and
16 NO₂ concentrations, especially at the low concentrations observed in many areas far from
17 sources, are crucial for evaluating the performance of three-dimensional, chemical
18 transport models of oxidant and acid production in the atmosphere. To meet this need,
19 NO_Y monitors have been installed at six sites in CASTNET as part of the NCore
20 program. At most sites, however, NO₂ is not currently monitored in CASTNET. The
21 same is true for HNO₂ and peroxyacyl nitrates, which can also contribute significantly to
22 total gas-phase reactive nitrogen. These species can be important contributors to N
23 deposition locally, especially near populated areas. Neither the NTN nor CASTNET
24 monitor reduced organic nitrogen compounds, which can also contribute significantly to
25 N deposition (see [Appendix 2.3.4](#)). The sparse geographic coverage and lack of
26 measurements for key species in these networks along with the awareness of modeling
27 uncertainties led to the initiation of the Total Deposition Science Committee (TDEP)
28 ([NADP, 2016](#)) to develop hybrid approaches to improve estimates of atmospheric
29 deposition. The TDEP approach is described in [Appendix 2.6](#).

2.4.2. NO₂, NO_X, and NO_Y

2.4.2.1. Network Monitoring

30 As described in [Appendix 2.4.1](#), a nationwide monitoring network is in place for routine
31 monitoring of NO₂, and NO_Y is measured in the nationwide NCore network. NO₂ is
32 routinely measured using the FRM chemiluminescence method based on the catalytic

1 reduction of NO₂ to NO, followed by reaction NO with O₃. However, the reduction of
2 NO₂ to NO on the MoO_x catalyst substrate also reduces other oxidized nitrogen
3 compounds (i.e., NO_Z compounds shown in the outer box of [Figure 2-3](#)) to NO. This
4 interference by NO_Z compounds has long been recognized following [Winer et al. \(1974\)](#)
5 who found NO was also produced by catalytic reduction of HNO₃, PAN, and organic
6 nitrates using this method. As a result of their experiments, [Winer et al. \(1974\)](#) concluded
7 that, “the NO_x mode of commercial chemiluminescent analyzers must be viewed to a
8 good approximation as measuring *total* gas-phase ‘oxides of nitrogen,’ not simply the
9 sum of NO and NO₂.” Numerous later studies, as noted in the ISA for Oxides of Nitrogen
10 ([U.S. EPA, 2016f](#)), have confirmed this conclusion. Further details were also described in
11 the 2008 ISA ([U.S. EPA, 2008a](#)).

12 Commercially available NO_x monitors have been converted to NO_y monitors by moving
13 the molybdenum oxide catalyst substrate to interface directly with the sample inlet to
14 improve the efficiency of reduction of NO_Z compounds susceptible to loss on inlet
15 surfaces. NO_x concentrations cannot be considered as a universal surrogate for NO_y.
16 However, near sources of fresh combustion emissions, such as highways, most of the
17 NO_y is present as NO_x. To the extent that all the major oxidized nitrogen species can be
18 reduced quantitatively to NO, measurements of NO_y concentrations should be more
19 reliable than those for NO_x concentrations, particularly at typical ambient levels of NO₂.
20 Exceptions might apply in locations near NO_x sources, where NO_x measurements are
21 likely to be less biased and confidence in measurement accuracy increases.

2.4.2.2. Remote Sensing

22 Satellite-based methods have also been used to measure NO₂. Remote sensing by
23 satellites is especially useful in areas where surface monitors are sparse. Retrieving NO₂
24 column abundances from satellite data typically involves three steps: (1) determining the
25 total NO₂ integrated line-of-sight (slant) abundance by spectral fitting of measurements
26 of backscattered solar radiation, (2) removing the stratospheric contribution by using data
27 from remote regions where the tropospheric column abundance is small, and (3) applying
28 an air mass factor to convert tropospheric slant columns into vertical columns. The
29 retrieval uncertainty is largely determined by steps 1 and 2 over remote regions where
30 there is little tropospheric NO₂, and by step 3, over regions of elevated tropospheric NO₂
31 ([Boersma et al., 2004](#); [Martin et al., 2002](#)). Satellite retrievals are largely limited to cloud
32 fractions <20%. A hybrid approach using data for NO₂ tropospheric column abundances
33 obtained by the Ozone Monitoring Instrument (OMI) on the Aura satellite coupled with
34 results from the GEOS-Chem, global-scale, three-dimensional, chemistry-transport model
35 has been developed by [Lamsal et al. \(2008\)](#) with updates by [Lamsal et al. \(2010\)](#). In this

1 approach, the surface mixing ratio divided by the column abundances calculated by the
2 GEOS-Chem model are used as the scaling factors to derive surface mixing ratios from
3 satellite-measured column abundances. This method provides estimates of surface NO₂
4 concentrations that are especially useful in data-sparse regions. The algorithm used to
5 derive the tropospheric columns of NO₂ is given in [Bucsela et al. \(2013\)](#). Note that this
6 algorithm was recently shown to produce NO₂ column abundances that are too high by
7 ~20% ([Marchenko et al., 2015](#)).

2.4.2.3. Research and Nonroutine Methods

8 Alternatively, multiple methods for observing components of NO_y have been developed
9 and evaluated in some detail. As a result of these methods, as applied in the field and the
10 laboratory, knowledge of the chemistry of odd-N species has evolved rapidly. Recent
11 evaluations of methods can be found in [Arnold et al. \(2007\)](#) for HNO₃; [Wooldridge et al.](#)
12 [\(2010\)](#) for speciated PANs; and [Pinto et al. \(2014\)](#) for HONO. However, it is worth
13 reiterating that the direct measurements of NO are still the most reliable of all.

2.4.3. Ammonia

2.4.3.1. Network Monitoring

14 The recently implemented AMoN for monitoring ammonia was described in
15 [Appendix 2.4.1](#). The passive sampling method relies on diffusion across a membrane
16 onto an absorbing substrate, which for NH₃ is H₃PO₃. The sampling period in AMoN is
17 2 weeks. [Puchalski et al. \(2011\)](#) compared the results from three passive samplers with
18 annular denuder systems (taken to be the reference method). The median relative
19 percentage difference between the Radiello passive samplers and the denuder systems
20 was -37% and the coefficient of variation among triplicate Radiello samplers was 10%.
21 [Puchalski et al. \(2015\)](#) further compared 2-week samples collected at five sites over the
22 course of a year by Radiello passive samplers with collocated annular denuder systems
23 (ADS) with different configurations. The mean relative percentage difference between
24 the ADS and AMoN samplers was -9% to be compared to a precision of 5% for both the
25 ADS and AMoN samplers.

2.4.3.2. Remote Sensing

1 In addition to these in situ techniques, remote sensing techniques have also been used to
2 measure NH₃. The Tropospheric Emission Spectrometer (TES) on the Aura satellite
3 [[Shephard et al. \(2011\)](#)], and references therein; [[Beer et al., 2008](#)] and the Infrared
4 Atmospheric Sounding Interferometer (IASI) on the MetOp-A satellite ([Van Damme et
5 al., 2014](#)) measured spectral features in the ν₂ vibrational band centered at around
6 950/cm (the so-called atmospheric window in the infrared). Operating specifications for
7 TES (spectral resolution, 0.06/cm; footprint 5.3 × 8.3 km²; 0.15–0.20 K noise) are
8 generally better than for IASI (spectral resolution, 0.50/cm; footprint 12 × 12 km²;
9 0.15–0.20 K noise). Although TES has higher spectral resolution, it has less dense spatial
10 coverage. Unlike satellite detection of atmospheric molecules by backscattered solar
11 radiation (e.g., NO₂ and SO₂), NH₃ is detected in the thermal infrared spectral range, so
12 data for both day and night can be obtained (satellite overpasses at the Equator at
13 approximately 1:30 a.m. and 1:30 p.m. for TES and 9:30 a.m. and 9:30 p.m. for IASI).
14 The sensitivity of the IR sounding technique for NH₃ increases with the thermal contrast
15 between the surface and the temperature of the air in the lower troposphere, and thus the
16 daytime crossing allows for increased detectability of NH₃ ([Clarisse et al., 2010](#)). NH₃ is
17 confined largely to the planetary boundary layer (PBL), with much lower concentrations
18 aloft in the free troposphere. TES retrievals are most sensitive to NH₃ at atmospheric
19 pressures between 700 and 900 hPa. The TES level of detectability for NH₃ is given by a
20 profile with a peak concentration of 1 ppbv, or equivalently a constant mixing ratio of
21 0.4 ppbv distributed over the pressure range of maximum sensitivity, provided there is
22 substantial thermal contrast.

23 [Pinder et al. \(2011\)](#) found that TES retrievals of NH₃ in the PBL captured the spatial and
24 seasonal variability of NH₃ over eastern North Carolina measured by surface
25 observations. Similarly, [Sun et al. \(2015a\)](#) found that column abundances measured by
26 TES over the San Joaquin Valley agreed with those measured by upward looking
27 instruments at the surface to within 2% and to within 6% for aircraft measurements. TES
28 columns were also shown to be reasonably well correlated ($R^2 = 0.67$) with median NH₃
29 measured at the surface by quantum cascade laser, thereby demonstrating the ability of
30 the satellite-based measurements to capture spatial variability in NH₃ between individual
31 pixels.

32 [Alvarado et al. \(2011\)](#) derived emissions factors for NH₃ in biomass burning plumes over
33 Canada using data from TES. Using data from IASI [R'Honi et al. \(2013\)](#) found total
34 column abundances for NH₃ in the plumes of Russian wildfires during the summer of
35 2010 that were two orders of magnitude larger than background values.

2.4.3.3. Research and Nonroutine Methods

1 Ambient instruments with much higher time resolution were compared by [Schwab et al.](#)
2 [\(2007\)](#) and [von Bobruzki et al. \(2010\)](#). [Schwab et al. \(2007\)](#) conducted a
3 laboratory-based intercomparison of ambient NH₃ instruments with seven instruments
4 using six methods sampling from a common manifold, including tunable diode laser
5 (TDLAS) absorption spectrometer, wet scrubbing long-path absorption photometer
6 (LOPAP), wet effusive diffusion denuder (WEDD), ion mobility spectrometer (IMS),
7 Nitrolux laser acousto-optical absorption analyzer, and a modified CL analyzer. [Schwab](#)
8 [et al. \(2007\)](#) reported that all instruments agreed to within ~25% of the expected
9 calibration value, with the exception of the CL analyzer which suffered from problems
10 related to its MoO_x conversion of NO_z to NO.

11 [von Bobruzki et al. \(2010\)](#) conducted a field intercomparison of ambient NH₃
12 measurements with 11 instruments using 8 methods including: 3 wet techniques (annular
13 rotating batch denuders, 1 with offline analysis and 2 with online analysis [AMANDA,
14 AiRRmonia]), 2 Quantum Cascade Laser Absorption Spectrometers (c-QCLAS,
15 DUAL-QCLAS), 2 photo-acoustic spectrometers, a cavity ring down spectrometer, a
16 chemical ionization mass spectrometer, an ion mobility spectrometer, and an open-path
17 Fourier transform infrared spectrometer. This study was unique in that the surrounding
18 field was fertilized with urea halfway through the campaign to increase average
19 concentrations of NH₃ from 10 to 100 ppb. Overall, R^2 was >0.84 with respect to the
20 ensemble mean for all instruments over the entire range of concentrations (<120 ppb),
21 with slopes ranging from 0.67 to 1.13. Higher variability was found at lower
22 concentrations (<10 ppb) with $R^2 > 0.52$ and slopes ranging from 0.42 to 1.15. Perhaps
23 the most consistent agreement between two instruments was found for the c-QCLAS and
24 AiRRmonia ($R^2 = 0.91$, slope = 0.86, intercept = 0.84 ppb for NH₃ <10 ppb; and
25 $R^2 = 0.91$, slope = 0.83, intercept = 0.34 ppb over the entire range of NH₃ concentrations).

26 Nitrolux-100 denuders were used both in the intercomparison study of [von Bobruzki et](#)
27 [al. \(2010\)](#) and in the one by [Puchalski et al. \(2011\)](#). Compared to the ensemble mean, the
28 slope was 0.97, the intercept was 1.86 ppb, and $R^2 = 0.98$ over the entire concentration
29 range. As noted by [von Bobruzki et al. \(2010\)](#), comparisons of this sort only show
30 relative performance of the instruments and not a functional relationship to a standard.

2.4.4. Sulfur Dioxide

2.4.4.1. Network Monitoring

1 In the nationwide monitoring network for SO₂, SO₂ is routinely measured by pulsed UV
2 fluorescence. This technique is a Federal Equivalence Method (FEM). The method's
3 principles and potential interferences have been described in detail in the 2008 ISA ([U.S.
4 EPA, 2008a](#)). However, measurements using this method are not as widely used as
5 measurements from the CASTNET. In the CASTNET, SO₂ is collected by capturing it on
6 filters and measured as sulfate following procedures described in [Appendix 2.4.5](#).

2.4.4.2. Remote Sensing

7 In addition to the above in situ methods, satellite-based measurements have also been
8 used to measure tropospheric SO₂ and to infer surface SO₂ concentrations with the aid of
9 the GEOS-Chem chemistry-transport model ([Nowlan et al., 2014](#); [Lee et al., 2011](#)).
10 Tropospheric column abundances of SO₂ are obtained by the Ozone Monitoring
11 Instrument (OMI) on the Aura satellite or the Scanning Imaging Absorption Spectrometer
12 for Atmospheric Cartography (SCIAMACHY) on Envisat and are combined with results
13 from the GEOS-Chem, global-scale, three-dimensional, chemistry-transport model to
14 derive surface concentrations of SO₂ (as they are for NO₂). [Lee et al. \(2011\)](#) associated
15 annual mean surface mixing ratios of SO₂ derived from the hybrid satellite/model
16 technique with ambient measurements of SO₂, ($R^2 = 0.66$ and 0.74 , slope = 0.70 and 0.93 ,
17 $n = 121$ and 115 , for OMI and SCIAMACHY, respectively).

18 The algorithms used to derive vertically integrated SO₂ abundances in the troposphere
19 undergo continuing refinement. For example, [Theys et al. \(2015\)](#) applied an algorithm
20 based on differential optical absorption spectroscopy ([Platt and Stutz, 2008](#)) combined
21 with a radiative transfer model. [Li et al. \(2013\)](#) developed an algorithm based on
22 principal components analysis, which has replaced the earlier standard algorithm
23 developed by [Krotkov et al. \(2008\)](#). The methods applied by [Theys et al. \(2015\)](#) and [Li et
24 al. \(2013\)](#) are designed to be operational for retrieving SO₂ in the PBL with an estimated
25 detection limit of ~0.5 Dobson units ($1 \text{ DU} = 2.69 \times 10^{16} \text{ molec/cm}^2$ corresponding to a
26 concentration of ~3 ppb if SO₂ is well mixed in a 2-km-deep mixed layer), or about half
27 that in the older standard method. [Table 2-4](#) summarizes sources of uncertainty for
28 individual OMI measurements of NO₂ and SO₂.

Table 2-4 Sources of uncertainty for individual Ozone Monitoring Instrument measurements in the study of [Nowlan et al. \(2014\)](#).

Source	NO ₂	SO ₂
OMI fitting error	~10 ¹⁵ molec/cm ²	~10 ¹⁶ molec/cm ²
Air mass factor	20%	15–45%
Stratospheric correction	2 × 10 ¹⁴ molec/cm ²	N/A
SO ₂ offset correction	N/A	2 × 10 ¹⁴ molec/cm ²
Profile shape	30%	10%

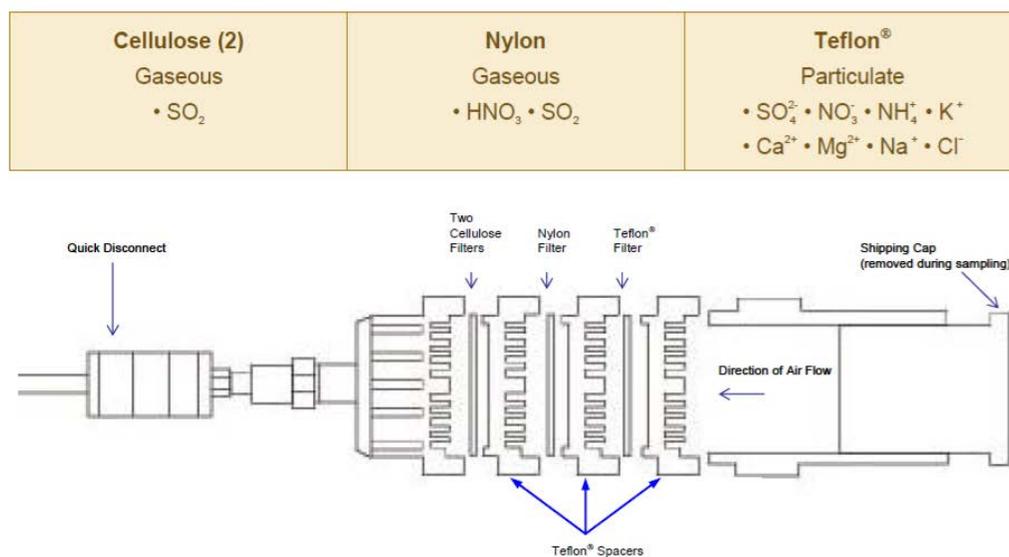

molec = molecules; N/A = not applicable; NO₂ = nitrogen dioxide; OMI = Ozone Monitoring Instrument; SO₂ = sulfur dioxide.
 Source: [Nowlan et al. \(2014\)](#).

1 The errors in the column measurements result mainly from uncertainties in the vertical
 2 profiles of NO₂ and SO₂, cloud fraction, cloud pressure, surface reflectivity, and particles
 3 used in the calculation of air mass factor. A correction is required to account for NO₂ in
 4 the stratosphere (produced from N₂O oxidation and cosmic ray interactions dissociating
 5 with N₂). The SO₂ offset correction refers to a global background correction arising from
 6 issues in spectral fitting, such as spectral correlations with O₃ and stray light within the
 7 instrument.

2.4.5. Filter-Based Concentration Measurements

8 As described in [Appendix 2.4.1](#), most measurements used for estimating deposition are
 9 from CASTNET, rather than from monitoring networks based on FRM and FEM
 10 methods. The CASTNET filter pack is shown in [Figure 2-6](#). Particulate matter is
 11 collected on the open-face Teflon filter, extracted in deionized water, and analyzed by ion
 12 chromatography (IC) for sulfate, nitrate, ammonium, and other species identified in
 13 [Figure 2-6](#). In the CASTNET filter pack, gases are collected downstream of the
 14 particulate species, with nitric acid collected on nylon filters and analyzed as NO₃⁻ by ion
 15 chromatography, and SO₂ on carbonate impregnated cellulose filters and analyzed as
 16 SO₄²⁻ by ion chromatography. Extensive intercomparisons of CASTNET methods with
 17 other measurement methods were described in the 2008 ISA ([U.S. EPA, 2008a](#)).

Figure I-4 Three-Stage Filter Pack

Ca²⁺ = calcium ion; Cl⁻ = chloride; HNO₃ = nitric acid; K⁺ = potassium ion; Mg²⁺ = magnesium ion; Na⁺ = sodium ion; NH₄⁺ = ammonium; NO₃⁻ = nitrate; SO₂ = sulfur dioxide; SO₄²⁻ = sulfate.

Air flows from right to left.

Source: [MACTEC \(2010\)](#).

Figure 2-6 Clean Air Status and Trends Network filter pack.

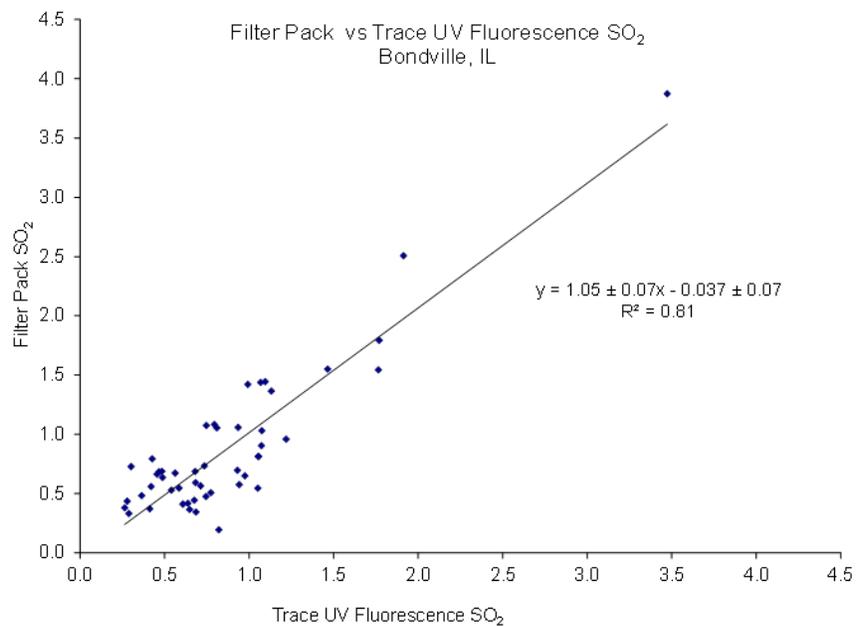

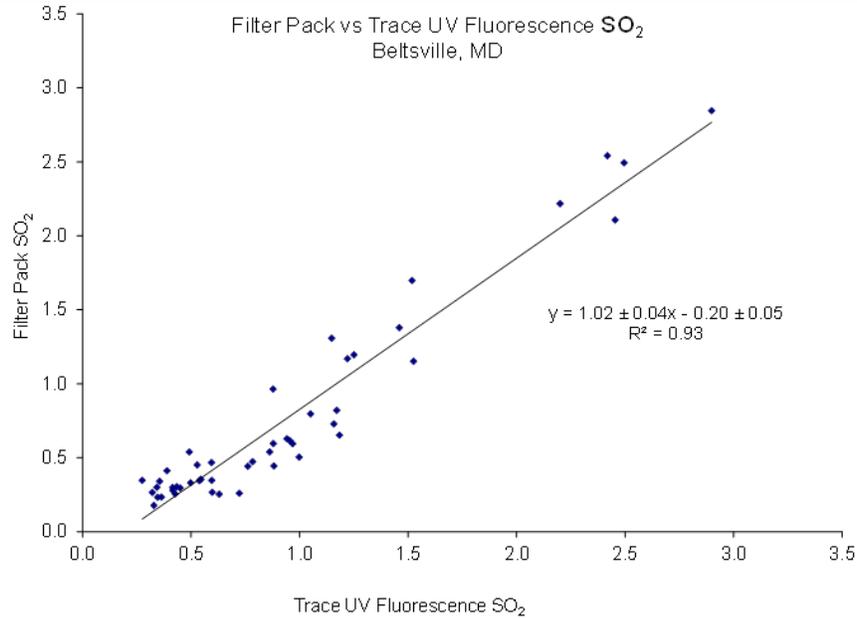

1 As can be seen in [Figure 2-6](#), SO₂ is measured by the CASTNET filter pack by IC
2 analysis of extracts from the cellulose filters. Because the nylon filter adsorbs some of the
3 SO₂ ([Sickles et al., 1999](#); [Sickles and Hodson, 1999](#)), SO₄²⁻ is also measured on nylon
4 and added to the SO₂ (expressed as SO₄²⁻) collected on the backup cellulose-fiber filters.

5 Uncertainties in CASTNET data are reported quarterly in a quality assurance report ([U.S.](#)
6 [EPA, 2016c](#)). Precision is determined as the absolute value of quarterly or annually
7 aggregated relative percentage difference for duplicate sample pairs collected with
8 collocated samplers at two sites. Data quality objectives for ammonium, nitrate, and
9 sulfate are within 20%, but reported precision for 2016 was well under this target, 2–5%
10 for sulfate, 5–13% for nitrate, and 2–6% for ammonium, where the range reflects that
11 there are two sites. Analytical accuracy was reported within 2% based on spiked
12 calibration verification samples. Further detail on uncertainty and data quality can be
13 found in ([U.S. EPA, 2016c](#)). Additional unknown uncertainty is associated with
14 volatilization of NH₄⁺ from collected PM. Substantial loss during sampling can occur
15 because collected NH₄NO₃ in PM is in a temperature dependent equilibrium with NH₃
16 and HNO₃ (see [Appendix 2.3.3](#)), leading to volatilization of both species after PM

1 collection. Loss of NH_4^+ during sampling was thoroughly reviewed in the 2008 ISA ([U.S.](#)
2 [EPA, 2008a](#)).

3 Results of an intercomparison of weekly average SO_2 data (ppbv) collected by the
4 CASTNET filter pack and trace level SO_2 monitors during all of 2014 at Bondville, IL
5 and Beltsville, MD are shown in [Figure 2-7](#) ([AMEC Environment & Infrastructure,](#)
6 [2015](#)).

7 In addition to CASTNET, pSO_4^{2-} , pNO_3^- are monitored in the Chemical Speciation
8 Network (CSN), and the Interagency Monitoring of Protected Visual Environments
9 (IMPROVE) network. Sampling and measurement methods for these networks were
10 described in detail by [Solomon et al. \(2014\)](#). In the CSN network, pNH_4^+ is also
11 measured, but as for CASTNet, it may be subject to volatilization error (volatilization of
12 NO_3^- is corrected).

SO₂ = sulfur dioxide; UV = ultraviolet.

Results for Beltsville, MD are shown in the upper panel and results for Bondville, IL are shown in the lower panel.

Figure 2-7 Comparison between weekly average measurements of sulfur dioxide using the Clean Air Status and Trends Network filter pack and the trace ultraviolet pulsed fluorescence monitor in 2014.

2.4.6. Deposition Measurements

1 Wet deposition is estimated as the product of pollutant concentration in precipitation and
2 precipitation depth (e.g., in rain or snow; see [Appendix 2.4.1](#)). Concentration in
3 precipitation is currently measured by the National Atmospheric Deposition
4 Program/National Trends Network (NADP/NTN) across a national network of sites using
5 a standard precipitation collector described in the 2008 ISA ([U.S. EPA, 2008a](#)).

6 Relatively high confidence has been assigned to wet deposition estimates because of
7 established capabilities for measuring relevant chemical components in precipitation
8 samples ([U.S. EPA, 2011a](#)). Measurement precision determined as the average absolute
9 percentage differences of replicate samples in the 2016 annual quality assurance report
10 was 1% or less for sulfate, nitrate, and ammonium, and absolute percentage difference
11 was no greater than 5% for sulfate and ammonium or 7% for nitrate for any single sample
12 pair ([U.S. EPA, 2016c](#)). Bias determined from internal blind samples was 2% or less for
13 sulfate and nitrate, and 6% or less for ammonium ([U.S. EPA, 2016c](#)).

14 In contrast, direct measurements of dry deposition flux are rare and difficult. Methods for
15 estimating dry deposition from field measurements fall into two major categories: surface
16 analysis methods, which include all types of estimates of contaminant accumulation on
17 surfaces of interest, and atmospheric deposition rate methods, which use measurements
18 of contaminant concentrations in the atmosphere and micrometeorological measurements
19 of atmospheric turbulence ([U.S. EPA, 2008a](#)). Emphasis here is placed on the latter class
20 of methods, which are more widely applicable because the accumulation methods are
21 subject to limitations such as the site specificity of the measurements and the restriction
22 to elements that are largely conserved within the vegetative system. Dry deposition
23 estimates using atmospheric deposition rate methods are based on field measurements of
24 a species or particle concentration gradient along with a measurement or estimate of its
25 turbulent diffusivity under the field conditions of the measurement ([Myles et al., 2012](#);
26 [Businger, 1986](#)). Examples include eddy covariance and aerodynamic gradient
27 techniques ([U.S. EPA, 2008a](#)). In the eddy covariance method, flux is calculated from the
28 covariance between fluctuations in wind velocity and concentration. Historically,
29 empirical estimates of deposition for wind tunnel and field conditions often have not
30 agreed well with theoretical predictions, probably because transport phenomena and
31 turbulence structure near surfaces are not well characterized ([U.S. EPA, 2004](#)). However,
32 improvement of dry deposition measurements is an active research area, both to reduce
33 measurement uncertainties and to improve modeling capabilities by better understanding
34 deposition processes and their parameterization in chemical transport models.

35 Progress in improving measurement capabilities has been triggered by the development
36 of continuous air sampling measurement techniques with higher sensitivity and temporal

1 resolution, with the objective of improving costs and measurement quality using
2 atmospheric deposition rate measurement methods. Concluding that the main reason for
3 the shortage of dry deposition measurements is the expense and complexity of
4 measurement methods, ([Almand-Hunter et al., 2015](#)) tested a dynamic flux chamber
5 using automated, inexpensive multispecies gas flux monitoring system for measurement
6 of a variety of pollutants, including NO_x, that would be needed to contend with the large
7 spatial and temporal variability in air-surface exchange rates of reactive compounds. A
8 dynamic chamber system was also developed to allow measurements of NO, NO₂, and O₃
9 measurements so that compensation points and deposition velocities (see [Appendix 2.5.2](#))
10 could be estimated ([Breuninger et al., 2012](#)).

11 As part of a series of measurements to be tested at several CASTNET sites, [Rumsey and](#)
12 [Walker \(2016\)](#) evaluated the ability of the MARGA 2S (Monitoring for AeRosols and
13 GAses) system to simultaneously measure fluxes of NH₃-HNO₃-NH₄NO₃ using the
14 aerodynamic gradient method to allow for an assessment of the errors due to the
15 instability of the particle phase, as well as SO₂ and SO₄²⁻, to allow for the investigation of
16 ammonium sulfate neutralization and codeposition between SO₂ and NH₃. Over a range
17 of meteorological conditions, median flux uncertainty was found to range from ≈31% for
18 NH₃ to ≈120% for NH₄⁺. The flux gradient technique was also applied to a forest clearing
19 as an example of a complex ecosystem with the objectives of improving deposition rate
20 accuracy and model parameterization for SO₂ ([Myles et al., 2012](#)). Deposition velocities
21 fluctuated considerably with a mean of 1.00 ± 0.48 cm/s, and the large variation was not
22 fully captured by estimates from widely used models ([Myles et al., 2012](#)). Uncertainties
23 in canopy resistance, including stomatal and nonstomatal processes were identified as
24 probable sources of uncertainty ([Myles et al., 2012](#)).

25 This approach has been successfully applied to measurements of a wide variety of
26 species. However, it is less suitable for HNO₃ and NH₃ because they are subject to
27 interactions with inlet surfaces of measuring devices. For example, in one study a
28 correction factor of 1.62 was reported for inlet surface interactions ([Breuninger et al.,](#)
29 [2012](#)). To address the problem of loss of HNO₃, NH₃, and other substances that interact
30 with sampling inlet surfaces during measurement, [Roscioli et al. \(2016\)](#) developed a
31 method to passivate inlet surfaces and thereby overcome this difficulty by allowing for
32 more rapid response measurements. [Min et al. \(2014\)](#) determined the net flux of NO and
33 NO₂ (at a frequency of 5 Hz) over a forest with estimated total systematic uncertainties of
34 <8 and <6%, and random errors of <25 and <21%, respectively.

35 Measurement methods are well developed for ideal conditions of flat, homogeneous, and
36 extensive landscapes and for chemical species for which accurate and rapid sensors are
37 available ([U.S. EPA, 2008a](#)). However, the strong dependence of dry deposition on

1 surface characteristics, which are highly spatially variable, causes in situ measurements
2 to be limited in applicability, especially in areas of high topographic relief
3 [e.g., ([Weathers et al., 2006](#))]. The lifetime in the boundary layer (~1 km depth) for
4 rapidly depositing species is ~1 day, implying that distances from source to deposition
5 are relatively short and that the deposition flux depends strongly on the nature and
6 strength of nearby sources. Deposition also shows strong temporal variability on
7 timescales ranging from diurnal to seasonal, as do wind regimes affecting a particular
8 site. In addition, cost and logistics make the eddy covariance and aerodynamic gradient
9 techniques impractical for monitoring networks.

10 Instead, dry deposition fluxes of gases and particles are estimated in CASTNET and by
11 chemistry-transport models, such as CMAQ, by an inferential technique described in the
12 2008 ISA ([U.S. EPA, 2008a](#)). In the inferential model approach, the deposition of a
13 pollutant is estimated by introducing a resistance component to account for the individual
14 chemical and biological processes that control pollutant adsorption and capture at natural
15 surfaces ([Hicks et al., 1987](#)). Ambient pollutant concentrations of O₃, SO₄²⁻, NO₃⁻, NH₄⁺,
16 SO₂, and HNO₃ are routinely collected at CASTNET dry deposition sites. Deposition
17 velocities based on local meteorological measurements were calculated using the
18 Multi-Layer Model (MLM) at U.S. EPA-sponsored CASTNET sites until 2010, when
19 meteorological measurements were discontinued at all but five U.S. EPA CASTNET
20 sites. Dry deposition fluxes are still reported at sites with discontinued meteorological
21 measurements using historical data. A disadvantage to this approach is that relevant
22 atmospheric species are not routinely measured. For example, NO₂ and peroxyacetyl
23 nitrate, which together consistently contribute 15 to 25% of estimated oxidized nitrogen
24 dry deposition, are not measured at CASTNET sites. Even for those species that are
25 routinely measured, network spatial coverage is sparse ([U.S. EPA, 2011a](#)).

26 Satellite-based measurements offer a potential means of greater coverage, but only a
27 limited number of deposition related applications have been described. ([Nowlan et al.,
28 2014](#)) combined satellite data with modeled NO₂ and SO₂ surfaces and vertically
29 integrated concentrations and deposition velocities to estimate deposition fluxes. SO₂ dry
30 deposition fluxes compared well with surface network based deposition fluxes.
31 Uncertainties in depositional flux estimates in this approach result from the combined
32 uncertainties in the satellite-derived surface concentrations and model-derived deposition
33 velocities and were estimated to be ~30% on average for both NO₂ and SO₂ over land. In
34 the absence of routine measurements, dry deposition is often modeled with CMAQ or
35 other modeling tools using relevant emissions, meteorological, and land use data, rather
36 than estimated from measured concentration measurements ([U.S. EPA, 2011a](#)).

1 Modeling dry deposition is particularly challenging over varying terrain and under
2 extremely stable conditions such as those occurring at night. Under optimal conditions
3 over a relatively small area where dry deposition measurements have been made,
4 uncertainties on the order of $\pm 30\%$ have been reported and larger uncertainties are likely
5 when the surface features in the built environment are not well known or when the
6 surface comprises a patchwork of different surface types, as is common in the eastern
7 U.S. ([U.S. EPA, 2008a](#)). For this reason, dry deposition is routinely estimated from
8 concentration measurements, usually from CASTNET data ([Appendix 2.4.5](#)) using a
9 hybrid approach based on both measured and modeled data ([Appendix 2.6](#)).

2.5. Modeling Chemistry, Transport, and Deposition

10 In this section, advances in modeling transport and deposition of species relevant to acid
11 and nutrient deposition are discussed, along with research progress on understanding
12 underlying transport and deposition processes. The use of chemical transport models
13 (CTMs) to model deposition was discussed extensively in the 2008 ISA ([U.S. EPA,
14 2008a](#)). Relevant new research and improvements in CTM modeling in general are
15 described in [Appendix 2.5.1](#). [Appendix 2.5.2](#) discusses environmental processes relevant
16 to understanding and modeling acid and nutrient deposition. [Appendix 2.5.2.1](#) begins
17 with an overview of fundamental processes of atmospheric deposition of gases and
18 particles, along with deposition velocities for some key gas-phase species. It also contains
19 discussions of research advances in three key processes that serve as major structural
20 uncertainties (lack of knowledge of the underlying science) in modeling deposition: NO_x
21 canopy processes, which involve both bidirectional gas exchange and NO_x chemistry
22 ([Appendix 2.5.2.2](#)); bidirectional exchange of ammonia ([Appendix 2.5.2.3](#)); and
23 transference ratios relating average ambient concentration to deposition flux
24 ([Appendix 2.5.2.4](#)). [Appendix 2.5.3](#) discusses model evaluation and uncertainty,
25 including comparisons between CTM and network-based wet deposition results.

2.5.1. Advances in Chemistry-Transport Model (CTM) Modeling

26 To understand the lifetime and fate of the varied forms of atmospheric sulfur and nitrogen
27 from emission to deposition, it is necessary to account for both atmospheric transport and
28 chemical transformations. CTMs simulate the relevant atmospheric transport processes
29 (e.g., horizontal and vertical advection and diffusion), as well as chemistry, aerosol
30 physics, deposition, and cloud processes. The 2008 ISA ([U.S. EPA, 2008a](#)) provided a
31 detailed description of the CTM models and their application to estimating deposition.
32 Continental-scale CTMs include CMAQ ([Appel et al., 2017](#)) and CAMx ([Koo et al.,](#)

1 [2015](#)), while GEOS-Chem ([Zhang et al., 2012a](#)) is an example of a global-scale model.
2 Most major regional-scale, air-related modeling efforts at U.S. EPA use the Community
3 Multiscale Air Quality (CMAQ) modeling system ([Byun and Schere, 2006](#); [Byun and](#)
4 [Ching, 1999](#)). Recent updates to CTM model design, and in particular to CMAQ, are
5 described here.

6 A number of complex atmospheric processes influence pollutant behavior between
7 emission and deposition and must be taken into account to achieve good model
8 performance. A variety of mechanisms operating over a wide range of spatial and
9 temporal scales transport heat, water, and pollutants horizontally and vertically through
10 the atmosphere. These mechanisms range from local-scale circulations (e.g., urban heat
11 islands) to hemispheric-scale transport by the jet stream. Long-range transport of
12 pollutants in the lower free troposphere associated with large-scale synoptic systems is
13 possible because flows are largely uncoupled from surface friction. Flows in the upper
14 planetary boundary layer (PBL), especially during the day, might not be as effective for
15 transporting pollutants over long distances because air can be mixed down to the surface
16 by turbulence. If these pollutants react with surface material or are taken up by
17 vegetation, they can be removed within a relatively short distance from their sources.

18 In addition to wind velocity, the distance scale for transport of a pollutant that is
19 relatively stable in the troposphere with respect to gas-phase reactions (i.e., chemical
20 lifetime > a few days) depends strongly on the pollutant's interactions with solid and
21 liquid surfaces and subsequent chemical transformations. Because NO and NO₂ are only
22 slightly soluble, they can be transported over longer distances in the gas phase than can
23 more soluble species like HNO₃ (and its anhydride, N₂O₅) and NH₃ that are depleted by
24 deposition to moist surfaces or taken up more readily on aqueous surfaces of particles or
25 on cloud drops. For example, measurements of the ratio of NH₃ to CH₄ in the San
26 Joaquin Valley indicate substantial loss of NH₃ to the surface within a few km of sources
27 of these gases ([Miller et al., 2015](#)), consistent with an NH₃ lifetime of minutes to a few
28 hours in this environment. On the other hand, a combination of models, remote sensing,
29 and in situ measurements over the eastern U.S. indicate an atmospheric lifetime for SO₂
30 of 19 ± 7 hours in summer increasing to 58 ± 20 hours in winter ([Lee et al., 2011](#)), which
31 indicates the potential for much longer-range transport of SO₂.

32 Numerous advances in atmospheric science have been codified in CTMs, including
33 gas-phase oxidant chemistry relevant for the formation of aerosol precursors and dry
34 deposition by gravitational settling ([Nolte et al., 2015](#)), improved representation of
35 meteorological processes in CTMs and interactions with aerosols ([Tuccella et al., 2015](#)),
36 and improved algorithms for understanding the influence of weather on emissions of
37 ammonia from agricultural lands ([Flechar et al., 2013](#)). Over the U.S. and Europe,

1 substantial reductions in sulfur dioxide and nitrogen oxides have created an opportunity
2 to compare the model results with the trends in ambient observations ([Banzhaf et al.,](#)
3 [2015](#); [Xing et al., 2015](#); [Civerolo et al., 2010](#)). Studies have shown that CMAQ is skilled
4 at capturing the seasonal and long-term changes in sulfate PM_{2.5} and nitrate PM_{2.5} as well
5 as total PM_{2.5} mass; however, the model performs less well for seasonal variability in
6 nitrate PM_{2.5}, owing to uncertainties in ammonia emission trends ([Banzhaf et al., 2015](#);
7 [Xing et al., 2015](#)).

2.5.2. Modeling Deposition

2.5.2.1. Wet and Dry Deposition of Gases and Particles

8 Considerable advances in both our understanding of atmospheric deposition and
9 modeling approaches to characterize it have taken place recently. Deposition is a
10 complicated process influenced by numerous atmospheric and deposition surface
11 properties, as well as chemical reactions and other processes that take place within
12 canopies of vegetation.

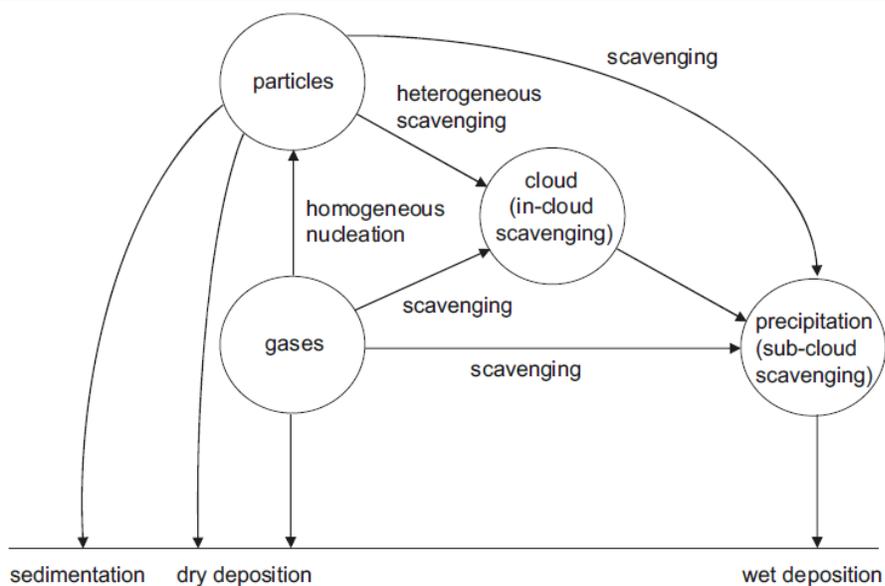

13 In [Figure 2-8, Möller \(2014\)](#) illustrates the pathways that transfer gaseous and particulate
14 pollutants from the atmosphere to the surface by deposition. Wet deposition occurs when
15 particulate and gaseous species are removed by cloud drops or by falling precipitation
16 (washout). Dry deposition occurs when they are removed without precipitation by
17 processes like turbulence and gravitational settling. In mountainous areas, a third
18 important type of deposition occurs, referred to as occult deposition ([Dollard et al.,](#)
19 [1983](#)), which is not shown in [Figure 2-8](#), and results from the impaction of droplets in
20 fogs or clouds on vegetation. Wet deposition is determined as the simple product of
21 concentration in precipitation and precipitation rate. Receptor (i.e., vegetation) surface
22 properties have little effect on wet deposition. Dry deposition is more difficult to
23 determine. It can be described as a flux F_d , the mass of pollutant deposited per unit area
24 of the Earth's surfaces where it deposits, or a deposition velocity that relates the dry
25 deposition flux F_d to a pollutant's ambient concentration:

$$F_d = v_d C$$

Equation 2-12

26 where C is the pollutant's concentration in mass in per unit volume, and v_d is the
27 deposition velocity, which relates a pollutant's deposition flux to its ambient
28 concentration.

1 Dry deposition of gases depends on leaf area, surface resistance to gas uptake,
2 interactions with biota through both stomatal and plant surface pathways, and
3 atmospheric reactivity, which can vary among depositing gases. Measurements of
4 average dry deposition velocities for gases over land surfaces are shown in [Table 2-5](#), and
5 an indication of the seasonal variability of deposition velocities over different land
6 surface types can be seen in [Table 2-6](#), which shows the variability in v_d for SO_2 .
7 Deposition velocities of other species are also expected to be spatially and temporally
8 variable.

Table 2-6 Deposition velocity (cm/s) for sulfur dioxide averaged over different land use types for summer and winter.

	Farmland		Grassland		Dec. Forest		Con. Forest		Urban		Water	
	Su	Wi	Su	Wi	Su	Wi	Su	Wi	Su	Wi	Su	Wi
Wet	1.0	1.0	1.0	1.0	3.0	1.5	2.0	2.0	1.0	1.0	0.5	0.5
Dry	0.7	0.5	0.6	0.4	1.5	0.5	0.7	0.5	0.1	0.1	0.5	0.5
Snow	--	0.	--	0.1	--	0.2	--	0.2	--	0.1	--	0.1

Con. = coniferous; Dec. = deciduous; Su = summer; Wi = winter.

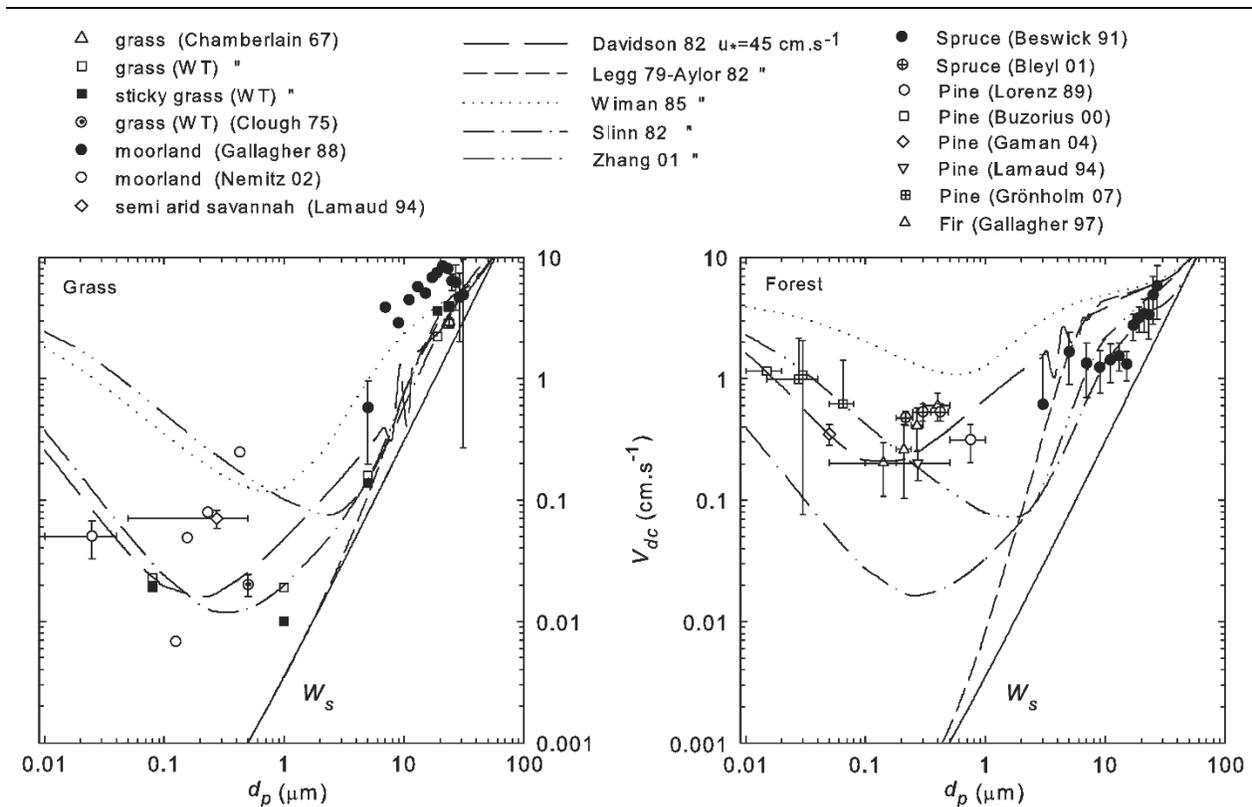

Source: [Möller \(2014\)](#).

1 A wide range of deposition velocities is observed among different atmospheric gas-phase
 2 species. HNO₃ is an example of gas with straightforward deposition behavior. It sticks
 3 easily to vegetative surfaces, i.e., there is a negligible surface resistance to HNO₃ uptake
 4 by vegetation, and its deposition rates are independent of leaf area or stomatal
 5 conductance, implying that deposition occurs to branches, soil, and the leaf cuticle as
 6 well as leaf surfaces. The HNO₃ *v_d* typically exceeds 1 cm/s and exhibits a diel pattern
 7 controlled by turbulence characteristics of midday maxima and lower values at night in
 8 the more stable boundary layer ([U.S. EPA, 2008a, 2004](#)). In contrast, NO₂ interaction
 9 with vegetation is more complicated. The uptake rate by foliage is related to stomatal
 10 conductance and is more variable. It may also be associated with concentrations of
 11 reactive species such as ascorbate in the plant tissue that react with NO₂. At very low
 12 NO₂ concentrations, emission from foliage is observed. Internal NO₂ appears to derive
 13 from plant N metabolism, and there is evidence for a compensation point, typically near

1 ~1 ppb, at which uptake and emission rates are equal and net flux is zero ([U.S. EPA,](#)
2 [2008a](#)).

3 Dry deposition of PM is influenced by a number of variables, including particle diameter,
4 atmospheric stability, deposition surface roughness, and the shape, stickiness, roughness,
5 and cross-sectional area of leaves. Greater roughness and leaf shape complexity increase
6 deposition. The diversity of particle sizes, atmospheric conditions, and surface
7 characteristics makes it difficult to estimate dry deposition ([U.S. EPA, 2008a, 2004](#)). The
8 appreciable effects of particle size, local micrometeorological conditions and surface
9 characteristics on deposition velocity can be seen in [Figure 2-9](#). The key to measurements
10 of v_d over surfaces covered by low vegetation is given in the left column and over forest
11 in the right column. These measurements are compared to six model formulations which
12 are shown as lines in the center column.

13 For particles $>10 \mu\text{m}$, V_d varies between 0.5 and 1.1 cm/s, and a minimum particle V_d of
14 0.03 cm/s exists for particles in the size range 0.1 to 1.0 μm , while deposition of particles
15 from the atmosphere to a forest canopy has been estimated as 2 to 16 times greater than
16 deposition in adjacent open terrain like grasslands or other low vegetation ([U.S. EPA,](#)
17 [2004](#)).

d_p = aerodynamic diameter of particle; V_{dc} = deposition velocity; W_s = Stokes settling velocity.

Notes: (Grönholm et al., 2007; Gaman et al., 2004; Nemitz et al., 2002; Zhang et al., 2001; Buzorius et al., 1998; Gallagher et al., 1997; Lamaud et al., 1994a; Lamaud et al., 1994b; Beswick et al., 1991; Lorenz and Murphy, 1989; Gallagher et al., 1988; Wiman and Ågren, 1985; Aylor, 1982; Davidson et al., 1982; Legg and Powell, 1979; Clough, 1975; Chamberlain, 1967).

Closed symbols correspond to wet or sticky surfaces or liquid particles; open symbols to dry surfaces or solid particles.

Figure 2-9 Modeled and measured deposition velocities over grass (left figure) and coniferous forest canopies (right figure) for particles of density 1 gm/cm^3 depositing under similar friction velocity (u^*) ($35 < u^* < 56 \text{ cm/s}$).

2.5.2.2. NO_x Canopy Processes

1 There are a number of ways that landscape characteristics influence the deposition
 2 process (U.S. EPA, 2008a, 2004). In terrain containing extensive vegetative canopies,
 3 any material deposited via precipitation to the upper stratum of foliage is likely to be
 4 intercepted by several foliar surfaces before reaching the soil. V_d is usually greater for a
 5 forest than for a nonforested area and greater for a field than for a water surface. The
 6 upwind leading edges of forests, hedgerows, and individual plants are primary sites of

1 coarse particle deposition, and upper canopy foliage tends to receive maximum exposure
2 to coarse and fine particles, but foliage within the canopy tends to receive primarily fine
3 particles. ([U.S. EPA, 2008a, 2004](#)). Several N_r species are deposited to vegetation, among
4 them HNO₃, NO₂, PAN (and other RONO₂), and NH₃.

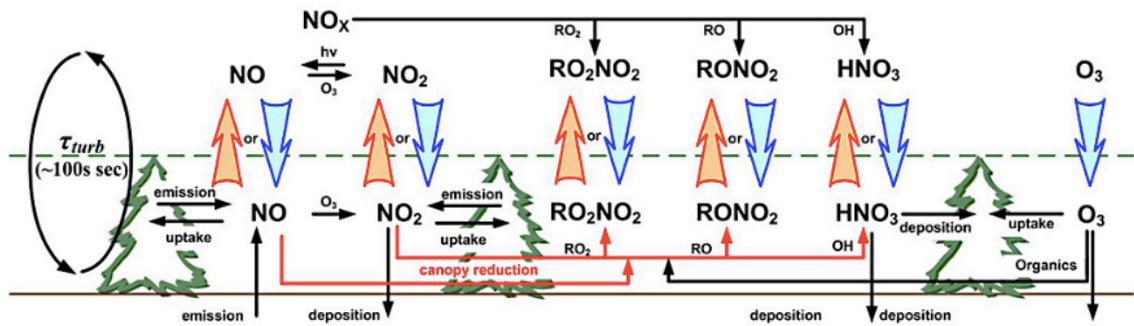

5 Wet, dry, and occult deposition all contribute N and S species to the forest canopy in
6 varying proportions. Deposited species can react on surfaces within the canopy, be taken
7 up by vegetation through stomata, be resuspended during stormy weather, or simply pass
8 through the canopy to the forest floor. Surface characteristics can influence foliar uptake,
9 chemical transformation, and resuspension. Landscape characteristics can affect wet
10 deposition via orographic effects and by the closer aerodynamic coupling to the
11 atmosphere of tall forest canopies as compared to the shorter shrub and herbaceous
12 canopies. The rainwater that passes directly through a canopy or is initially intercepted by
13 aboveground vegetative surfaces and subsequently drips from the canopy is measured as
14 throughfall. The fraction of the precipitation that drains from outlying leaves and
15 branches and is channeled to the stem of plants is classified as stemflow. Throughfall and
16 stemflow inputs constitute the majority of incident precipitation in forests and can
17 account for 70 to 90% of incoming precipitation in most cases, with the remainder lost to
18 interception within the canopy ([Levia and Frost, 2003](#)). Compared to wet deposition
19 measurements in the open, the magnitude of deposition from throughfall and stemflow
20 can either be smaller (e.g., from evaporation from canopy surfaces) or larger (e.g., from
21 resuspension of previously deposited material). The type of vegetation is important for
22 characterizing throughfall. For example, [Templer et al. \(2015a\)](#) found that the cycling of
23 N, particularly the rate of throughfall for NH₄⁺, is significantly different in conifer
24 compared to deciduous forest sites. Rainfall introduces new wet deposition and also
25 redistributes previously dry-deposited particles throughout the canopy. Intense rainfall
26 may contribute substantial total particulate inputs to the soil, but it also removes
27 bioavailable or injurious pollutants from foliar surfaces, while low-intensity events may
28 enhance foliar uptake through the hydrating of some previously dry-deposited particles
29 ([U.S. EPA, 2004](#)).

30 Chemistry within the canopy can also be important. Very fast measurements of NO₂ flux
31 are confounded by the rapid interconversion of NO and NO₂ with O₃, and the biosphere
32 also interacts with NO_x through hydrocarbon emissions and their subsequent reactions to
33 form multifunctional RONO₂, including isoprene nitrates, which can account for a
34 substantial fraction of total N deposition. NO₂ emissions also show UV dependence, and
35 both photo-induced and dark production of HNO₂ from NO₂ have been observed on leaf
36 surfaces, especially wet surfaces, although there is no consensus concerning chemical
37 mechanisms ([U.S. EPA, 2008a](#)). It was recently reported that NO₂ deposition velocities
38 would have been overestimated by up to 80% if NO₂ photolysis had not been considered

1 [\(Breuninger et al., 2012\)](#). Both biotic interactions and reaction chemistry further
2 complicate our understanding of N deposition and our ability to estimate deposition
3 velocity.

4 Some species, most prominently HNO₃, can be characterized by unidirectional exchange,
5 whereas bidirectional exchange is more appropriate for most other species. Bidirectional
6 exchange is often described in terms of a compensation point, defined as the ambient
7 concentration above which a net uptake of the trace gas occurs and below which the trace
8 gas is released ([Ganzeveld et al., 2002](#)). A two-pathway process description can be used
9 to describe bidirectional exchange in a forest canopy [see e.g., ([Fowler et al., 2009](#);
10 [Loubet et al., 2001](#)): (1) a stomatal pathway, which is bidirectional and modeled using a
11 stomatal compensation point and (2) a plant surface pathway, which denotes exchange
12 with water or waxes on the plant surface.

13 Understanding the exchange of reactive nitrogen species in the forest canopy has always
14 been challenging. One of the most comprehensive studies focusing on this question has
15 been the Biosphere Effects on AeRosols and Photochemistry Experiment (BEARPEX)
16 conducted in 2009 ([Min et al., 2014](#)) that examined fluxes and transformations of NO_x
17 within a forest canopy on the western slope of the Sierra Madre Range in 2009. The
18 study's results, shown schematically in [Figure 2-10](#), indicate the existence of active
19 chemical interactions within the forest canopy in which NO emitted from soil or
20 transported from elsewhere is oxidized to NO₂ and then to peroxy and alkyl nitrates and
21 HNO₃. These pathways represent alternative mechanisms to plant uptake that have the
22 net effect of reducing the soil NO that escapes the forest canopy as NO_x is converted to
23 peroxy nitrates and alkyl nitrates that can be transported to the atmosphere above the
24 canopy on very short time scales (~100s of seconds). The fraction of NO emitted by soil
25 that can be lost to the atmosphere above the canopy depends on the relative time scales
26 for transport through the canopy versus chemical transformation and foliar uptake.
27 Likewise, NO or NO₂ transported from elsewhere can also be oxidized to organic nitrates
28 within the canopy. The organic nitrates formed can either be taken up within the canopy
29 or transported upward through the forest canopy to act as reservoirs of NO_x that can
30 reform downwind.

HNO₃ = nitric acid; hv = solar photon; OH = hydroxyl radical; NO = nitric oxide; NO₂ = nitrogen dioxide; NO_x = sum of NO and NO₂; O₃ = ozone; RO = alkoxy radicals; RO₂ = organic peroxy radicals; RONO₂ = alkyl nitrates; RO₂NO₂ = peroxy nitrates.

Bold arrows in blue (downward) and red (upward) represent the direction of the flux of each species across the canopy surface. Red thin arrows within canopy indicate the nitrogen oxides removal processes within the canopy in addition to plant uptake.

Source: [Min et al. \(2014\)](#).

Figure 2-10 Schematic of the interactions involved in the exchange of nitrogen oxides between the atmosphere and the forest canopy as identified by [Min et al. \(2014\)](#).

1 The organic nitrates consist in large measure of isoprene- and monoterpene-derived
 2 nitrates. [Nguyen et al. \(2015\)](#) measured fluxes of organic nitrates on a tall tower in the
 3 Talladega National Forest (AL) in June 2013 as part of the Southern Oxidant and Aerosol
 4 Study (SOAS). They found that fluxes of organic nitrogen formed by reactions of
 5 nitrogen oxides (NO, NO₂, NO₃) with isoprene and monoterpene oxidation products
 6 constituted ~15% of the flux of oxidized N to the forest canopy, with most of the rest
 7 from HNO₃.

2.5.2.3. Bidirectional Exchange of NH₃

8 NH₃ can also be both emitted and deposited from plants and soils in a bidirectional
 9 exchange. [Farquhar et al. \(1980\)](#) observed the existence of a compensation point for
 10 ammonia due to gas exchange through the stomata of leaves. NH₃ in the stomata results
 11 from dissociation equilibria of NH₄⁺ produced physiologically in the leaves, followed by
 12 equilibrium partitioning into air in the stomata ([Sutton et al., 1998](#)). Further research
 13 indicated that NH₃ deposition rates to leaf surfaces were often faster than stomatal uptake
 14 ([Sutton et al., 1993](#)) and that NH₃ can both react to form particulate NH₄⁺ and evaporate
 15 from deposited PM within the canopy ([Nemitz et al., 2004](#); [Brost et al., 1988](#)). Moisture
 16 and plant type are strong influences, because deposition is more efficient on wet surfaces
 17 ([Sutton et al., 1995](#)), evaporation occurs under drying conditions ([Fowler et al., 2009](#)),

1 and plant emissions are controlled by the physiological importance of NH_4^+ in
2 intercellular fluids of plants ([Sutton et al., 1998](#)). Copollutants also play a role because
3 NH_3 deposition is enhanced by the presence of atmospheric acids like SO_2 ([Sutton et al.,](#)
4 [1995](#); [McLeod et al., 1990](#)).

5 The complex pattern of NH_3 sources and sinks with strong horizontal gradients of NH_3
6 concentration ([Fowler et al., 2009](#)) presents problems for simple bidirectional exchange
7 models ([Sutton et al., 1998](#)). These problems have been addressed through the concept of
8 a canopy compensation point to include exchange with leaf surfaces ([Flechard et al.,](#)
9 [1999](#); [Sutton et al., 1998](#)), as well as decomposing leaf litter and soil surfaces ([Nemitz,](#)
10 [2000](#)) in addition to stomatal exchange to describe bidirectional exchange ([Burkhardt et](#)
11 [al., 2008](#); [Sutton et al., 1998](#)). Emission flux is particularly high from recently fertilized
12 soils ([Fowler et al., 2009](#); [Sutton et al., 1998](#)) and after leaf-cutting events ([Nemitz et al.,](#)
13 [2009](#)).

14 According to the 2008 ISA ([U.S. EPA, 2008a](#)), large areas of the U.S. are very near the
15 NH_3 compensation point for most of the year, resulting in a highly dynamic air-surface
16 flux, which is prone to shifts in magnitude and direction. Bidirectional NH_3 fluxes with
17 some periods of deposition and some periods of emission are typical for fertilized and
18 grazed agricultural ecosystems, while forests and other unfertilized ecosystems are
19 usually sinks for NH_3 ([Fowler et al., 2009](#)). Smaller emissions can also occur in semi
20 natural ecosystems ([Fowler et al., 2009](#)).

21 Recently, regional scale modeling studies began to include canopy compensation points
22 and parameterize bidirectional exchange ([Dennis et al., 2010](#); [Kruit et al., 2010](#)), and a
23 bidirectional exchange model for NH_3 based on observations from North Carolina field
24 sites ([Walker et al., 2013](#)) was developed for the CMAQ modeling system and an
25 agroecosystem model was included in CMAQ Version 5.0 to estimate NH_3 emissions,
26 transport, and deposition from agricultural practices ([Bash et al., 2013](#)). Including
27 bidirectional exchange in deposition modeling substantially improves agreement between
28 modeling results and ambient observations. A large bias of -19% has been observed in
29 annual wet deposition of NH_4^+ when modeling results were compared with ambient
30 measurements without bidirectional exchange included in the model ([Appel et al., 2011](#)).
31 NH_4^+ was underestimated throughout the year, but the largest underestimations were for
32 winter and spring in the Eastern U.S. ([Appel et al., 2011](#)). The NH_4^+ wet deposition bias
33 was reduced by a factor 3, from -19 to -6% , by including bidirectional exchange in
34 CMAQ ([Appel et al., 2011](#)).

35 Poor temporal and spatial representation of NH_3 emissions in areas with fertilizer
36 application was also identified as a source of bias ([Appel et al., 2011](#)). When CMAQ was
37 coupled with the U.S. Department of Agriculture's (USDA) Environmental Policy

1 Integrated Climate (EPIC) agroecosystem model to improve characterization of fertilizer
2 emissions in annual simulations, NH₃ dry deposition decreased by 45%, total NH_x
3 deposition decreased by 15%, and total N deposition decreased by 5% compared to
4 modeling without bidirectional exchange ([Bash et al., 2013](#)). In sensitivity tests of key
5 parameters in dry deposition modeling, the largest uncertainty was observed for the
6 change of unidirectional to bidirectional flux, but uncertainties of 5% or less in total
7 nitrogen deposition were reported ([Dennis et al., 2013](#)). Although this is a small
8 difference nationwide, changes can locally be up to 50%, and only 66% of the 12 × 12
9 grid cells modeled showed changes of less than 10% ([Dennis et al., 2013](#)).

10 Recent modeling studies have also improved insight into local areas and conditions under
11 which bidirectional flux most strongly affects deposition estimates. For example,
12 accounting for bidirectional flux resulted in a 17% increase in NH₃ emissions from
13 agricultural operations ([Massad et al., 2010](#)) compared with a 5% increase in
14 domain-wide NH₃ emissions ([Dennis et al., 2013](#)). Increases in NH₃ emissions from
15 including bidirectional flux in semi natural ecosystems mostly occurred in areas of the
16 western U.S. with low emissions, where emissions were not included in existing
17 inventories. Seminal ecosystems in the eastern U.S. isolated from agricultural
18 emissions exhibited changes of less than 1%. Seasonal differences were also observed,
19 with greater NH₃ emissions observed in summer and winter, but emissions up to 45%
20 lower in fall and in spring when bidirectional exchange was included ([Bash et al., 2013](#)).

2.5.2.4. Transference Ratios

21 Ratios of modeled or measured concentrations of SO_x and NO_y to their deposition, or
22 transference ratios (TR_{SO_x}, TR_{NO_y}) were proposed by [Scheffe et al. \(2011\)](#) as a means to
23 link ambient air quality to deposition, and can be extended to NH_x Transference ratios for
24 NO_y, SO_x, and NH_x are given by:

- 25 • TR_{NO_y} = (annual wet + dry deposition of NO_y)/annual average ambient
26 concentration of NO_y
- 27 • TR_{SO_x} = (annual wet + dry deposition of SO_x)/annual average ambient
28 concentration of SO_x
- 29 • TR_{NH_x} = (annual wet + dry deposition of NH_x)/annual average ambient
30 concentration of NH_x

31 These ratios are expressed in units of distance/time (as a velocity). In the 2011 Policy
32 Analysis for the NO_x/SO_x NAAQS review ([U.S. EPA, 2011a](#)), the transference ratios
33 were multiplied by measured ambient concentrations of NO_y and SO_x to estimate a flux.

1 The transference ratio is an aggregate of multiple forms of nitrogen or sulfur. For
2 example, the transference ratio for NO_Y includes NO_2 and HNO_3 , which have very
3 different deposition rates, chemical reaction rates, and atmospheric lifetimes. Close to
4 emission sources where fresh NO_X emissions have had little time to react, the ratio of
5 HNO_3 to NO_2 is smaller than farther from emission sources. Accordingly, there is
6 considerable spatial and temporal variability ([Sickles et al., 2013](#)) in transference ratios,
7 in part governed by the relative abundance of compounds with short and relatively longer
8 atmospheric lifetimes.

9 In practice, a regional modeling approach using a modeling system such as CMAQ or
10 CAMx is used in the calculation of transference ratios by simulating the relevant
11 transport processes discussed in [Appendix 2.5.1](#). [Sickles and Shadwick \(2013\)](#) estimated
12 that TR_{SO_X} and TR_{NO_Y} could be given to within 25–35% of observed values using
13 observations of atmospheric concentration and deposition at some monitoring sites in the
14 eastern U.S. The study noted that accounting for year-to-year variability in precipitation
15 could lower the uncertainty. The transport processes described in [Appendix 2.5.1](#) imply
16 that wet deposition should not necessarily be well correlated with surface concentrations
17 due to differences in the direction or spatial extent of transport in the boundary layer
18 compared to cloud levels. Dry deposition fluxes are more directly related to surface
19 concentrations. In a follow-on study, [Sickles et al. \(2013\)](#) calculated transference ratios
20 using measurements from CASTNET and NADP monitoring networks with CMAQ
21 model results and found the relative difference ranged from –37 to 64%. The authors
22 caution that this range should not be considered a definitive assessment of uncertainty
23 because relative differences do not reflect the extent to which the monitor is
24 representative of the grid-cell average modeled by CMAQ.

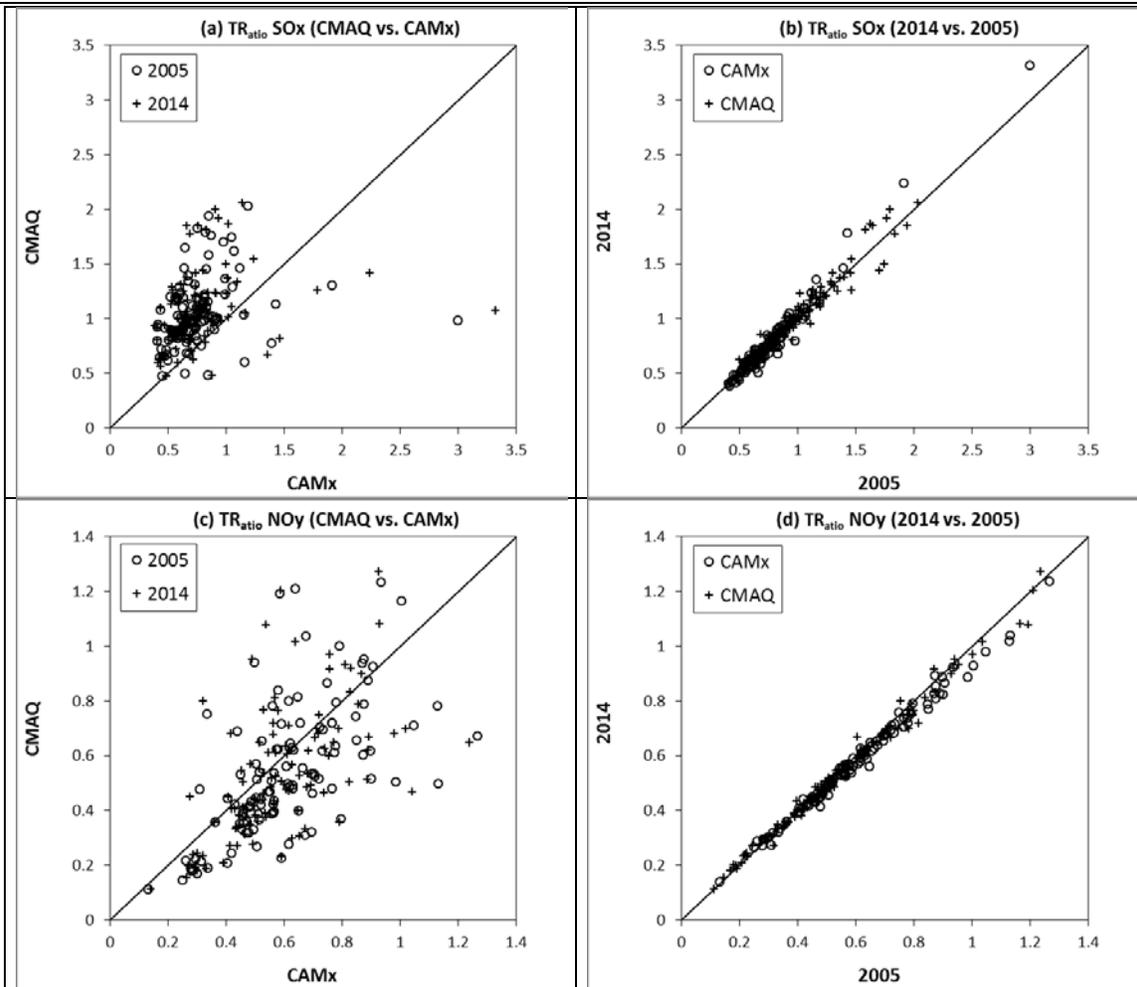

25 [Koo et al. \(2012\)](#) and [Koo et al. \(2015\)](#) raised the issue of model dependence on the
26 calculation of depositing species and transference ratios. [Koo et al. \(2012\)](#) compared
27 model results for concentrations of SO_2 , SO_4^{2-} , HNO_3 , and NO_3^- and corresponding dry
28 deposition fluxes from CMAQ and CAMx to those measured at CASTNET sites. They
29 also compared model results for wet deposition to NADP/NTN measurements. On an
30 annualized basis, mean normalized errors (MNEs) in gas-phase concentrations ranged
31 from ~25 to ~100%. MNEs in dry deposition were much larger and ranged from ~50 to
32 >300% and MNE in wet deposition ranged from ~40 to ~100% with no clear preference
33 for one model over another. MNE for NH_4^+ in dry and wet deposition ranged from ~35 to
34 70%. [Koo et al. \(2012\)](#) also found evidence for spatial variability in TR_{SO_X} and TR_{NO_Y}
35 across the U.S. and within selected ecosystems (roughly a few hundred km across).

36 [Koo et al. \(2015\)](#) compared simulations of transference ratios computed using CMAQ
37 and CAMx for two model years, 2005 and 2014, (see [Figure 2-11](#)) and found that TR_{SO_X}

1 was much higher in CMAQ than in CAMx: however, differences were much smaller for
2 TR_{NO_Y} . R^2 values for TR_{NO_Y} between the two models was 0.37 for 2005 and 0.33 for
3 2014. For TR_{SO_X} , R^2 was 0.073 for 2005 and 0.072 for 2014. Note that each point shown
4 in [Figure 2-11](#) represents the average over 365×24 model entries and are dissimilar to
5 measurement artifacts. The outlying point (in the lower right) is from the Weminuche
6 Wilderness IMPROVE site (WEMI) in the Rockies and likely is the result of the
7 difficulty mesoscale models have in simulating precipitation and flow patterns in areas of
8 high relief and indicates further work is needed in this regard. Note that the disagreement
9 in TR_{SO_X} by CMAQ is mostly due to an error in CMAQ emissions of SO_2 that has since
10 been corrected. There is no consistent geographic pattern of agreement or disagreement
11 between the two simulations.

12 A more complete understanding of the causes of differences between model simulations
13 requires understanding the differences in how major chemical and physical processes
14 have been parameterized, thus underscoring the importance of accurately representing
15 emissions, transport, chemistry, and deposition. Both models used different modules to
16 represent these processes. In addition, these results might imply that the metrics used
17 need further scrutiny. Note again that the results shown in [Koo et al. \(2012\)](#) and [Koo et](#)
18 [al. \(2015\)](#) were obtained using older versions of CMAQ and CAMx and that CTMs are
19 continually undergoing improvement. In this regard, detailed comparisons with
20 observations and intercomparisons between the most current versions of these models
21 might help explain these findings.

22 [Koo et al. \(2015\)](#) also found very small differences between simulations for model years
23 2005 and 2014 from either CMAQ or CAMx for both NO_Y and SO_X , indicating the ratios
24 are relatively invariant at least over an annual time scale. This result is not surprising,
25 because with the long averaging time, concentrations and deposition rates can better track
26 emissions changes.

CAMx = Comprehensive Air Quality Model with Extensions; CMAQ = Community Multiscale Air Quality; NO_y = oxides of nitrogen; SO_x = sulfur oxides; TR_{ratio} = transference ratio.

Source: Adapted from [Koo et al. \(2015\)](#).

Figure 2-11 Scatterplots showing transference ratios for oxidized nitrogen and sulfur oxides comparing the Community Multiscale Air Quality model to the Comprehensive Air Quality Model with Extensions in (a) and (c) and comparing 2005 to 2014 in (b) and (d).

1 To summarize, recent studies have found that using transference ratios for estimating the
 2 deposition flux from atmospheric measurements has lower uncertainty when applied at an
 3 annual timescale. The transference ratio can vary spatially, and an estimate of uncertainty
 4 and variability depends on the spatial scale of interest. Finally, previous studies have
 5 highlighted some of the uncertainties when using models to calculate the transference

1 ratio, but a comprehensive assessment of uncertainty is not available. When the
2 transference ratio is calculated using observations of atmospheric concentrations from
3 monitoring networks, the deposition flux for oxidized sulfur and oxidized nitrogen can be
4 estimated to within 25 to 35%.

2.5.3. Model Evaluation and Uncertainty

5 CMAQ model estimates were recently compared to monitoring network observations and
6 results were reported as normalized mean bias statistics ([U.S. EPA, 2011a](#), [2009c](#)). Total
7 nitrate concentrations were overestimated by CMAQ, with predictions averaged over
8 each of 4 years ranging from 22 to 26% higher than observed concentrations ([U.S. EPA,](#)
9 [2011a](#)). Model performance was described as good for total SO_x, but the ability to
10 partition SO_x into sulfate and SO₂ was identified as an area that needed improvement
11 ([U.S. EPA, 2011a](#)). SO₂ concentrations were overestimated, with CMAQ predictions
12 ranging from 39 to 47% higher than observed concentrations. Sulfate concentrations were
13 underestimated, with CMAQ predictions ranging from 9 to 17% lower than observed
14 concentrations ([U.S. EPA, 2011a](#)). A disadvantage of this type of comparison is that
15 modeled concentrations are outputted for a 12 × 12 km grid, while measured
16 concentrations are from a single point within that grid.

17 Wet deposition estimates from CTMs were extensively evaluated using wet deposition
18 data collected over the U.S. as part of the National Atmospheric Deposition Program's
19 National Trends Network. [Simon et al. \(2012\)](#) have summarized model evaluation studies
20 published before 2010, and [Table 2-7](#) summarizes the studies since 2010.

21 While measurements comparing model outputs to observations provide one perspective
22 on the uncertainty in the fate and transport of atmospheric N and S, another approach to
23 quantifying uncertainty is to estimate the sensitivity of the model results with respect to
24 the uncertain range of parameters relevant to deposition calculations. A study by [Dennis](#)
25 [et al. \(2013\)](#) examined a range of uncertainties relevant to dry deposition using the
26 CMAQ model. This study found little change (<5%) in total deposition, despite changes
27 in dry deposition parameters because competing processes in the model tended to
28 rebalance and compensate. Changes in a single grid cell were as large as 20%.

29 There are also structural uncertainties that are difficult to assess in applying CTM models
30 to estimate deposition. The main structural uncertainties are associated with canopy
31 effects of NO_x, bidirectional exchange of NH₃, and transference ratios that relate average
32 concentration to deposition. These factors are discussed in [Appendix 2.5.2](#).

Table 2-7 Reported comparisons of chemical transport models and observations of nitrogen and sulfur wet deposition

		Model	Metric
Appel et al. (2011)	7.9% normalized mean bias	CMAQ	Annual, wet deposition, sulfate, continental U.S.
Appel et al. (2011)	-12.8% normalized mean bias	CMAQ	Annual, wet deposition, ammonium, continental U.S.
Appel et al. (2011)	-12.8% normalized mean bias	CMAQ	Annual, wet deposition, ammonium, continental U.S.
Appel et al. (2011)	-15% normalized mean bias	CMAQ	Annual, wet deposition, nitrate, continental U.S.
Appel et al. (2011)	0.5 kg/ha median bias	CMAQ	Annual, wet deposition, nitrate, continental U.S.
Zhang et al. (2012a)	6.5% mean normalized bias	GEOS-Chem	Annual, wet deposition, sulfate, continental U.S.
Zhang et al. (2012a)	10% mean normalized bias	GEOS-Chem	Annual, wet deposition, nitrate, continental U.S.
Zhang et al. (2012a)	7.4% mean normalized bias	GEOS-Chem	Annual, wet deposition, ammonium, continental U.S.
Koo et al. (2012)	45 to 99% normalized mean error	CMAQ	Annual, wet deposition, sulfate, continental U.S.
Koo et al. (2012)	38 to 99% normalized mean error	CMAQ	Annual, wet deposition, nitrate, continental U.S.
Koo et al. (2012)	45 to 66% normalized mean error	CMAQ	Annual, wet deposition, ammonium, continental U.S.
Williams et al. (2017a)	0.34 kg ha ⁻¹ mean error	CMAQ	Annual, wet deposition, inorganic nitrogen, Pacific Northwest

2.6. Geographic Distribution of Concentration and Deposition

1 Maps of national distributions of emissions, atmospheric concentrations, and deposition
2 fluxes of relevant species are presented in this section. The first two sections are limited
3 to deposition maps and are intended provide a broad overview of the extent and recent
4 trends for acid deposition ([Appendix 2.6.1](#)) and total nitrogen deposition, including
5 relative contributions of reduced and oxidized nitrogen ([Appendix 2.6.2](#)). The subsequent
6 three sections contain data on geographic distributions of emissions, ambient

1 concentrations and deposition of oxidized nitrogen ([Appendix 2.6.3](#)), reduced nitrogen
2 ([Appendix 2.6.4](#)), and sulfur oxides ([Appendix 2.6.5](#)), including key species in each of
3 these classes.

4 Emission maps in [Appendix 2.6.3](#), [Appendix 2.6.4](#), and [Appendix 2.6.5](#) are from an
5 earlier version of U.S. EPA's National Emissions Inventory than described in
6 [Appendix 2.2](#). Ambient concentration maps in these sections are from a variety of
7 sources, depending on the availability of data.

8 Deposition maps in [Appendix 2.6.1](#), [Appendix 2.6.2](#), [Appendix 2.6.3](#), [Appendix 2.6.4](#),
9 and [Appendix 2.6.5](#) are based on the approach of [Schwede and Lear \(2014a\)](#) which
10 combines measured and modeled values to produce spatially aggregated maps of wet,
11 dry, and total (wet plus dry) deposition of nitrogen and sulfur species across the U.S. Wet
12 deposition is based on concentrations measured in rainwater collected at NADP/NTN
13 monitoring sites combined with precipitation estimates interpolated by PRISM
14 (Parameter-elevation Regression Slopes Model) using inverse distance weighting (IDW).
15 In their approach to dry deposition, [Schwede and Lear \(2014a\)](#) measured values of
16 species concentrations in air at monitoring site locations and used bias-corrected
17 modeling results from CMAQ (currently at 12-km horizontal resolution) to fill in gaps
18 between sites and provide composition and deposition information for species not
19 measured (PANs, NO₂, and HONO) in the routine monitoring networks. Distributions of
20 species that undergo dry deposition are derived mainly by fusion of data from the Clean
21 Air Status and Trends Network (CASTNET), the National Atmospheric Deposition
22 Program (NADP), Ammonia Monitoring Network (AMoN), and the Southeastern
23 Aerosol Research and Characterization (SEARCH) network. Parameterizations in CMAQ
24 are used to calculate deposition velocities for gases and particles ([Pleim and Ran, 2011](#)).
25 Note that CMAQ includes bidirectional exchange for NH₃ ([Bash et al., 2012](#)), but not for
26 other species such as NO₂. Dry deposition fluxes are then combined with wet fluxes to
27 estimate total deposition. Details on interpolation, special treatment for particulate
28 species calculations, and procedures to correct for bias are described in detail by [Schwede
29 and Lear \(2014a\)](#).

30 Efforts have also been made to achieve greater consistency by relying more heavily on
31 WRF/CMAQ simulations for estimating wet deposition. Effects of biases in CMAQ wet
32 deposition are corrected by adjusting the modeled wet deposition by the ratio of observed
33 precipitation interpolated by PRISM to WRF precipitation. In this approach, it is assumed
34 that the ratio of observed to modeled precipitation is well correlated with the ratio of
35 observed to modeled wet deposition, but not (necessarily) that wet deposition scales
36 linearly with precipitation ([Appel et al., 2011](#)). Likewise, estimates of dry deposition
37 could be obtained using CMAQ evaluated by comparison with monitoring results.

1 This approach resulted from efforts to improve estimates of atmospheric deposition by
2 advancing the science of measuring and modeling atmospheric wet, dry, and total
3 deposition of atmospheric species. Recognizing that the thin geographic coverage and the
4 lack of species measurements described in [Appendix 2.4.6](#) are not ideal for estimating
5 dry deposition on a national scale, the National Acid Deposition Program established the
6 Total Deposition Science Committee (TDEP) with this mission in 2011, with an initial
7 goal of providing estimates of total S and N deposition across the U.S. for use in
8 estimating critical loads and other assessments, where loading results in the acidification
9 and eutrophication of ecosystems ([NADP, 2016](#)). Following this hybrid approach to
10 mapping total deposition that combines measured and modeled values, measured values
11 are given more weight at the monitoring locations, and modeled data are used to fill in
12 spatial gaps and provide information on chemical species that are not measured by
13 routine monitoring networks. This effort provides continuous spatial and temporal
14 coverage of total deposition estimates in the U.S., something previously unavailable
15 ([NADP, 2016](#)).

16 Limitations to the TDEP approach are: (1) interpolation leads to a minimization of
17 extreme values and a lower than actual variability, (2) data are limited to sites that meet
18 network completion criteria, (3) discontinuities in trends can occur for intermittent
19 monitoring data, (4) characterization of wet and dry organic nitrogen components is
20 uncertain and likely incomplete, (5) deposition in urban areas is not well represented
21 because the monitoring sites used are primarily in rural areas, and (6) occult deposition is
22 not well understood and might not be characterized accurately. An additional potential
23 drawback is that a mass balance is not maintained, although the mass balance error was
24 small in a similar effort combining measured wet deposition and bias corrected modeled
25 deposition ([Schwede and Lear, 2014a](#)).

26 Differences in wet deposition of NH_4^+ , NO_3^- , and SO_4^{2-} and N + S expressed as H^+
27 equivalents between the two, 3-year periods 1989–1991 and 2012–2014 across the U.S.
28 are shown in [Figure 2-13](#), [Figure 2-25](#), [Figure 2-31](#), and [Figure 2-38](#). These figures are
29 based on data obtained by the NADP/NTN. The maps were constructed by summing
30 gridded values and then taking the difference between the two, 3-year averages using data
31 from the NADP website. Although instructive, these results should be viewed with some
32 caution, as errors are incurred because development of a map spanning the CONUS
33 requires extensive interpolation between monitoring sites, which are often distant from
34 each other. The TDEP values shown on the maps are derived from NADP/NTN wet
35 deposition measurements at 4-km resolution coupled with CMAQ results for dry
36 deposition at 12 km. [Weathers et al. \(2006\)](#) found evidence for substantial spatial
37 variability in deposition with altitude, generally at smaller scales than used for TDEP. In
38 particular, they found evidence for factors of 4–6 variability in N and S deposition

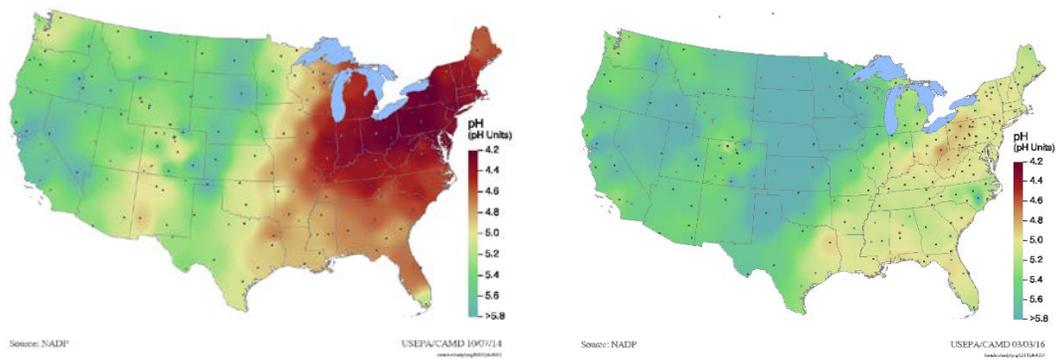

1 throughout Acadia National Park (121 km²) and Great Smoky Mountains National Park
2 (2,074 km²); deposition rates averaged over the two parks were ~70% higher than
3 inferred using only in situ point measurements. As might be expected, deposition
4 increased with elevation because of the increased importance of cloud deposition and dry
5 deposition (due to higher winds and hence increased turbulence). As noted by the NADP,
6 uncertainty within maps of wet deposition varies geographically and has not been
7 quantified. These maps are meant to provide a general indication of large-scale features
8 in the patterns and long-term changes in deposition.

9 [Appendix 2.6.6](#) and [Appendix 2.6.7](#) summarize concentration and deposition data from
10 other approaches. [Appendix 2.6.6](#) describes distributions of dry deposition of NO₂ and
11 SO₂ from satellite-based measurements of tropospheric vertical column abundance and
12 model input derived by [Nowlan et al. \(2014\)](#). [Appendix 2.6.7](#) describes recent estimates
13 of background concentrations, deposition fluxes, and sources and methods used to obtain
14 them.

15 Additional maps on the portion of the NADP website dedicated to the Total Deposition
16 (TDEP) program (<http://nadp.sws.uiuc.edu/committees/tdep/tdepmaps/>) are shown in
17 [Appendix 2.7](#). They present a comprehensive overview of changes in various parameters
18 related to deposition from 2000–2013. Each map shows two 3-year periods, 2000–2002
19 and 2011–2013. Although uncertainty has not been fully characterized using the TDEP
20 approach, they are instructive because they give an indication of how various estimates
21 carried out with the same approach have changed over the past decade.

2.6.1. pH and H⁺ Equivalentents

22 Long-term trends in rainwater pH over the CONUS between the two periods 1989 to
23 1991 and 2012 to 2014 are shown in [Figure 2-12](#). Substantial improvement in the quality
24 of rainwater in terms of pH has occurred from the earlier to the later period. [Figure 2-12](#)
25 is a remarkable demonstration of the effectiveness of the Clean Air Act Amendments,
26 showing that the steep reductions of NO_x and SO₂ emissions described in [Appendix 2.2](#)
27 coincide with a sharp decline in pH.

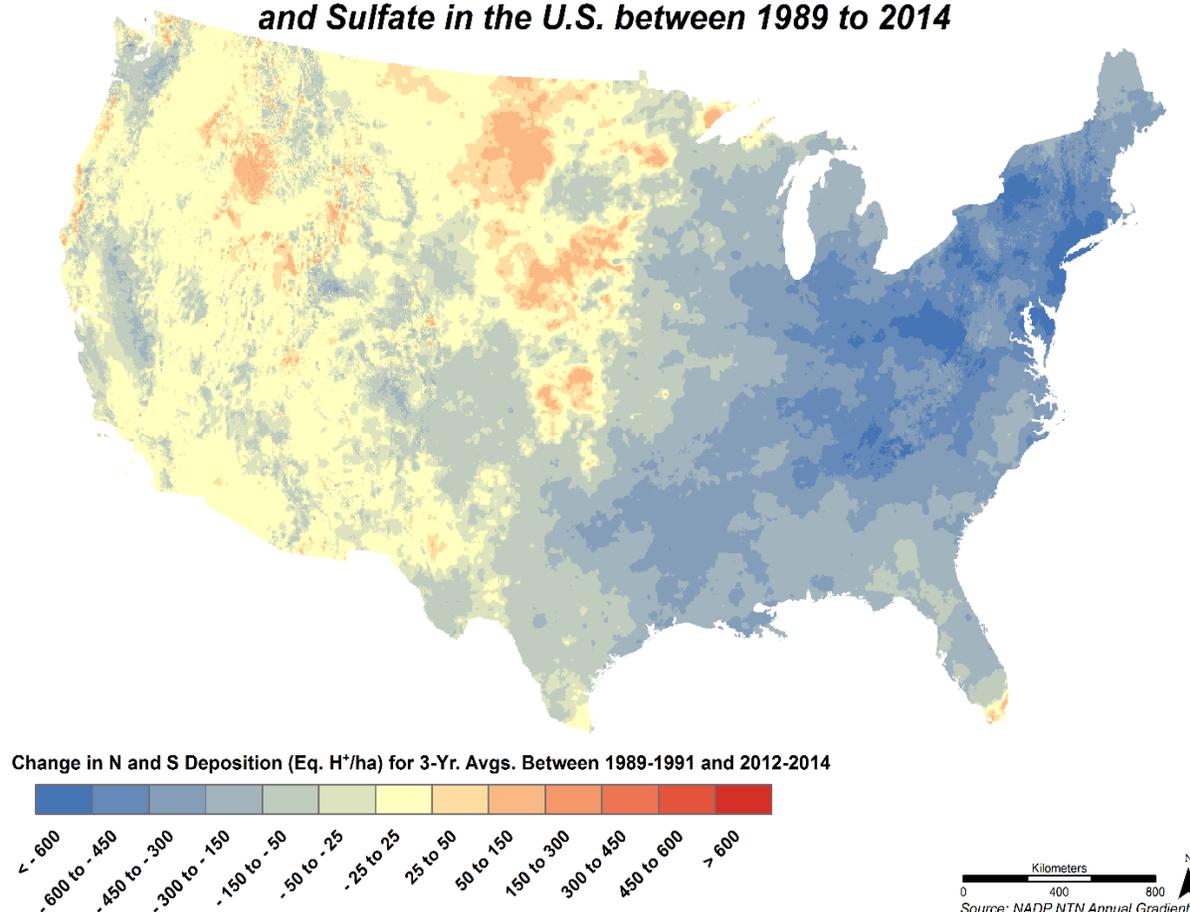

Source: NADP/U.S. EPA/CAMD.

Figure 2-12 (Left) pH of rainwater, 1989–1991; (Right) pH of rainwater, 2012–2014.

1 However, there are areas, especially in the eastern U.S. near the upper Ohio River Valley,
 2 where the pH of rainwater is still much lower than the reference pH of ~5.65 (for
 3 equilibrium with CO₂) that has often been used as a benchmark when characterizing the
 4 excess acidity of rainwater. (Note that the reference CO₂ concentration used to determine
 5 this value is 316 ppm, atmospheric CO₂ concentrations are now over 400 ppm, resulting
 6 in a lowering of pH by ~0.05 units.) As noted by [Galloway et al. \(1976\)](#), the major
 7 contributors to free acidity in rainwater for pH <5.6 are the strong mineral acids HNO₃
 8 and H₂SO₄. However, weak acids (e.g., organic acids) can contribute substantively to free
 9 acidity at pH levels seen throughout much of the U.S. (see [Appendix 2.3.5](#)). For example,
 10 concentrations of formic acid and acetic acid (pK_a = 3.75, 4.76) measured in rainwater at
 11 pH ~5 by [Avery et al. \(2006\)](#) are on the order of 10 μM, which is comparable to
 12 concentrations of NO₃⁻ and SO₄²⁻ measured in rainwater. Additionally, in areas like the
 13 Northwest where the pH of stream water can be around or even larger than 5.6,
 14 acidification of streams by CO₂ might also need to be considered ([Ou et al., 2015](#)).

15 The change in acid loading (H⁺ equivalents) due to wet deposition of NO₃⁻, NH₄⁺, and
 16 SO₄²⁻ ions in precipitation expressed as H⁺ equivalents between the two, 3-year periods
 17 1989–1991 and 2012–2014 across the U.S. based on data obtained by the NADP/NTN is
 18 shown in [Figure 2-13](#). Substantial decreases in acid loading are seen in the eastern U.S.,
 19 with areas in the central and western U.S. showing smaller positive or negative changes
 20 or essentially no change.

Change in Nitrogen and Sulfur Wet Deposition from Nitrate, Ammonium, and Sulfate in the U.S. between 1989 to 2014

H⁺ = hydrogen ion; eq = H⁺ equivalent.

Figure 2-13 Difference in wet deposition of nitrate, ammonium, and sulfate expressed as hydrogen ion equivalents (eq/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2012 to 2014.

1 This map was constructed by summing gridded values and then taking the difference
2 between the two, 3-year averages using data from the NADP website. Although
3 instructive, these results should be viewed with some caution, as errors are incurred
4 because development of a map spanning the CONUS requires extensive interpolation
5 between monitoring sites, which are often distant from each other. As noted by the
6 NADP, uncertainty within maps of wet deposition varies geographically and has not been
7 quantified. These maps are meant to provide a general indication of large-scale features
8 in the patterns and long-term changes in deposition. In viewing maps such as these one
9 should bear in mind that the rates and patterns of deposition are continually changing due

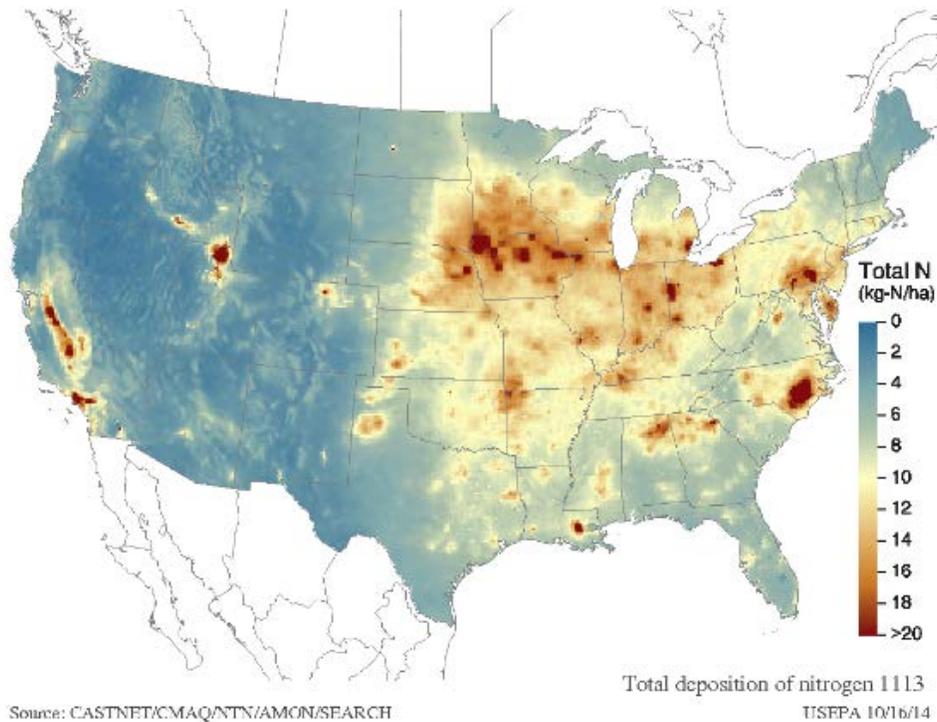

1 to ongoing implementation of control measures and shifting patterns of population
2 growth, and industrial and agricultural activities.

2.6.2. Total Nitrogen

3 [Figure 2-14](#) shows total deposition of N, which is given by the sum of all NO_y and NH_x
4 species considered by CMAQ. Fluxes are based on the method developed by [Schwede](#)
5 [and Lear \(2014a\)](#) as outlined above and are given in terms of kg N/ha/yr.

6 As can be seen from [Figure 2-14](#), the highest deposition of nitrogen occurs in a broad
7 swath across the Midwest, and in more localized patches across the U.S. Total N
8 deposition can be put in context by comparing the deposition amounts in [Figure 2-14](#) to
9 estimates of critical load, which is the N deposition amount below which no significant
10 harmful effects on sensitive elements of the environment occur. These are typically
11 below 10 kg N/ha/yr and can be as low as 2–3 kg N/ha/yr in both eastern and western
12 locations ([Lee et al., 2016](#); [Ellis et al., 2013](#)), amounts which are firmly below the
13 estimated deposition amounts in [Figure 2-14](#) over wide areas of the U.S. [Ellis et al.](#)
14 [\(2013\)](#) observed that critical loads were exceeded in 24 of 45 parks, and [Lee et al. \(2016\)](#)
15 observed that critical loads were exceeded at more locations in the western U.S., but by
16 larger amounts in the eastern U.S.

17 Inspection of [Figure 2-15a](#) and [b](#) shows that many of these areas are dominated either by
18 deposition of NH_x emitted mainly by agriculture (e.g., California’s Central Valley, Upper
19 Midwest), or NO_y resulting from oxidation of nitrogen oxides emitted mainly by
20 combustion sources (e.g., the Northeast, Southwest). As might be expected when
21 considering all forms of NO_y , total deposition tends to be much higher near urban and
22 suburban areas. Note also that deposition of N_r , based on the hybrid
23 measurements/modeling approach, is dominated by reduced forms across the CONUS as
24 a whole.

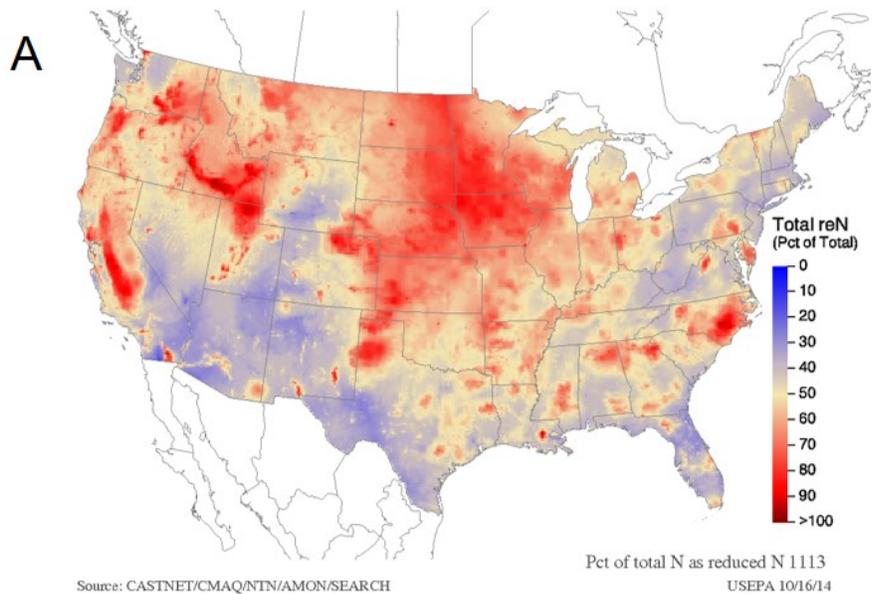

N = nitrogen; N_r = reactive nitrogen.
 Source: CASTNET/CMAQ/NTN/AMON/SEARCH.

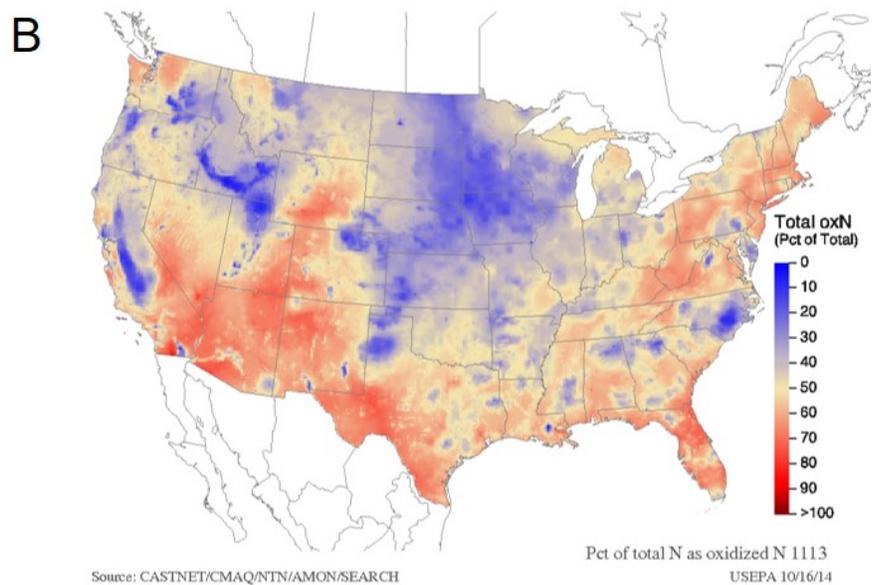

Figure 2-14 Total (wet + dry) deposition of nitrogen (kg N/ha/yr) over the contiguous U.S. 2011–2013.

1 Dry deposition of gas-phase N (as HNO₃ and NH₃) exceeds dry deposition of particulate
 2 forms (pNO₃⁻, NH₄⁺) over most of the CONUS according to the hybrid method. Overall,
 3 deposition of N is mainly as reduced forms, with a maximum over the north-central U.S.
 4 The Central Valley of California, northern Utah, and eastern North Carolina are among
 5 other areas of high deposition of reduced N. In general, dry deposition of N, in either
 6 oxidized or reduced form, exceeds wet deposition across the CONUS. However, based on
 7 discussions in earlier sections, uncertainties for dry deposition are likely much larger than
 8 for wet deposition.

9 As mentioned earlier, several species potentially important for deposition are not
 10 measured in CASTNET. [Figure 2-16](#) shows dry deposition for oxidized nitrogen species
 11 (e.g., PAN, other organic nitrates, HONO) calculated by CMAQ.

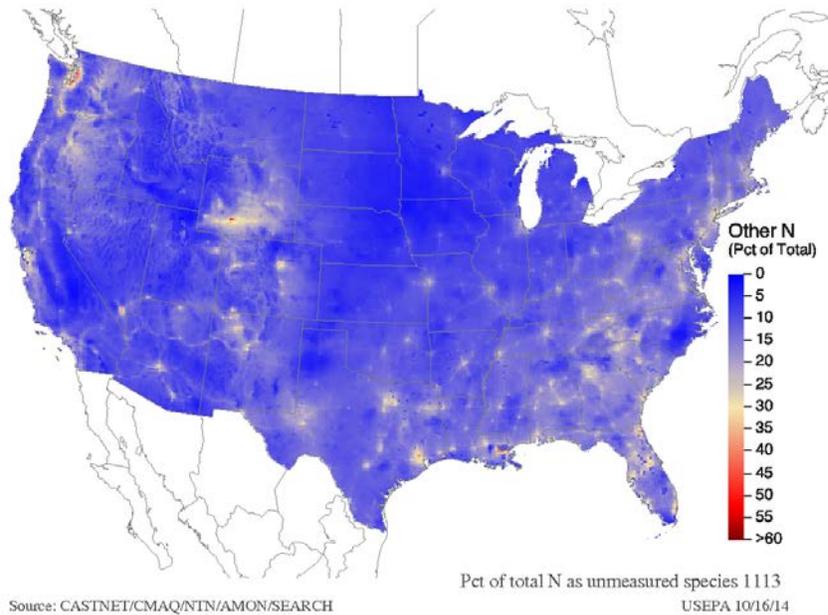

reN = reduced nitrogen.
Source: CASTNET/CMAQ/NTN/AMON/SEARCH

oxN = oxidized nitrogen.
Source: CASTNET/CMAQ/NTN/AMON/SEARCH.

Figure 2-15 (A) Percentage of total nitrogen deposition as reduced inorganic nitrogen over the contiguous U.S. 2011–2013. (B) Percentage of total nitrogen deposition as oxidized nitrogen over the contiguous U.S. 2011–2013.

N = nitrogen.
 Source: CASTNET/CMAQ/NTN/AMON/SEARCH.

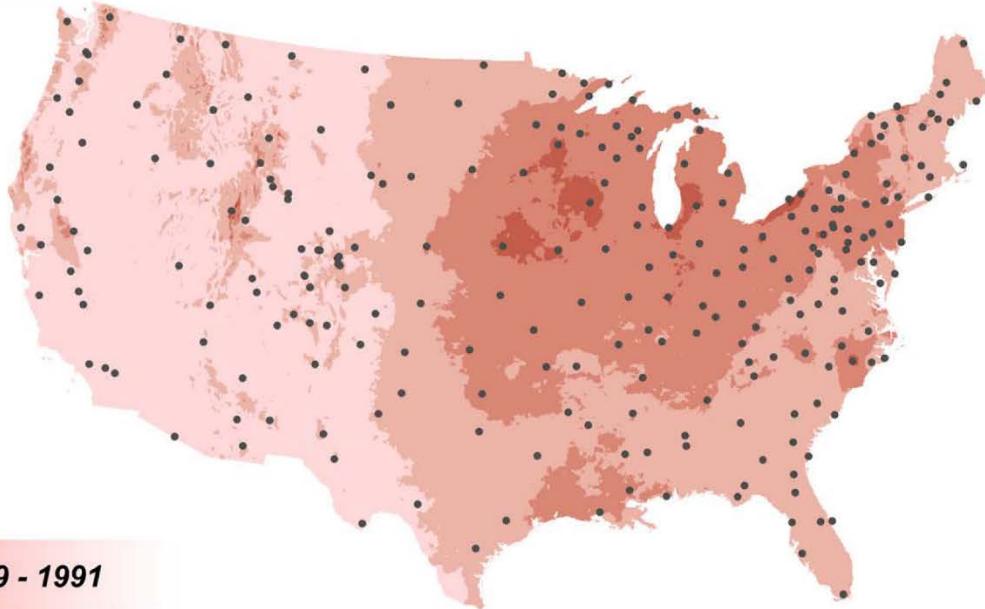

Figure 2-16 Three-year average percentage of total nitrogen deposition by species (i.e., those species that are not measured in the networks) simulated by the Community Multiscale Air Quality modeling system.

1 As seen in [Figure 2-16](#), deposition of these species can contribute substantially to N
 2 deposition, especially near strong sources, in particular large urban areas. [Turnipseed et](#)
 3 [al. \(2006\)](#) also indicated that not accounting for these species can result in significant
 4 underestimates of N deposition.

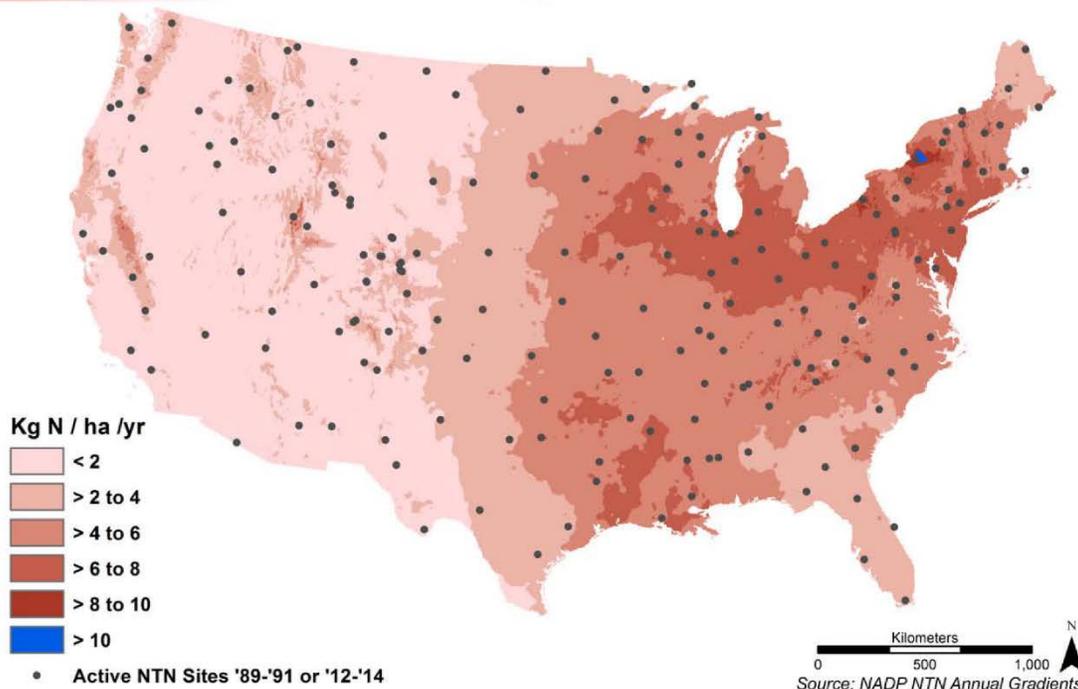

5 [Figure 2-17](#) shows long-term trends in total wet deposition of N ($\text{NH}_4^+ + \text{NO}_3^-$) binned in
 6 increments of 2 kg N/ha/yr for comparison to critical loads estimates. Although it is
 7 apparent that N wet deposition has decreased overall across the U.S., there are areas
 8 showing increases. Also shown are NTN sites active during either period.

Sum NO_3^- and NH_4^+ Wet Deposition by 3-Yr. Averages

2012 - 2014

1989 - 1991

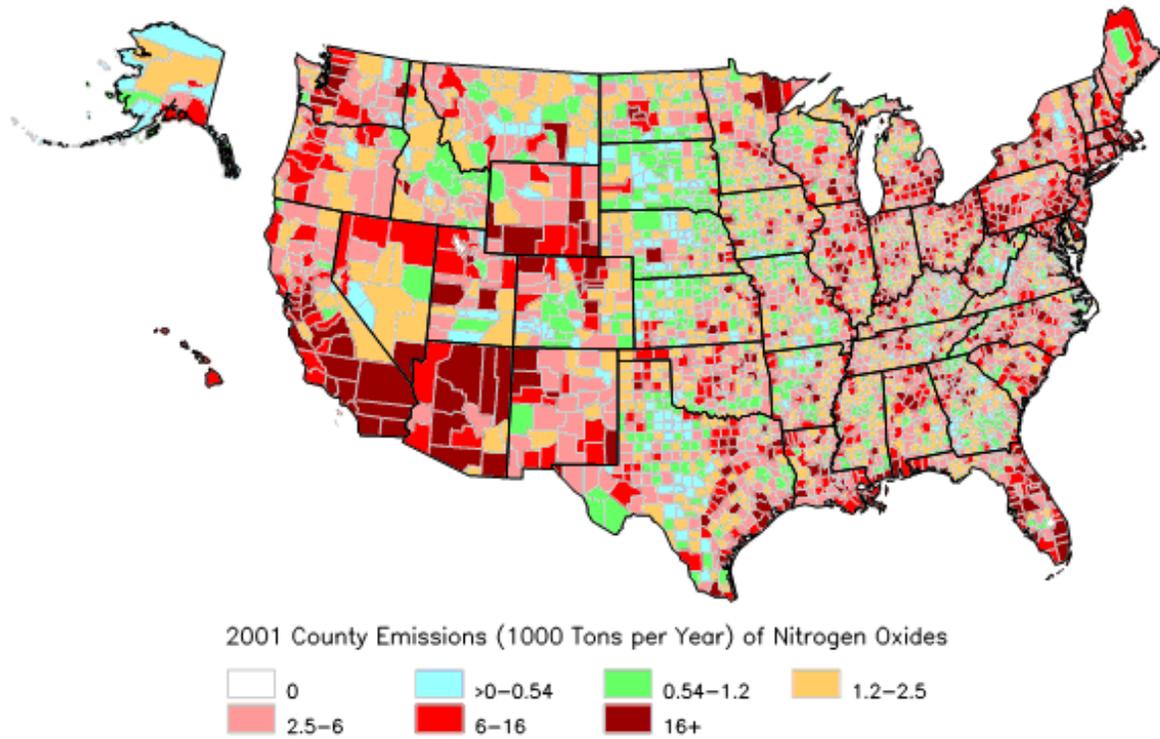

NTN = National Trends Network; N = nitrogen; NH_4^+ = ammonium; NO_3^- = nitrate.

Figure 2-17 Wet deposition of ammonium + nitrate (kg N/ha/yr) over the contiguous U.S. in two, 3-year periods, 2012 to 2014 and 1989 to 1991. Also shown are active National Trends Network sites in either period.

1 Studies at individual sites (e.g., on the coast of North Carolina) have shown that about
2 30% of wet deposition of N consisted of organic N, 20–30% of which was then available
3 to primary producers on timescales of hours to days ([Peierls and Paerl, 1997](#)). In addition,
4 [Benedict et al. \(2013\)](#) found that wet deposition of organic nitrogen contributed 18% of
5 total quantified reactive nitrogen deposition and 25% of wet nitrogen deposition at Rocky
6 Mountain National Park between November 2008 and November 2009. Trends in total
7 (wet + dry) deposition of total ($\text{NO}_Y + \text{NH}_X$) nitrogen between 2000 and 2013 are
8 described with maps in [Appendix 2.7](#).

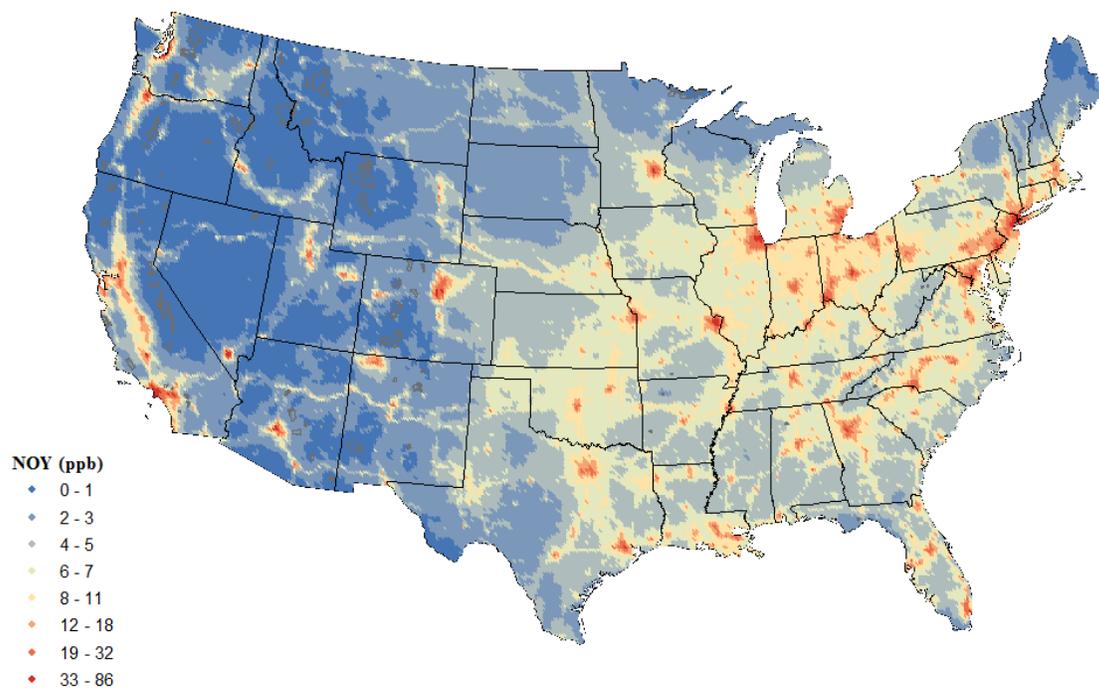

2.6.3. Oxidized Nitrogen

9 County level NO_X emissions are shown in [Figure 2-18](#). The emission map is currently
10 being updated and [Figure 2-18](#) shows estimated emissions from 2001. At present, areas
11 of high emissions that stretch over numerous counties are in the Northeast, Southern
12 Great Lakes region, and Florida. The distribution of ambient NO_Y concentrations is
13 shown in [Figure 2-19](#). However, because NO_Y is only measured at a small number of
14 sites, this map is based solely on CMAQ model output. The distribution of NO_2 (shown
15 in [Figure 2-20](#)) is derived from satellite data (OMI) and output from the GEOS-Chem
16 model using the method outlined in [Appendix 2.6.3](#). Distributions of HNO_3 , pNO_3^- ,
17 pNH_4^+ , SO_2 , and pSO_4^{2-} are based on data from the CASTNET. Note, however, that
18 because of artifacts relating to measurement of HNO_3 and pNO_3^- ([Appendix 2.4.5](#)), the
19 measurement of total nitrate ($\text{TN} = \text{HNO}_3 + \text{pNO}_3^-$) is judged to be more reliable than
20 measurements of its components.

Source: [U.S. EPA \(2008a\)](#).

Figure 2-18 Distribution of annual NO_x emissions in 2001.

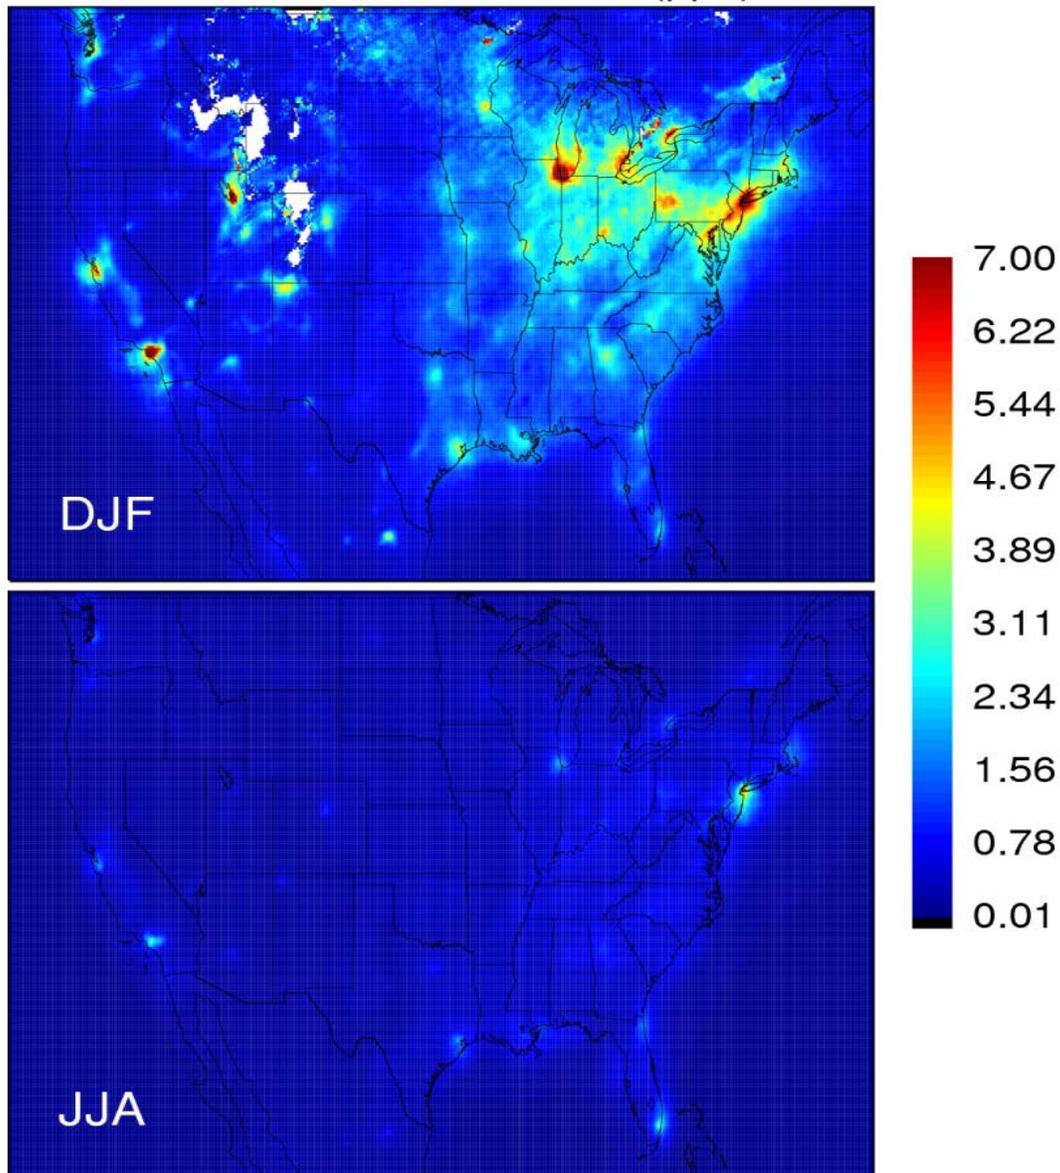

NO_y = oxidized nitrogen species.

Source: U.S. EPA/OAQPS.

Figure 2-19 **Distribution of annual average total oxidized nitrogen species concentrations for 2011 simulated by Community Multiscale Air Quality modeling system.**

OMI-derived surface NO₂ (ppb)

DJF = December, January, February; JJA = June, July, August; NO₂ = nitrogen dioxide; OMI = Ozone Monitoring Instrument.

Note: Images shown were constructed by Dr. Lok Lamsal of Universities Space Research Association from data obtained by the OMI on the Aura satellite (<http://aura.gsfc.nasa.gov/scinst/omi.html>) using the algorithm described in [Bucsela et al. \(2013\)](#). Output from the GEOS-Chem, global-scale, three-dimensional, chemistry-transport model to derive surface concentration fields from the satellite data as described in [Lamsal et al. \(2008\)](#) and [Lamsal et al. \(2010\)](#).

Top panel (winter; December, January, February). Lower panel (summer; June, July, August).

Figure 2-20 Seasonal average surface nitrogen dioxide mixing ratios in parts per billion for winter (upper panel) and summer (lower panel) derived by the Ozone Monitoring Instrument/GEOS-Chem model for 2009–2011. The Ozone Monitoring Instrument has an overpass at approximately 1:30 p.m. local standard time.

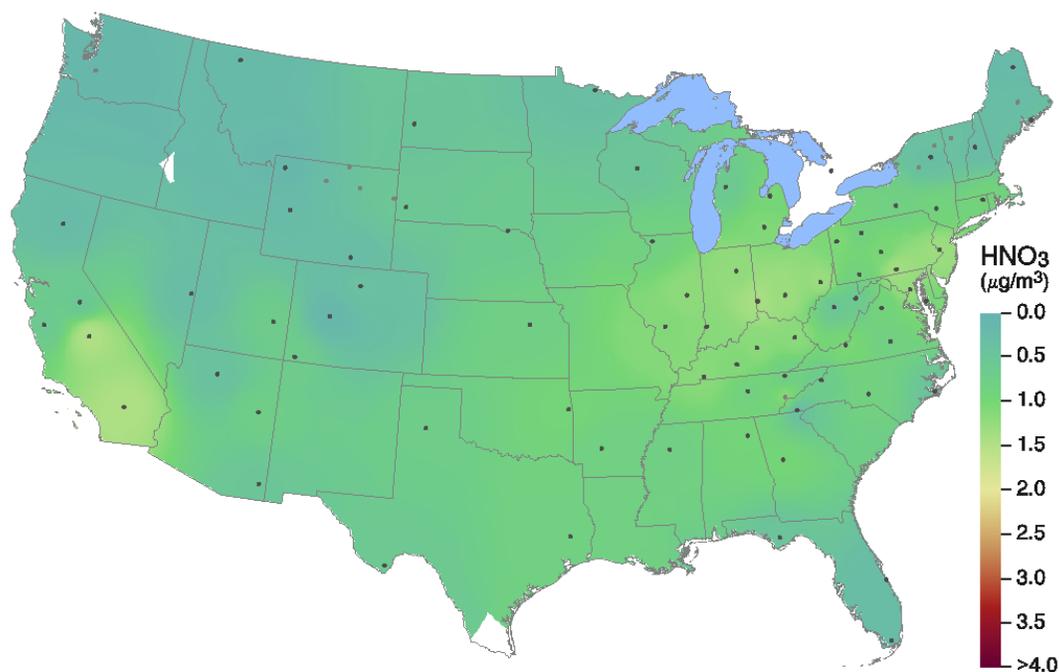

1 As seen in the figure, highest values are found in and around urban areas. In general,
2 much broader areas of high concentrations (>~5 ppb) are found in the eastern U.S., with
3 many areas in the western U.S. subjected to concentrations <1 ppb, which implies that
4 concentrations of components that might pose a hazard are also lower than 1 ppb because
5 NO_Y refers to the sum of oxidized N species.

6 [Figure 2-20](#) through [Figure 2-22](#) describe geographic concentration patterns for three
7 major oxidized nitrogen species, NO_Y, HNO₃, and pNO₃⁻. [Figure 2-20](#) shows seasonal
8 average NO₂ concentrations derived using the hybrid (OMI-satellite/GEOS-Chem-model)
9 approach described in [Appendix 2.4.2.2](#). Large variability in NO₂ concentrations is
10 apparent in [Figure 2-20](#). As expected, the highest NO₂ concentrations are seen in large
11 urban regions, such as in the Northeast Corridor, and lowest values are found in sparsely
12 populated regions located mainly in the West. Minimum hourly values can be less than
13 ~10 ppt, leading to a large range between maximum and minimum concentrations.
14 Although overall patterns of spatial variability are consistent with the current
15 understanding of the behavior of NO₂, not much confidence should be placed on values
16 <~100 ppt due to limitations in the satellite retrievals. Surface NO₂ concentrations tend to
17 be higher in January than in July, largely reflecting lower planetary boundary layer
18 heights in winter. Such seasonal variability is also evident on a local scale, as measured
19 by surface monitors. For example, in Atlanta, GA, NO_X measurements also exhibited
20 higher concentrations in winter and lower concentrations in summer, when NO_X is more
21 rapidly removed by photochemical reactions. For example, see [U.S. EPA \(2008b\)](#).

22 [Figure 2-21](#) shows ambient concentrations of HNO₃. Elevated concentrations of HNO₃
23 are notable in southern California, the Midwest, the south-central U.S., and the
24 Mid-Atlantic states. Conversion of NO₂ to HNO₃ takes place over a timescale of 1 to
25 several hours, during which time appreciable transport can occur.

26 [Figure 2-22](#) shows 3-year average concentrations of particulate nitrate (pNO₃⁻) across the
27 CONUS. Average pNO₃⁻ concentrations were highest in the Upper Midwest with a
28 notable maximum at the junction of Iowa, Wisconsin, Missouri, and Illinois. The high
29 values in the Upper Midwest are expected to be found during winter for reasons noted in
30 [Appendix 2.3.3](#). Elevated levels were also observed in central California in the San
31 Joaquin Valley, central Pennsylvania, central Florida, and through much of the Midwest.
32 Based on IMPROVE and CSN monitoring network data, ammonium nitrate
33 concentrations are highest in California and the Midwest ([Hand et al., 2012c](#)). It is worth
34 noting that at several monitoring sites in the central and northern Great Plains, NO₃⁻ and
35 SO₄²⁻ are increasing at a rate of over 5% per year ([Hand et al., 2012a](#)). [Hand et al.](#)
36 ([2012a](#)) suggested that this increase might be related to oil and gas exploration and

1 production in the region, transport from oil and gas fields in Alberta, and also to
2 expansion of EGUs to meet the demands of population growth.

NO_3^- = nitrate.

Source: CASTNET/U.S. EPA-CAMD 10/09/14.

Figure 2-22 Three-year average (2011–2013) surface concentrations of particulate nitrate based on monitoring data obtained at Clear Air Status and Trends Network sites (black dots).

1 [Figure 2-23](#) shows the depositional flux of NO_Y over the CONUS 2011–2013. In
 2 constructing [Figure 2-23](#) and maps that include pNO_3^- deposition estimates, the
 3 assumption was made that 80% of pNO_3^- is in the fine mode and 20% is in the coarse
 4 mode. Note also, the monitors in CASTNET do not use size-selected inlets. As shown in
 5 [Figure 2-9 \(Appendix 2.5.2.1\)](#), the deposition velocity of particles increases dramatically
 6 with particle size due to gravitational settling, resulting in higher deposition rates than
 7 calculated if pNO_3^- were found mainly in the fine mode. However, to the extent there is
 8 displacement of HNO_3 by acid S species in fine particles as occurs in the eastern U.S. due
 9 to much higher emissions of SO_2 than in the western U.S. [e.g., ([Wolff, 1984](#)); especially
 10 in coastal areas where displacement of Cl^- in marine aerosol occurs], higher levels of
 11 pNO_3^- would be found in coarse mode particles (see [Appendix 2.3.3](#). During the Tampa
 12 Bay Study, measured and modeled (using CMAQ) concentrations of HNO_3 and pNO_3^- in
 13 $\text{PM}_{10-2.5}$ were much higher than pNO_3^- in $\text{PM}_{2.5}$. [Wolff \(1984\)](#) found that most pNO_3^- (as

1 NH_4NO_3) is found in the fine mode in Denver but in the coarse mode (associated with
2 Ca^{2+} and Mg^{2+}) in measurements made in Detroit and rural South Dakota, Louisiana, and
3 Virginia. [Blanchard et al. \(2013\)](#) found a range of 32 to 63% for the fraction of pNO_3^- in
4 $\text{PM}_{10-2.5}$ versus $\text{PM}_{2.5}$ particles in the Southeast. [Lee et al. \(2008\)](#) found that most pNO_3^-
5 was in the coarse mode at Grand Canyon and Great Smoky Mountains, corroborating
6 earlier findings at Yosemite and Big Bend national parks. They also found that both
7 coarse and fine mode pNO_3^- were important at Brigantine National Wildlife Refuge, NJ
8 and San Geronio Wilderness Area, CA. [Lefer and Talbot \(2001\)](#) also found that NO_3^-
9 sampled at Harvard Forest, MA between March and October was mainly found in the
10 coarse mode with a mass median diameter of $4.8 \pm 1.5 \mu\text{m}$. These results indicate
11 considerable regional variability in the ratio of pNO_3^- in the fine and coarse modes and
12 consequently additional uncertainty in estimates of pNO_3^- deposition.

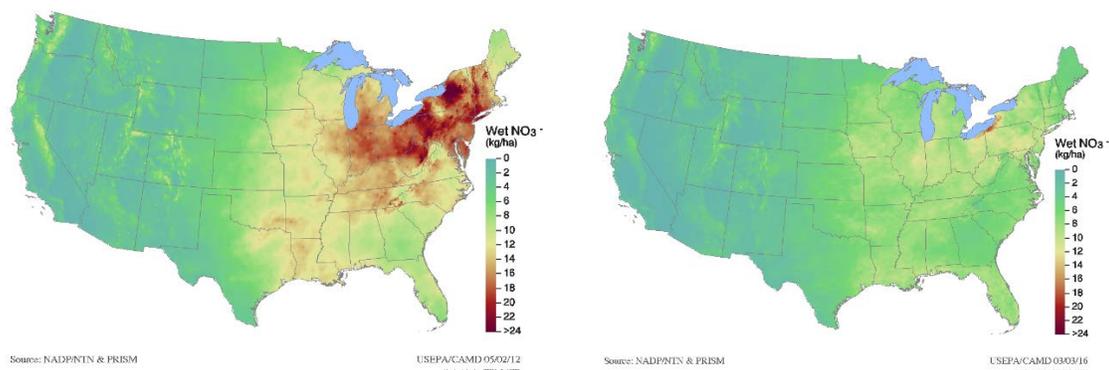

oxN = oxidized nitrogen.

Source: CASTNET/CMAQ/NTN/AMON/SEARCH.

Figure 2-23 Total oxidized nitrogen deposition over the contiguous U.S. 2011–2013.

13 [Figure 2-24](#) and [Figure 2-25](#) show that most locations in the U.S. show decreases in wet
14 deposition of NO_3^- , which are associated with NO_x emissions control measures since the
15 passage of the 1990 Clean Air Act amendments. However, some areas, located mainly in

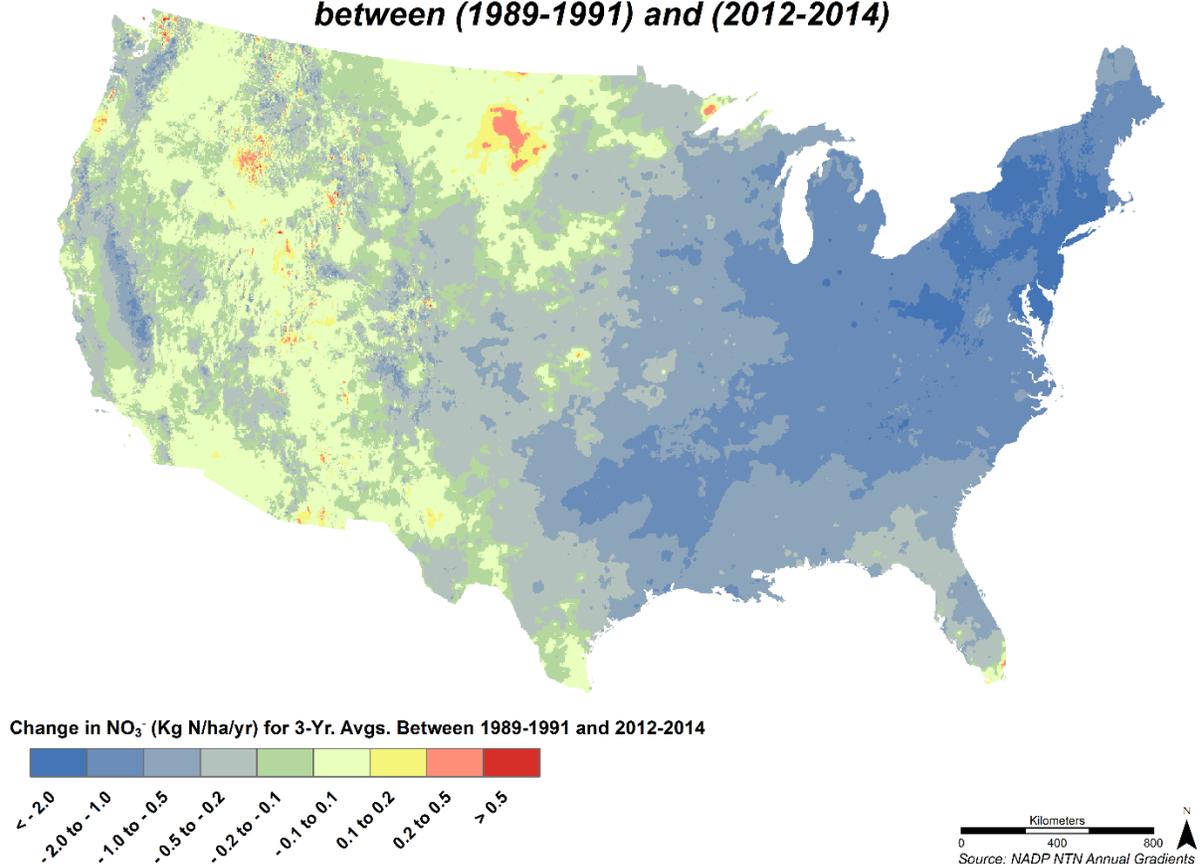

1 the West show increases. As noted earlier, [Hand et al. \(2012a\)](#) suggested that this
2 increase might be related to oil and gas exploration and production in the region,
3 transport from oil and gas fields in Alberta, and also to expansion of motor vehicles and
4 EGUs to meet the demands of population growth. The large area with the strongest
5 increases in the north-central U.S. corresponds to oil and gas operations in the Bakken
6 Shale. Trends in total (wet + dry) deposition of oxidized nitrogen between 2000 and 2013
7 are described with maps in [Appendix 2.7](#).

Source: NADP/U.S. EPA/CAMD.

N = nitrogen; NO_3^- = nitrate.

Figure 2-25 **Difference in wet deposition of nitrate (kg N/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2012 to 2014. The range of positive values is smaller than that for negative values.**

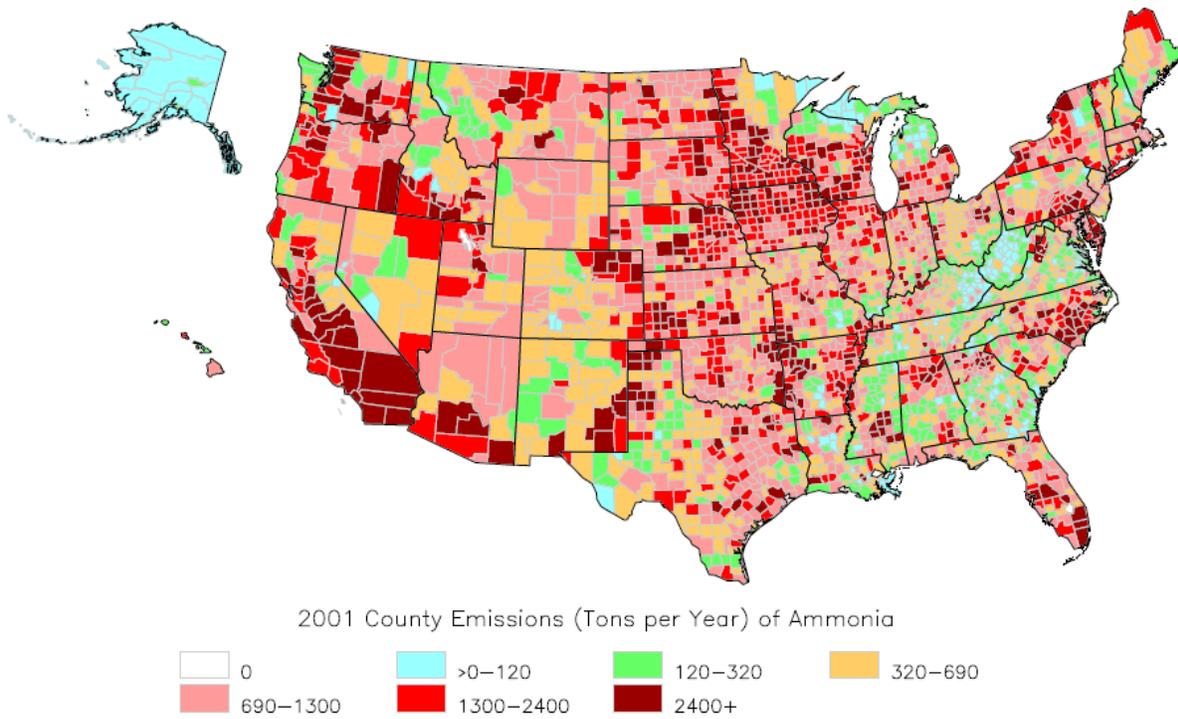

2.6.4. Reduced Nitrogen

1 [Figure 2-26](#) shows county-level annual total NH_3 emissions. The emissions map is in the
2 process of being updated, but geographic features are similar between the present day and
3 the 2001 data in [Figure 2-26](#). The pattern of geographic distribution is somewhat different
4 than for NO_x emissions ([Appendix 2.6.3](#)), reflecting the widely distributed and rural
5 nature of NH_3 emissions, compared to NO_x emissions, which are largely urban or from
6 large point sources. Widespread areas of high emissions are in the Midwest and
7 California.

1 [Figure 2-27](#) and [Figure 2-28](#) show maps for the reduced inorganic nitrogen species, NH_3
2 and pNH_4^+ . The distribution of NH_3 was obtained from the Ammonia Monitoring
3 Network (AMoN). Highest concentrations of NH_3 were measured in Salt Lake City, UT
4 at $15 \mu\text{g}/\text{m}^3$. All other annual average concentrations for 2012 were lower than $5 \mu\text{g}/\text{m}^3$.
5 The Salt Lake City site is located near feed lots, perhaps explaining in large part why
6 levels were much higher there than at other sites. In general, areas of highest NH_3
7 concentration correspond well with areas of highest NH_3 emissions, as shown in the 2008
8 ISA for Oxides of Nitrogen ([U.S. EPA, 2008b](#)). Note that confidence in the magnitude
9 and inter-monitor precision of NH_3 measurements has increased since the 2008 ISA ([U.S.](#)
10 [EPA, 2008a](#)), also see [Appendix 2.4.3.1](#). However, sparseness of the monitoring network
11 still presents uncertainty in describing the nationwide distribution of NH_3 concentrations.

12 Particulate NH_4^+ concentrations were obtained from CASTNET, and were highest in
13 Illinois-Indiana-western Ohio, along with high values in central Pennsylvania and central
14 California. These locations correspond generally to highest concentrations of pNO_3^- and
15 moderate-to-high concentration locations for NH_3 . In addition, some of the areas with
16 high NH_3 concentrations, such as southern Wisconsin or Salt Lake City, do not appear to
17 have elevated pNH_4^+ .

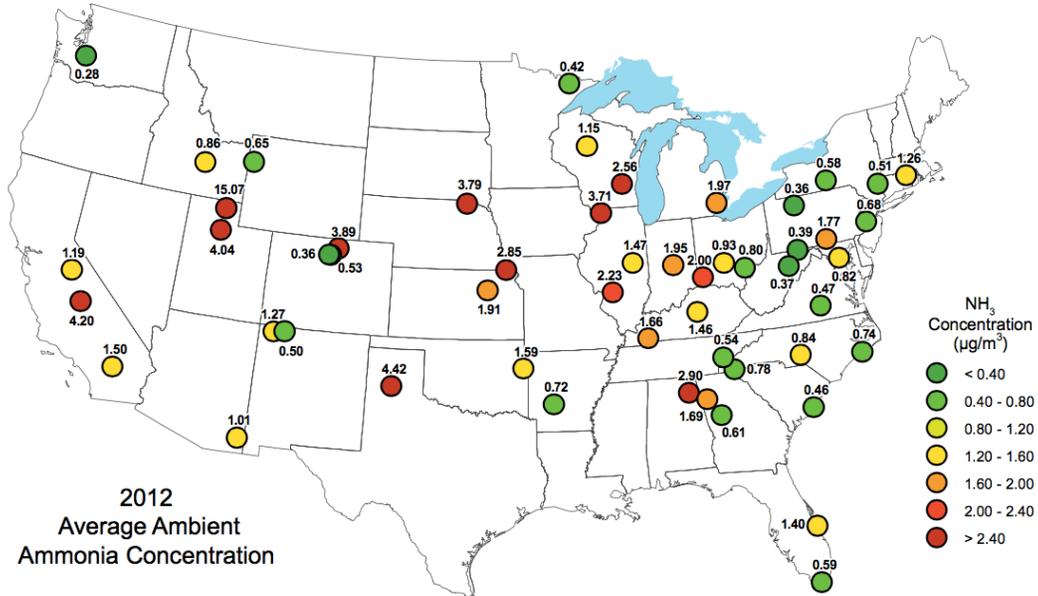

18 [Figure 2-29](#) shows the depositional flux of NH_x over the CONUS 2011–2013.

Figure 2-29 Total reduced inorganic nitrogen deposition over the contiguous U.S. 2011–2013.

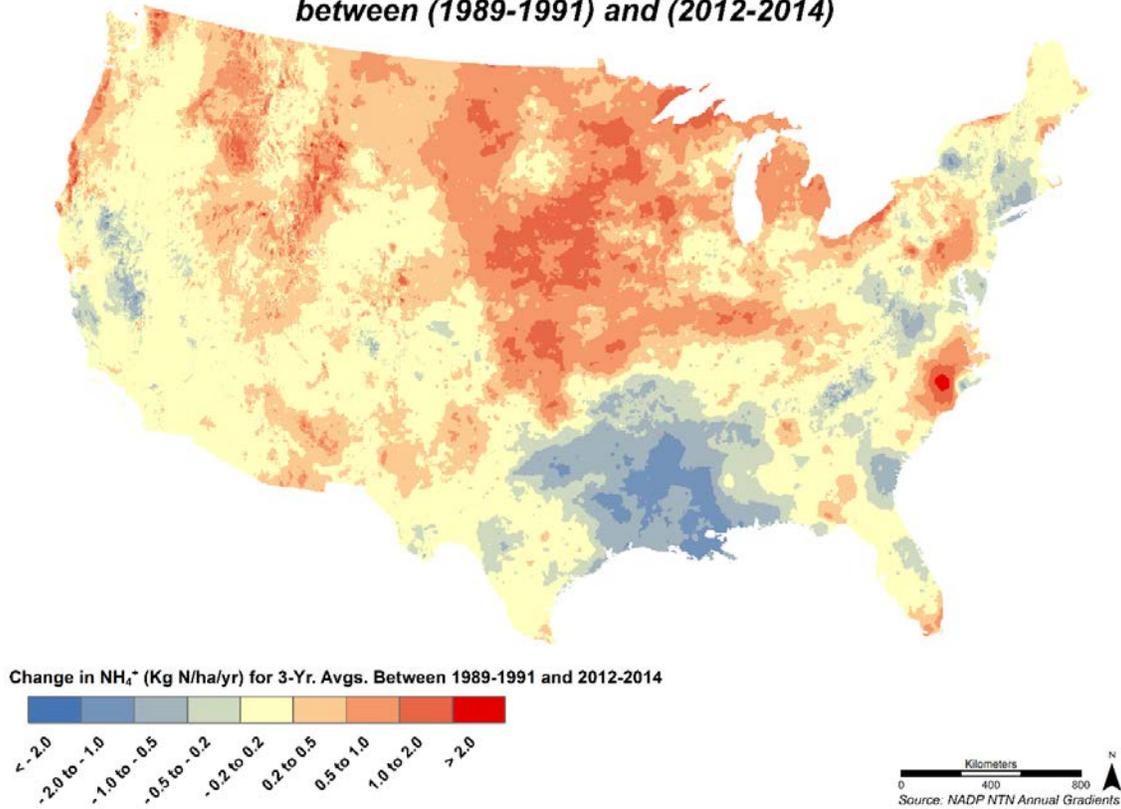

1 [Figure 2-30](#) and [Figure 2-31](#) shows large increases in wet deposition of NH_4^+ centered in
 2 eastern North Carolina and throughout the north-central U.S. and decreases in the Gulf
 3 States. The situation is more nuanced than shown in that some sites show small increases
 4 and others small decreases. In general, large-scale increases in wet deposition of NH_4^+ ,
 5 rather than decreases, are seen across the U.S. in agreement with the analysis of [Li et al.](#)
 6 [\(2016d\)](#). Trends in total (wet + dry) deposition of reduced nitrogen between 2000 and
 7 2013 are described with maps in [Appendix 2.7](#).

2.6.5. Sulfur Oxides

- 1 [Figure 2-32](#) shows the west-to-east increasing gradient in SO_2 emissions, with greater
- 2 emissions in most counties east of the Mississippi than in most counties in the West. The
- 3 emissions map is being updated, but geographic patterns have changed little. Widespread
- 4 areas of high emissions that encompass numerous counties are in the Northeast, the Ohio
- 5 Valley, and parts of the South and West.

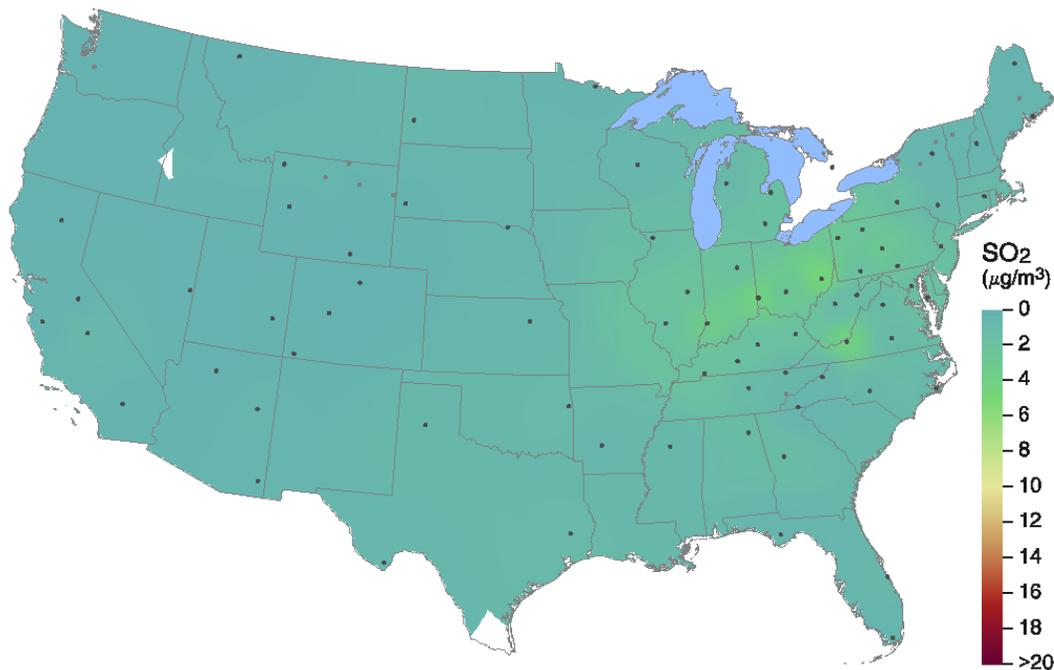

Source: [U.S. EPA \(2008a\)](#)

Figure 2-32 Distribution of annual sulfur dioxide (SO₂) emissions by county from the 2014 National Emissions Inventory.

1 [Figure 2-33](#) and [Figure 2-34](#) show the distribution of atmospheric concentrations of
 2 gas-phase SO₂ and particulate phase SO₄²⁻. Elevated SO₂ concentrations persist along the
 3 Ohio River Valley and western Virginia, but concentrations have decreased substantially
 4 over the last decade throughout the eastern U.S. Comparison between the national SO₂
 5 distributions ([Figure 2-33](#)) for 2011–2013 and the ones for 1989–1991 and 2003–2005
 6 presented in the 2008 ISA ([U.S. EPA, 2008a](#)) demonstrated continual decreases in SO₂
 7 concentrations across the nation.

8 Both concentrations and seasonal variability of sulfate are substantially higher in the
 9 eastern U.S. than in the West ([Hand et al., 2012c](#)). Based on air pollution monitoring
 10 network data (IMPROVE and CSN), sulfate concentrations on a national scale are
 11 steadily decreasing across the U.S. Between 1992 and 2010, annual mean sulfate
 12 concentrations at rural sites decreased fairly consistently at a rate of –2.7% per year. This
 13 decline has become even steeper more recently, with annual mean concentrations
 14 decreasing by an average of –4.6% per year from 2002 to 2010. The decrease appears to
 15 be due to decreasing SO₂ emissions from power plants ([Hand et al., 2012b](#)). While the
 16 nationwide trend is for a reduction in sulfate concentrations, there are seasonal and

1 regional increasing trends, specifically in the central and northern Great Plains in winter,
2 and in the western U.S. in spring ([Hand et al., 2012a](#)). Both sulfate and nitrate are
3 increasing at a rate of over 5% per year at several monitoring sites in the central and
4 northern Great Plains ([Hand et al., 2012c](#)).

Figure 2-34 Three-year average (2011–2013) surface concentrations of particulate sulfate based on monitoring data obtained at Clean Air Status and Trends Network sites (black dots).

1 [Figure 2-35](#) shows wet plus dry deposition of SO_x (SO₂ + SO₄²⁻) over the CONUS.
 2 Maximum deposition occurs over the Ohio River Valley (southeastern Ohio, West
 3 Virginia, and western Pennsylvania). [Figure 2-36](#) shows a good deal of spatial variability
 4 in the percentage of dry deposition across the CONUS. In the area of highest total
 5 deposition in the Mid-Atlantic states, dry deposition of SO₂ is dominant and dry
 6 deposition of pSO₄²⁻ is very minor component of dry deposition of SO_x. Wet deposition
 7 dominates in the Pacific Northwest, northern New England and in general in the central
 8 U.S. Note that deposition of organic sulfur species (e.g., methane sulfonic acid) or SO₂
 9 and/or SO₄²⁻ produced by the oxidation of organic S species is not included.

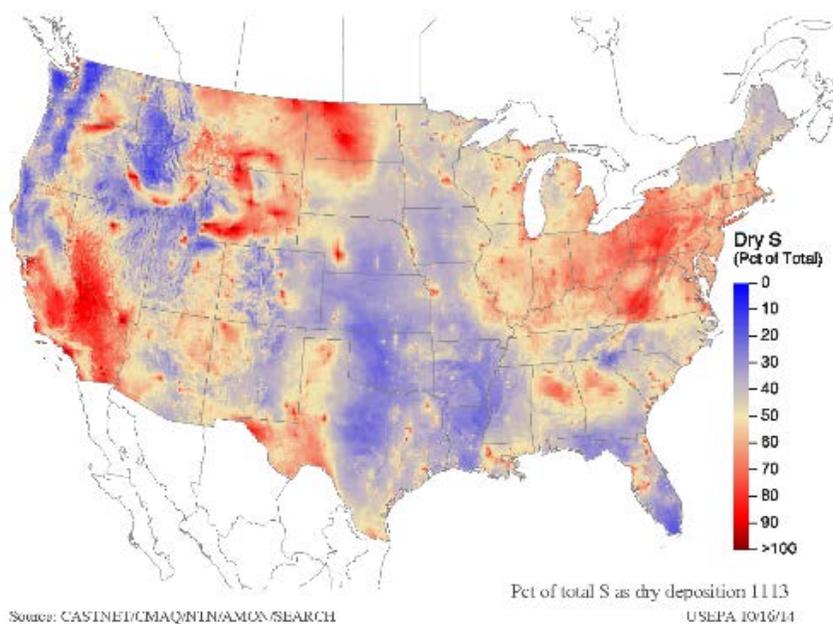

Source: CASTNET/CMAQ/NTN/AMON/SEARCH

S = sulfur.

Source: CASTNET/CMAQ/NTN/AMON/SEARCH.

Figure 2-35 Total deposition of sulfur (kg S/ha/yr) over the contiguous U.S. 2011–2013.

S = sulfur.
 Source: CASTNET/CMAQ/NTN/AMON/SEARCH.

Figure 2-36 Percentage of deposition of total sulfur as dry deposition over the contiguous U.S. 2011–2013.

1 [Figure 2-37](#) and [Figure 2-38](#) show that the pattern for changes in wet deposition of SO_4^{2-}
 2 is similar to that for NO_3^- with strongest decreases in the East, but with many areas in the
 3 western U.S. showing some increase. Reasons for this increase are similar to those for
 4 NO_3^- as noted by [Hand et al. \(2012a\)](#).

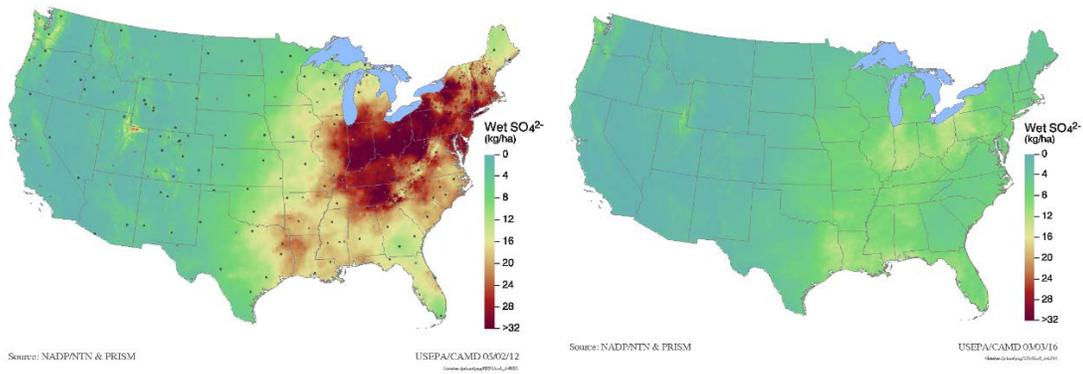

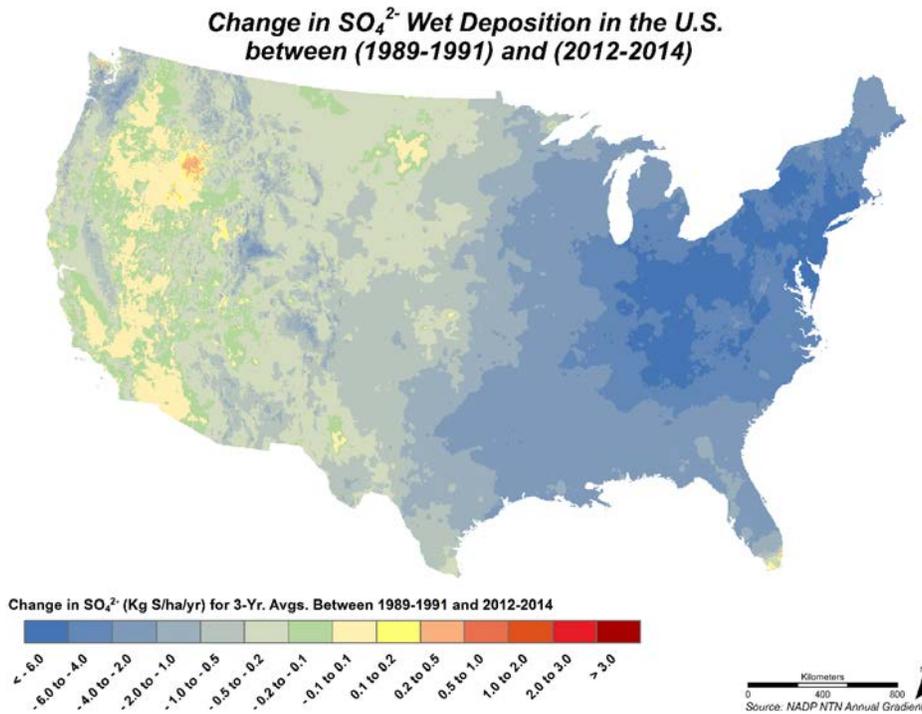

Figure 2-37 (Left) sulfate wet deposition, 1989–1991; (Right) sulfate wet deposition, 2012–2014.

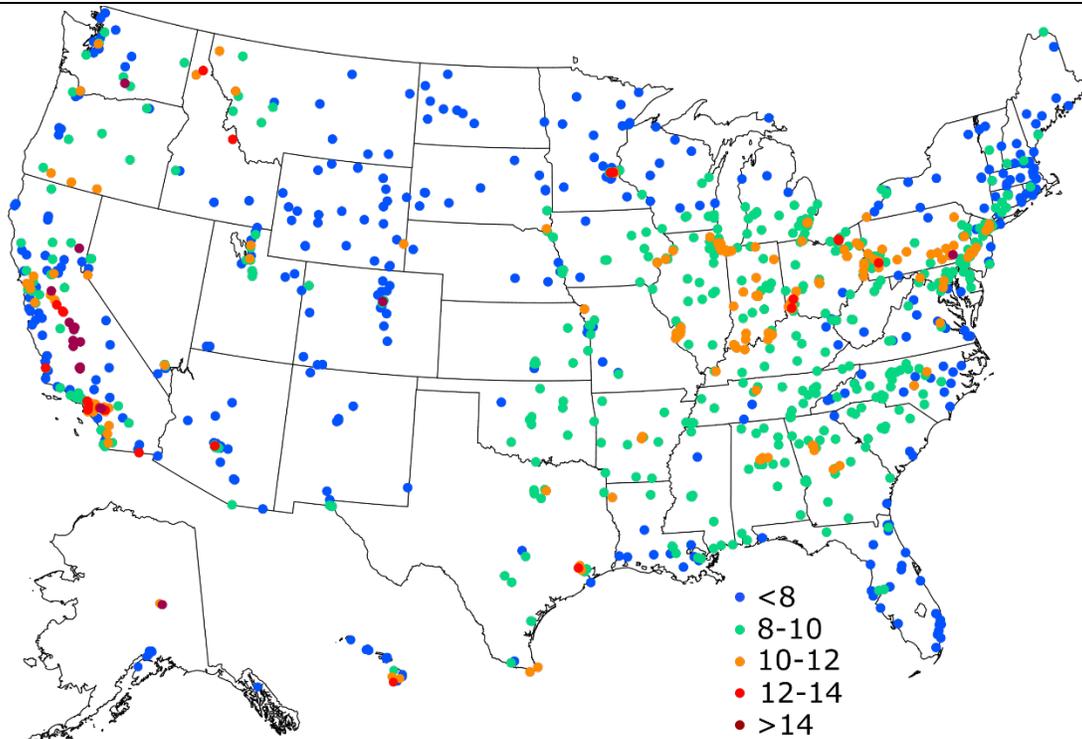

S = sulfur; SO_4^{2-} = sulfate.

Figure 2-38 Difference in wet deposition of sulfate (kg S/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2012 to 2014. The range of positive values is much smaller than for negative values.

1 The increases in wet deposition of SO_4^{2-} in the north-central U.S. correspond to those for
2 NO_3^- and are in the immediate vicinity of the Bakken Shale. There is a high degree of
3 interannual variability in deposition in some areas, especially those showing increases
4 (e.g., Logan, UT/Idaho), making source attribution difficult. Trends in total (wet + dry)
5 deposition of sulfur between 2000 and 2013 are described with maps in [Appendix 2.7](#).

2.6.6. Particulate Matter (PM)

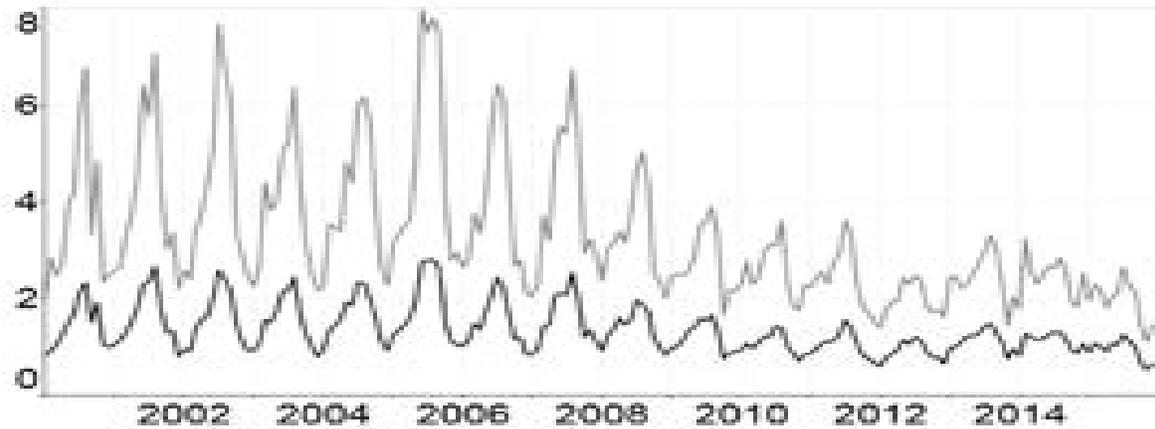

6 [Figure 2-39](#) shows the 3 year mean of the 24-hour $\text{PM}_{2.5}$ concentrations for $\text{PM}_{2.5}$
7 network monitoring sites across the U.S. from 2013–2015. Emissions are not shown
8 because the majority of $\text{PM}_{2.5}$ mass is often produced by atmospheric reactions (see
9 [Appendix 2.3](#)). Some of the highest $\text{PM}_{2.5}$ concentrations are in the San Joaquin Valley
10 and the Los Angeles-South Coast Air Basin of California. However, in general 3-year
11 average 24-hour $\text{PM}_{2.5}$ concentrations are higher in the Eastern U.S. than in the Western
12 U.S. An area of the highest concentrations in the Eastern U.S. can be seen in the Ohio
13 Valley. From [Appendix 2.3.6](#) is the same area where SO_4^{2-} and NO_3^- account for the
14 greatest fraction of $\text{PM}_{2.5}$, indicating that at least in the Eastern U.S., the highest $\text{PM}_{2.5}$
15 concentrations also correspond to PM with greatest fraction mass account for by SO_4^{2-}
16 and NO_3^- .

Source: U.S. Source: EPA 2016 analysis of Air Quality System network data 2013–2015.

Figure 2-39 3-year average concentrations of particulate matter smaller than 2.5 μm diameter (PM_{2.5}) 2013–2015.

1 A further indication that the fraction of mass contributed by SO₄²⁻ and NO₃⁻ may increase
 2 with increasing PM_{2.5} concentration is demonstrated by [Figure 2-40](#). [Figure 2-40](#) shows
 3 that a decrease in national average PM_{2.5} between 2000 and 2015 is paralleled by a
 4 similar decrease in SO₄²⁻. Since SO₄²⁻ has been the most abundant component of PM_{2.5},
 5 the steep decline in SO₂ emissions ([Appendix 2.2](#)) has led to a sharper decrease in SO₄²⁻
 6 concentrations than in concentrations of other PM_{2.5} components. As indicated by
 7 [Figure 2-39](#), in those areas where SO₄²⁻ concentrations remain high, the SO₄²⁻ fraction of
 8 PM_{2.5} mass is also still high in the Eastern U.S.

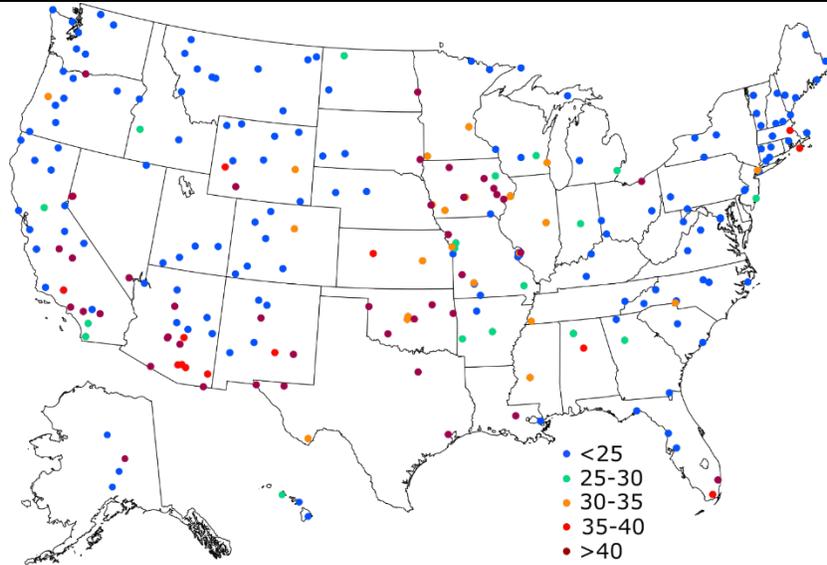

Notes: **back** = mean, **gray** = 90th percentile.

Source: [Chan et al. \(2018\)](#).

Figure 2-40 National monthly average concentrations of particulate matter smaller than 2.5 µm diameter (PM_{2.5}; top) and sulfate in PM_{2.5} (bottom) from 2000–2015 (concentrations in µg/m³).

1 For completeness, [Figure 2-41](#) shows PM_{10-2.5} concentrations. The highest concentrations
 2 are observed in Southwest and Great Plains. These are the same areas where crustal
 3 material accounts for the greatest fraction of PM_{2.5} as described in [Appendix 2.3.6](#), and
 4 PM_{10-2.5} is also largely composed of crustal material, which has little impact on acid or
 5 nutrient deposition.

Source: EPA 2016 analysis of Air Quality System network data 2013–2015.

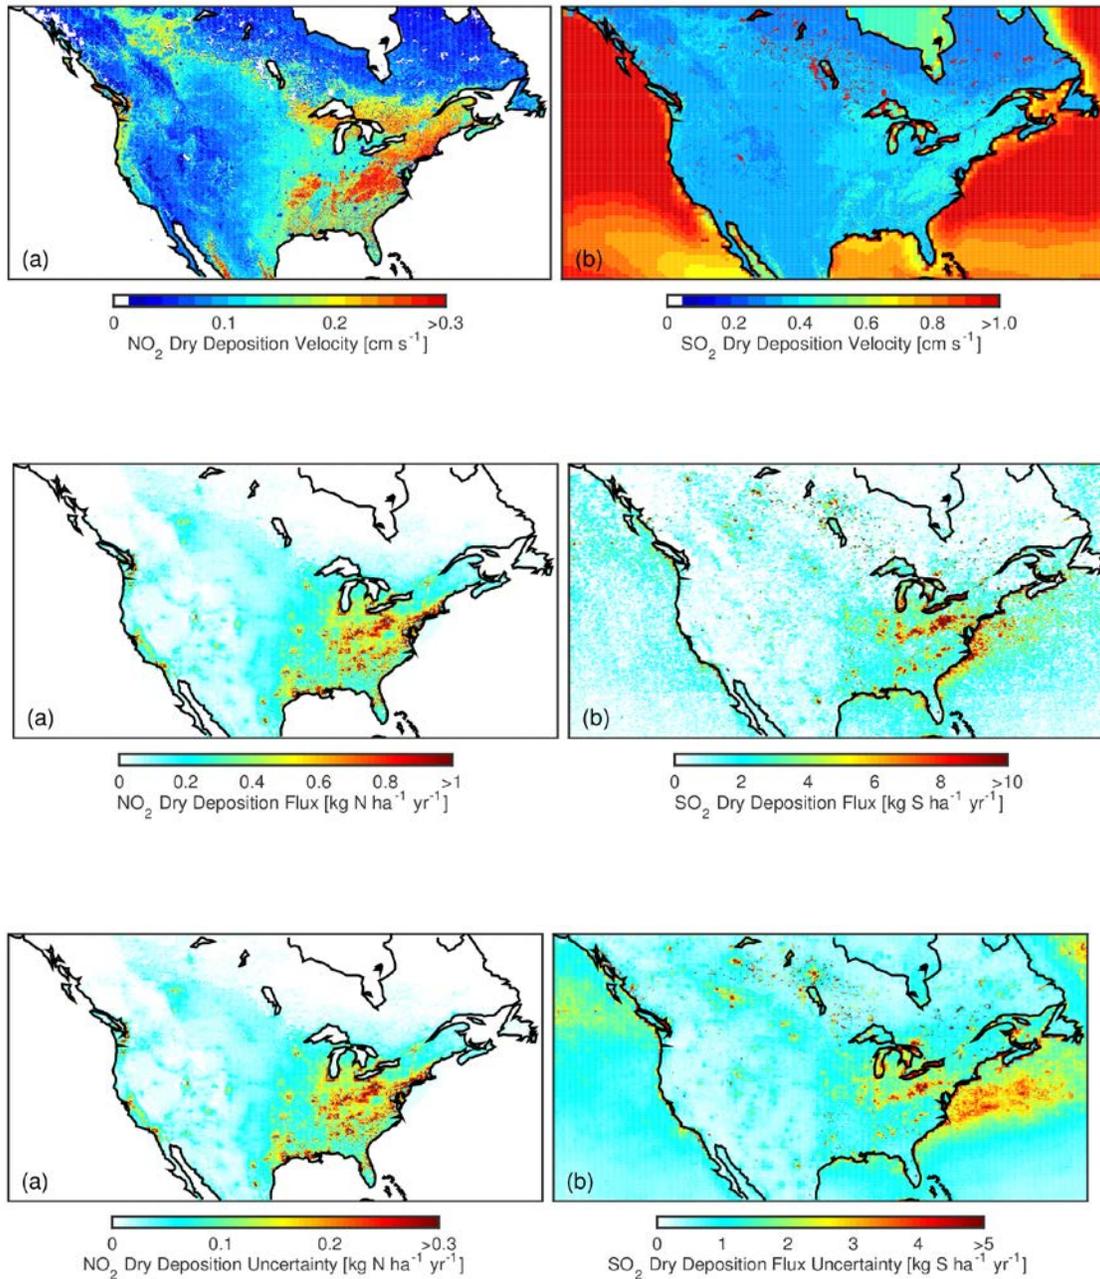

Figure 2-41 98th percentile concentrations for PM_{10-2.5} between 2013–2015.

2.6.7. Distributions of Dry Deposition of Nitrogen Dioxide and Sulfur Dioxide Derived Using Satellite-Based Measurements and Chemistry Transport Models

1 [Figure 2-42](#) shows the annual average dry deposition velocities and fluxes of NO₂ and
 2 SO₂ for 2005 to 2007 and their estimated uncertainties derived by [Nowlan et al. \(2014\)](#)
 3 using data derived from the Ozone Monitoring Instrument (OMI) on board the Aura
 4 satellite and model parameters from the GEOS-Chem three-dimensional,
 5 chemistry-transport model.

6 As shown in [Figure 2-42](#), higher fluxes for both NO₂ and SO₂ occur in the East than in
 7 the West. In particular, there is a band of high dry deposition for NO₂ and SO₂ along the
 8 Ohio River. High depositional fluxes for NO₂ are also seen along the Northeast Corridor
 9 and in scattered locations throughout the East. In addition, there is a noticeable plume of
 10 SO₂ over the western Atlantic Ocean. Average, relative uncertainty in the flux estimates
 11 for both NO₂ and SO₂ are ~30% over land and are not much higher over the Atlantic
 12 Ocean south of Massachusetts and Nova Scotia. Increased SO₂ deposition, especially
 13 near shore, is expected based on the likelihood of off-shore transport of SO₂ and NO₂
 14 along with other pollutants by synoptic weather systems. Note that bidirectional exchange
 15 for NO₂ (and a number of other gases) has not been implemented yet in GEOS-Chem or

1 in CMAQ. Note also that in this study, the algorithms used to derive NO₂ and SO₂
2 columns are older than more recent ones with lower detection limits. These results,
3 however, do illustrate the potential of the hybrid, satellite/model approach for mapping
4 deposition at the continental scale.

N = nitrogen; NO₂ = nitrogen dioxide; S = sulfur; SO₂ = sulfur dioxide.

Source: [Nowlan et al. \(2014\)](#).

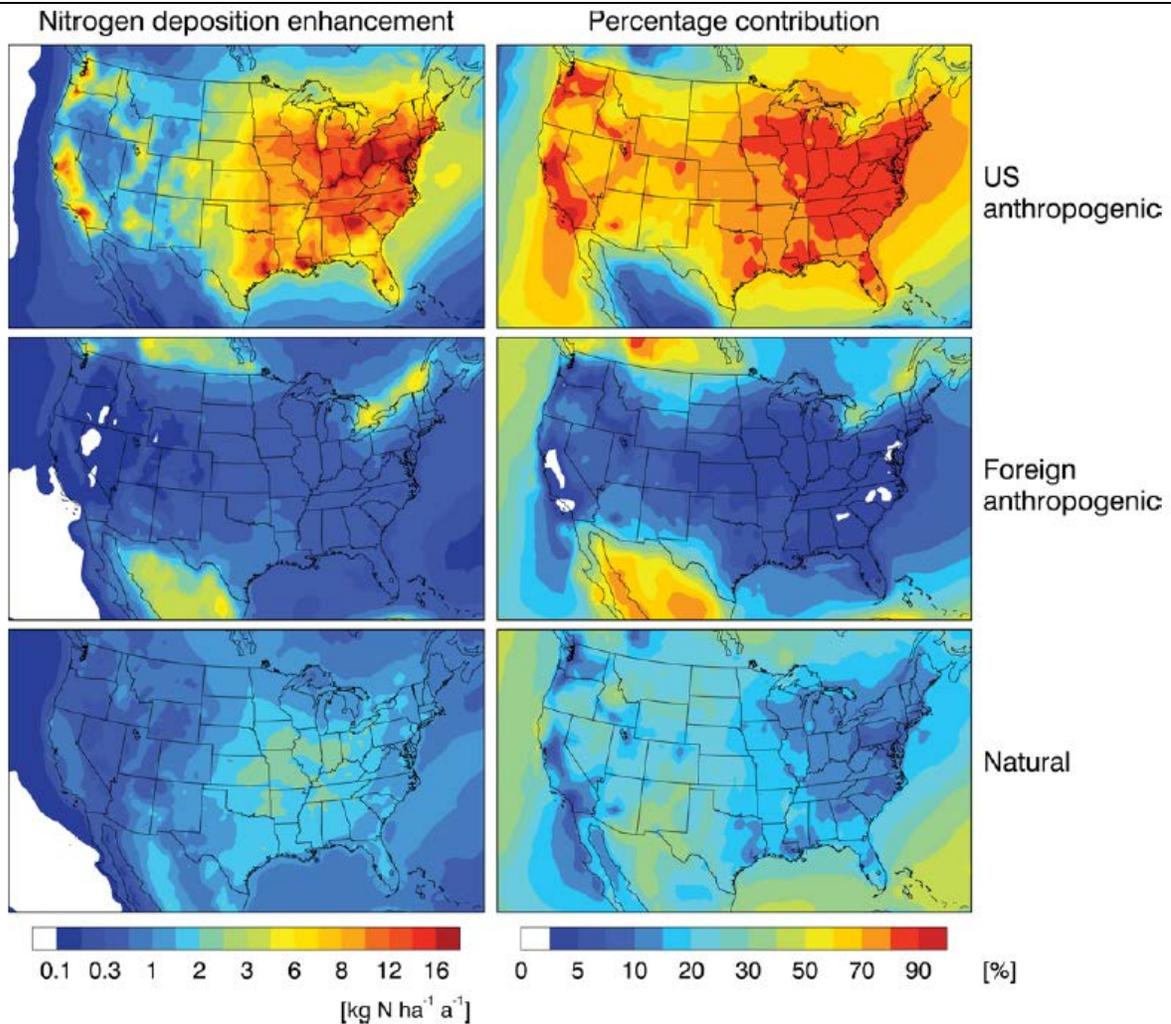

Figure 2-42 Top panel: modeled deposition velocities for nitrogen dioxide and sulfur dioxide for 2005 to 2007; middle panel Satellite-model estimates of annual mean dry deposition fluxes of nitrogen dioxide and sulfur dioxide; bottom panel: uncertainties in estimates.

2.6.8. Background Concentrations and Deposition

1 Background refers here to those concentrations or fluxes that do not result from U.S.
2 anthropogenic emissions. Background sources of N include natural sources like lightning,
3 wildfires, and emission from soils. Background sources of SO_x include natural sources,
4 such as volcanos or oxidation of reduced sulfur species (H₂S, [CH₃]₂S) emitted in
5 anaerobic environments, and anthropogenic sources from outside the U.S. Background
6 levels so defined facilitate separation of pollution levels that can be controlled by U.S.
7 regulations (or through international agreements with neighboring countries) from levels
8 that are generally uncontrollable by the U.S.

9 [Kim et al. \(2014a\)](#) found increases in nitrate concentrations in the mixed layer of the
10 North Pacific Ocean, extending to near-shore areas off the west coast of the U.S., with
11 attendant changes in the status of N limitation. Because NH₃ and NH₄⁺ are so highly
12 soluble, they are likely to be removed in rain during ascent before trans-Pacific transport.
13 Because SO₂ is much less soluble than NH₃, it can be transported to the free troposphere
14 by the warm conveyor belt system before it is oxidized to SO₄²⁻ in cloud droplets or on
15 the surfaces of mineral dust particles. The survivability of nitrate is intermediate,
16 depending on the form the nitrate takes.

17 [Zhang et al. \(2012a\)](#) computed N deposition rates from background sources and from
18 domestic anthropogenic sources using GEOS-Chem. According to their estimates, most
19 of the eastern U.S. and parts of states along the Pacific Coast received >10 kg/ha/yr N
20 deposition. The version of GEOS-Chem used (8.2.3) is the same as described in [Zhang et](#)
21 [al. \(2011a\)](#) and used in the 2013 ISA for Ozone and Other Photochemical Oxidants ([U.S.](#)
22 [EPA, 2013c](#)). [Figure 2-43](#) shows contributions from domestic anthropogenic, foreign
23 anthropogenic, and natural emissions to total (wet + dry) annual nitrogen deposition over
24 the CONUS for 2006 calculated by [Zhang et al. \(2012a\)](#) using the GEOS-Chem global
25 scale CTM with a horizontal resolution of 1/2° by 2/3°.

Source: [Zhang et al. \(2012a\)](#).

Figure 2-43 Contributions to oxidized and reduced nitrogen deposition from U.S.: anthropogenic (top), foreign anthropogenic (middle), and natural sources (bottom).

1 The upper panel of [Figure 2-43](#) shows that highest values from U.S. anthropogenic
 2 sources are found in the eastern U.S., in and downwind of the Ohio River Valley, and in
 3 and around urban areas. The middle panel of [Figure 2-43](#) shows highest contributions
 4 from foreign anthropogenic sources in regions of the CONUS bordering Canada and
 5 Mexico. Note the band of highest contribution in upper New York State as a result of
 6 emissions in southern Canada. There is also some indication in the Pacific Northwest of
 7 smaller contributions due to transport from Eurasia. The pattern of N deposition in the
 8 simulation for natural sources in [Figure 2-43](#) (bottom panel), however, shows maximum

1 deposition throughout the central U.S., with the highest values over the Midwest,
2 reflecting a combination of NO_y emissions from lightning in the south-central U.S., from
3 biomass burning throughout the Southeast, and from soils, mainly in the Midwest. The
4 background contribution to N deposition is typically <30% over the eastern U.S. and
5 typically 30 to 50% in the western U.S. where N deposition is already lower. Overall,
6 according to these simulations, U.S. anthropogenic emissions account for 78% of N_r
7 deposition over the CONUS. Foreign anthropogenic emissions and natural emissions
8 account for 6 and 16% respectively of total N deposition in this model simulation.

9 Background concentrations of SO₂ were calculated using the MOZART-2 global model
10 of tropospheric chemistry ([Horowitz et al., 2003](#)) and were presented in the 2008 ISA for
11 Sulfur Oxides ([U.S. EPA, 2008c](#)). Background SO₂ concentrations are estimated to be
12 below 10 parts per trillion (ppt) over much of the U.S. Maximum background
13 concentrations of SO₂ of ~30 ppt are found in the western U.S. In the Northwest, where
14 there are large geothermal sources of SO₂, the contribution of background sources to total
15 SO₂ is 70 to 80%; however, absolute SO₂ concentrations are still on the order of ~2 ppb
16 or less. With the exception of the West Coast, where volcanic SO₂ emissions cause high
17 background concentrations, background sources contribute <1% to present-day SO₂
18 concentrations in surface air in the CONUS. Over the eastern U.S., the predicted
19 background contribution to SO_x deposition was <10% and even smaller (<1%) where
20 present-day SO_x deposition is highest. The predicted contribution of background sources
21 to S deposition was highest in the western U.S. at >20% because of the geothermal
22 sources of SO₂ and oxidation of DMS in surface water of the eastern Pacific. In
23 comparison, values observed at several relatively remote sites cited in the 2008 ISA for
24 Sulfur Oxides ([U.S. EPA, 2008c](#)) ranged from 20 to 40 ppt.

25 As noted earlier, volcanic sources of SO₂ in the U.S. are found in the Pacific Northwest,
26 Alaska, and Hawaii. The greatest potential domestic effects from volcanic SO₂ occur on
27 the island of Hawaii. Nearly continuous venting of SO₂ from Mauna Loa and Kilauea
28 produces SO₂ in high concentrations of ~5 ppm lasting for periods of up to 1 hour [see
29 Figure 2-34 and Figure 2-35 in the 2008 ISA for Sulfur Oxides; ([U.S. EPA, 2008c](#))] at
30 two national park sites near the Kilauea caldera and the nearby east rift zone. The latter
31 emits several times as much SO₂ as the Kilauea caldera. The two measurement sites
32 within the national park are <3 km from the summit emission source and ~10 km from
33 the east rift source and are affected by the two sources during southerly and easterly
34 winds. A number of communities and population centers are within the same distance
35 from the east rift gas source that affects these two monitoring sites. When the normal
36 trade wind flows are disrupted, emissions from the sources can be brought directly to
37 these various communities. Because these communities are located at a similar distance
38 from the large east rift emission source as the national park monitoring stations, it is

1 probable that these communities are subjected to SO₂ concentrations as high as those
2 measured within Hawaii Volcanoes National Park.

3 When considering emission sources further afield, intercontinental transport of O₃ and
4 PM has been the focus of efforts by the Task Force on Hemispheric Transport of Air
5 Pollution (HTAP). To the extent that N and S species are transported along with O₃ and
6 PM, they also contribute to deposition following subsidence to the surface. Modeling
7 studies estimate that only a small fraction of nitrogen and sulfur emissions are transported
8 to and deposited within a continent different than the source of the emissions ([Stock et
9 al., 2013](#); [Roy et al., 2012](#); [Sanderson et al., 2008](#)). Global scale modeling results
10 reported in the 2008 ISA ([U.S. EPA, 2008a](#)) and in the latest ISAs for Oxides of Nitrogen
11 Health Criteria ([U.S. EPA, 2016f](#)) and Sulfur Oxides Health Criteria ([U.S. EPA, 2017c](#))
12 also indicate that intercontinental transport of oxidized and reduced nitrogen, SO₂, and
13 SO₄²⁻ are likely minor background sources of these species. Of greater importance are
14 localized emissions from natural sources. These include emissions of NO from soils and
15 lightning and emissions of SO₂ from geothermal and biogenic sources.

16 Background PM_{2.5} concentrations that would occur in the U.S. in the absence of
17 anthropogenic emissions in continental North America were reported in the 2009 PM ISA
18 ([U.S. EPA, 2009a](#)). They include contributions from natural sources throughout the world
19 and from anthropogenic sources outside continental North America. These are both
20 primary and secondary natural and anthropogenic components. Estimated PM_{2.5} were
21 estimated to be less than 1 µg/m³ on an annual basis, with maximum daily average values
22 in a range from 3 to 20 µg/m³ and a peak of 63 µg/m³ at the nine national park sites
23 across the U.S. ([U.S. EPA, 2009a](#)).

24 Just as pollutants can be transported into the U.S., they can also be transported outward.
25 For example, wet deposition of pollutants emitted in eastern North America occurs over
26 the North Atlantic Ocean. Deposition of N species is an important source of nutrients to
27 the western North Atlantic ([Zamora et al., 2011](#)). [Dennis et al. \(2013\)](#), based on CMAQ
28 modeling results, estimated that ~1/3 of oxidized N emissions and slightly less than 1/3
29 of NH₃ emissions in the U.S. are transported out over the North Atlantic Ocean. Although
30 the average pH of rainwater at Bermuda is ~5, reflecting deposition of acidic species
31 emitted in North America, this additional source of acidity is at most only ~2% of that
32 due to anthropogenic CO₂ ([Bates and Peters, 2007](#)).

33 With well-validated models, it is possible to compare the relative role of different
34 emission and removal processes. Adj oint models ([Henze et al., 2009](#)) are particularly
35 useful for understanding the relative contribution of emission sources to dry and wet
36 deposition of different nitrogen and sulfur containing compounds. For example, [Lee et al.
37 \(2016\)](#) found that half of nitrogen deposition at Federal Class I areas, such as national

1 parks, can be attributed to emission sources within 500 km and 90% of nitrogen
2 deposition is due to emission sources within 1,500 km. (Malm et al., 2013) simulated
3 conservative tracer transport from ammonia source regions with the GEOS-Chem model
4 to estimate that roughly equal amounts of ammonia deposition in Rocky Mountain
5 National Park (RMNP), CO was from within or outside Colorado, with most of the
6 transport into Colorado coming from the West. Thompson et al. (2015) reported that 40%
7 reduced nitrogen deposition in RNMP was from outside Colorado.

8 Background rainwater pH and background deposition in remote areas worldwide has
9 considerably lower H⁺ and N deposition levels than in more populated areas, as described
10 in Appendix 2.6. Galloway et al. (1982) measured the pH of rainwater at five remote sites
11 worldwide and measured pH values ranging from 4.8 to 5.0. At some sites acidity was
12 attributed to long range transport of acid sulfate, while at others a mixture of strong and
13 weak acids attributed to both anthropogenic and natural sources was observed. They
14 concluded that a pH of 5 was a good lower limit estimate for natural contributions. Curtis
15 et al. (2018) estimated nitrogen and sulfur deposition in remote inland areas of Greenland
16 and reported 0.13 to 0.19 kg N/ha/yr for total nitrogen, 0.8 to 0.11 kg N/ha/yr for NO₃⁻,
17 0.05 to 0.09 kg N/ha/yr for NH₄⁺, and 0.08 to 0.13 kg S/ha yr for SO₄²⁻.

2.7. Supplemental Material on Changes in Deposition since 2000

18 Maps on the portion of the NADP website dedicated to the Total Deposition (TDEP)
19 program (<http://nadp.sws.uiuc.edu/committees/tdep/tdepmaps/>) and shown in this section
20 present a comprehensive overview of changes in various parameters related to deposition
21 over 2000–2013. Changes between two, 3-year periods, 2000 through 2002 and 2011
22 through 2013 are summarized in this section. The most notable changes in the
23 geographical distribution of total (wet + dry) deposition of NO_y + NH_x between these
24 two time periods are found in areas with extensive agriculture (e.g., the San Joaquin
25 Valley, southern Idaho/northern Utah, and the Midwest), which show large increases in
26 total deposition of N (see Figure 2-44). There are also shifts in the distribution of wet and
27 dry deposition towards a greater predominance of dry deposition in these areas (see
28 Figure 2-45, Figure 2-46, and Figure 2-47). Deposition of oxidized nitrogen has declined
29 markedly throughout the eastern U.S. and southern California between the periods
30 2000–2002 and 2011–2013 (see Figure 2-48, Figure 2-49, Figure 2-50, and Figure 2-51)
31 due mainly to large decreases in dry deposition of total nitrate (TNO₃ = HNO₃ + pNO₃⁻;
32 see Figure 2-52). The decreases in total nitrate across the CONUS are generally due to
33 decreases in HNO₃ (see Figure 2-53). Decreases in dry deposition of pNO₃⁻ have
34 generally been smaller, reflecting the smaller contribution of pNO₃⁻ to TNO₃. Exceptions
35 include areas such as Florida, Texas, and southern California where dry deposition of

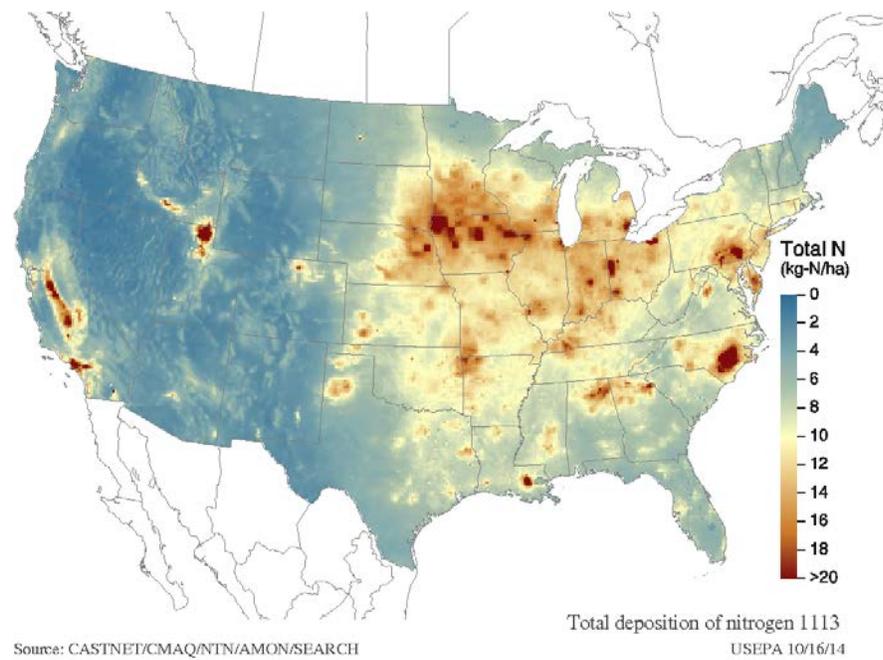

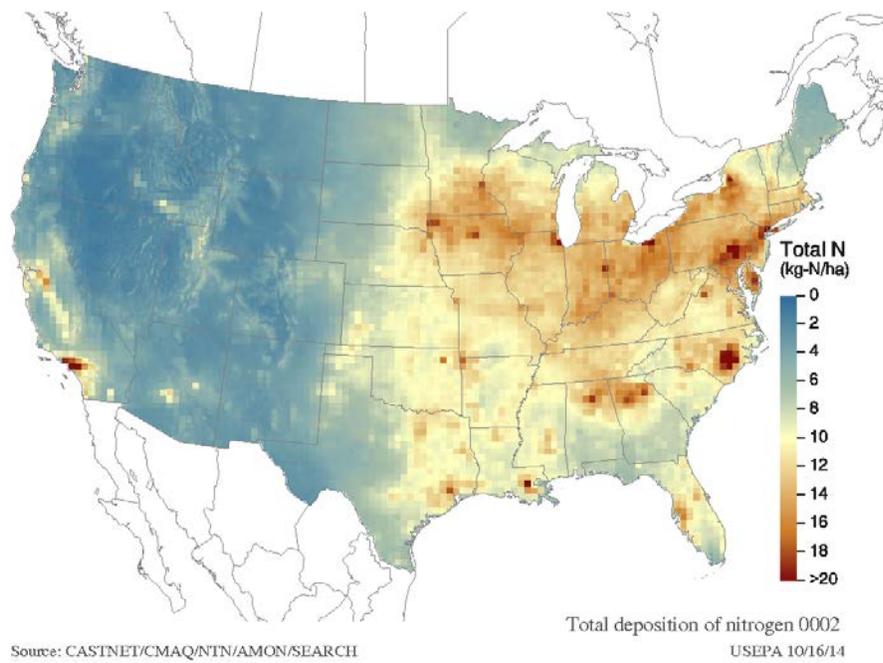

1 pNO₃⁻ has been much greater than HNO₃ in the earlier period and has decreased
2 substantially (see [Figure 2-54](#)). Other N species, mainly NO₂ also show large decreases
3 (see [Figure 2-55](#) and [Figure 2-56](#)), especially near urban source areas. Using OMI data,
4 [Krotkov et al. \(2016\)](#) found decreases in column (vertically integrated) abundances of
5 NO₂ of ~40% from 2005 to 2014 over the U.S.

6 In contrast to deposition of oxidized N, deposition of reduced inorganic N has seen large
7 increases (see [Figure 2-57](#) and [Figure 2-58](#)). Several hotspots (the San Joaquin Valley,
8 southern Idaho, and several areas in the central and eastern U.S.) have increased
9 markedly in size (see [Figure 2-57](#)) between the two periods. Dry deposition of NH₃ has
10 been the major contributor to the increase (see [Figure 2-59](#)), while dry deposition of
11 pNH₄⁺ has largely decreased between the two periods (see [Figure 2-60](#)). Between the two
12 periods, emissions of NO_x have decreased resulting in lower formation rates of HNO₃
13 that could react with NH₃ to form pNH₄NO₃.

14 Deposition of oxidized and reduced N have undergone geographic shifts with
15 corresponding shifts in the contributions of each to total N deposition on regional and
16 smaller scales (compare [Figure 2-48](#) and [Figure 2-49](#) to [Figure 2-57](#) and [Figure 2-58](#)).
17 For example, deposition of oxidized N in the Northeast has decreased substantially, but
18 deposition of reduced N has increased substantially in the central U.S. Sizable shifts are
19 also seen in the fractional contributions of total N deposition as dry deposition of both
20 oxidized and reduced forms (compare [Figure 2-47](#) and [Figure 2-62](#)).

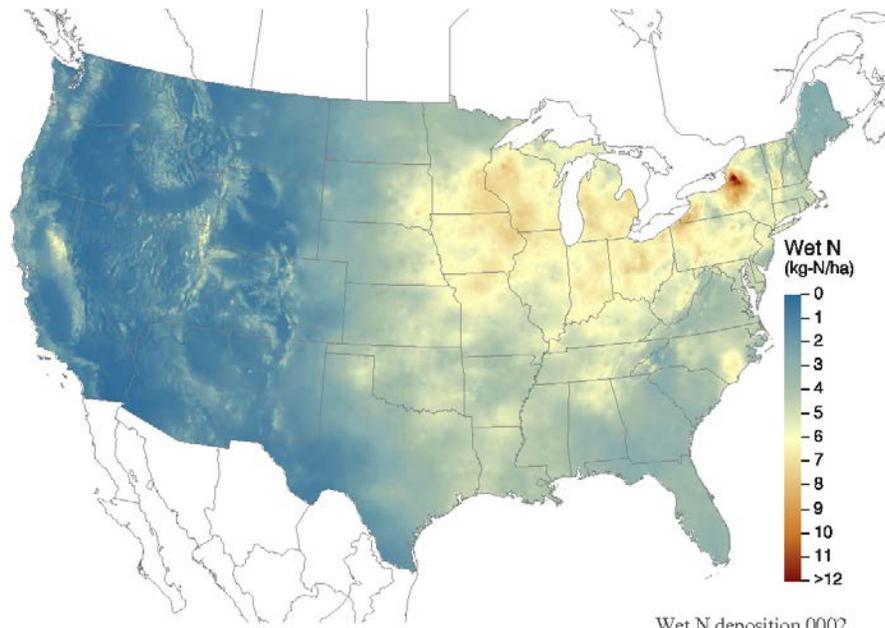

21 Substantial declines in the deposition of S have occurred over the past 15 years,
22 particularly in the Ohio River Valley (see [Figure 2-63](#)), with generally much smaller
23 declines in wet deposition (see [Figure 2-64](#)) than for dry deposition (see [Figure 2-65](#)).
24 Despite these declines, S deposition is still highest in the Ohio River Valley. Except for
25 small shifts in several areas, the proportion of S dry deposited has been rather similar (see
26 [Figure 2-66](#)). Dry deposition of SO₂ is still dominant over pSO₄²⁻—in eastern Ohio and
27 central Pennsylvania (compare [Figure 2-66](#) and [Figure 2-67](#) to [Figure 2-68](#)). These
28 decreases are consistent with those derived by [Krotkov et al. \(2016\)](#) who detected
29 decreases in the column (vertically integrated) abundance of SO₂ of ~75 % for the period
30 2005 to 2014 over the Ohio River Valley and southwestern Pennsylvania. These
31 decreases reflect reductions in emissions mandated by the Clean Air Act Amendments
32 and other regulatory requirements.

33 As noted earlier, these estimates of change in deposition were derived from CMAQ
34 output and data from measurement networks. Each of these components has its own set
35 of uncertainties, and the estimates of deposition and the changes over time should be
36 viewed in this light.

APPENDIX 3. DIRECT PHYTOTOXIC EFFECTS OF GASEOUS OXIDIZED NITROGEN AND SULFUR ON VEGETATION

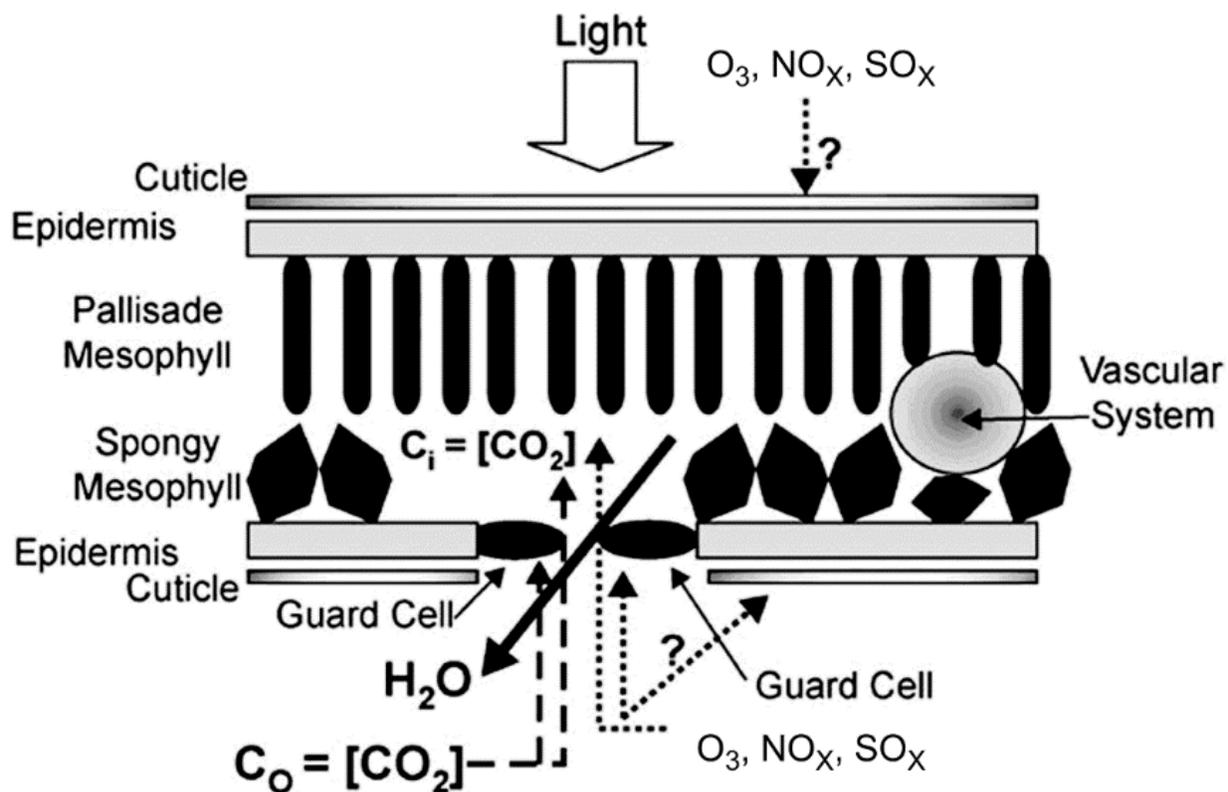

1 This appendix provides a brief overview of the exposure and phytotoxic effects of
2 gaseous forms of oxidized nitrogen (N) and sulfur (S) compounds on vegetation. The
3 main focus of this ISA is understanding the ecological impact of oxidized N and S and
4 that the major effects of these compounds on ecosystems are through acidifying
5 deposition and N enrichment deposition. However, direct effects of gaseous oxidized N
6 and S could augment the effects of deposition on vegetation, and direct effects of gaseous
7 N and S may be apparent in some areas. The effect of sulfur dioxide (SO₂) gas on
8 vegetation is discussed in [Appendix 3.2](#). [Appendix 3.3](#) discusses the effects of nitric
9 oxide (NO), nitrogen dioxide (NO₂), and peroxyacetyl nitrate (PAN) on vegetation.
10 [Appendix 3.4](#) presents information on the direct effects of nitric acid (HNO₃) vapor on
11 vegetation, including lichens. A summary section with causal determinations based on a
12 synthesis of the body of information on the biological effects of exposure to these gases
13 is presented in [Appendix 3.5](#).

3.1. Introduction

14 The effects of gaseous pollutants such as SO₂, NO₂, NO, HNO₃, and ozone (O₃) on
15 vegetation have been studied since at least the early 19th century ([Holmes et al., 1915](#);
16 [Haywood, 1905](#)). Methodologies have been developed to study the effects of gaseous
17 exposures to these pollutants in the laboratory, greenhouse, and in the field. The
18 methodologies to study the effects of gaseous pollutants on vegetation have been recently
19 reviewed in the 2013 Ozone ISA and 2006 Ozone AQCD [Air Quality Criteria
20 Document; ([U.S. EPA, 2013c, 2006a](#))]. A thorough description of the methodologies
21 used to expose vegetation to gaseous pollutants can be found in Section 9.2 of the 2013
22 Ozone ISA ([U.S. EPA, 2013c](#)), AX9.1 of the 2006 Ozone AQCD ([U.S. EPA, 2006a](#)), and
23 Section 9.2 in the 1993 Oxides of Nitrogen AQCD ([U.S. EPA, 1993](#)).

24 Uptake of gaseous pollutants in a vascular plant canopy is a complex process involving
25 adsorption to surfaces (leaves, stems, and soil) and absorption into leaves. These
26 pollutants penetrate into leaves primarily in gaseous forms through the stomata. The
27 surface cuticle provides a protective barrier to gaseous pollutant exposure, although there
28 is evidence for limited uptake across the cuticle ([Zhang et al., 2003](#); [Kerstiens et al.,](#)
29 [1992](#)). Pollutants must be transported from the bulk air to the leaf boundary layer to reach
30 the stomata. The transport of pollutants through a boundary layer into the stomatal region

1 is by diffusion. Studies of transport through the boundary layer are based on aerodynamic
2 concepts and usually relate to smooth surfaces that are not typical of leaf-surface
3 morphology ([Gates, 1968](#)). Once through the boundary layer, the gas enters the leaf
4 through the stomata. The entry of gases into a leaf is dependent upon gas-phase chemical
5 processes and physical characteristics of surfaces, including stomatal aperture. The
6 aperture of the stomata is controlled largely by the prevailing environmental conditions,
7 such as humidity, temperature, light intensity, and water availability. When the stomata
8 are closed, as occurs under dark or drought conditions, resistance to gas uptake is very
9 high and the plant has a very low degree of susceptibility to injury ([Figure 3-1](#)). The
10 stomatal control of uptake of gaseous pollutants is described in more detail in AX9.2 of
11 the 2006 Ozone AQCD ([U.S. EPA, 2006a](#)) and Section 9.3.1.5 of the 1993 Oxides of
12 Nitrogen AQCD ([U.S. EPA, 1993](#)). Note that unlike vascular plants, mosses and lichens
13 do not have a protective cuticle barrier to gaseous pollutants, which is a major reason for
14 their sensitivity to gaseous S and N.

Abbreviations: C_i = internal CO₂ in leaf; C_o = CO₂ of the atmospheric air; CO₂ = carbon dioxide; H₂O = water; SO_x = sulfur oxides; NO_x = oxides of nitrogen; O₃ = ozone.

Figure 3-1 The microarchitecture of a dicot leaf. While details among species vary, the general overview remains the same. Light that drives photosynthesis generally falls upon the upper (adaxial) leaf surface. Carbon dioxide, oxides of sulfur, oxides of nitrogen, and ozone gases generally enter by diffusion through the guard cells (or stomata) on the lower (abaxial) leaf surface, while water vapor exits through the stomata (transpiration).

3.2. Direct Phytotoxic Effects of Sulfur Dioxide on Vegetation

1 It has been known since the early 1900s that exposure to SO₂ can cause plant damage and
 2 death ([Wislicenus, 1914](#)). The large sources of historic SO₂ emissions were ore smelters.
 3 Sulfides in the ore were oxidized during smelting and resulted in large releases of SO₂.
 4 Emissions from large ore smelters in the U.S. and Canada resulted in large areas denuded
 5 of vegetation surrounding these facilities ([Thomas, 1951](#); [Swain, 1949](#)). Much of the

1 damage to the vegetation was due to acute effects of high concentrations of SO₂.
2 However, as early as 1923, researchers recognized that SO₂ might decrease plant growth
3 without producing acute symptoms of foliar injury ([Stoklasa, 1923](#)). In the 1950s through
4 the early 1980s, there was much research on the effects of SO₂ on vegetation, as well as
5 the interaction with pollutants such as O₃ and NO₂. Since then, there has been much less
6 research on the effects of SO₂ on vegetation, especially in the U.S., due to the decreasing
7 ambient concentrations of SO₂ ([U.S. EPA, 2012a](#)) (see [Figure 3-2](#) for max 3-hour SO₂
8 concentrations for 2016). The effects of SO₂ on vegetation are summarized below.

9 Currently, SO₂ is the only criteria pollutant with a secondary NAAQS distinct from the
10 primary standard. This standard is to protect acute foliar injury resulting from SO₂
11 exposure. The standard is a 3-hour average of 0.50 ppm and was promulgated in 1971 to
12 protect against the adverse effects of acute foliar injury in vegetation. The 1982 AQCD
13 for Particulate Matter and Sulfur Oxides concluded that controlled experiments and field
14 observations of vegetation supported retaining this secondary standard ([U.S. EPA, 1982b,](#)
15 [d, 1971](#)).

16 Acute foliar injury usually occurs within hours of exposure, involves a rapid absorption
17 of a toxic dose, and involves a collapse or necrosis of plant tissues. Another type of
18 visible injury is termed chronic injury and is usually a result of variable SO₂ exposures
19 over the growing season. After entering the leaf, SO₂ is converted to sulfite (SO₃²⁻) and
20 bisulfite (HSO₃⁻) ions, which may be oxidized to sulfate (SO₄²⁻). Sulfate is about
21 30 times less toxic than sulfite and bisulfite. The conversion of sulfite and bisulfite to
22 sulfate results in net H⁺ production in the cells. [Kropff \(1991\)](#) proposed that the
23 appearance of SO₂-induced leaf injury was likely due to a disturbance of intracellular pH
24 regulation. [Kropff \(1991\)](#) listed several studies in which the pH of homogenates of leaf
25 cells only shifted towards greater acidity when plants were lethally damaged from
26 long-term SO₂ exposures ([Jäger and Klein, 1977](#); [Grill, 1971](#); [Thomas et al., 1944](#)). The
27 appearance of foliar injury can vary significantly among species and growth conditions
28 (which affect stomatal conductance). Currently, there is no regular monitoring for SO₂
29 foliar injury effects in the U.S.

12

Besides foliar injury, long-term lower SO₂ concentrations can result in decreased photosynthesis, growth, and yield of plants. These effects are cumulative over the growing season and are often not associated with visible foliar injury. As with foliar injury, the effects of these injuries vary among species and growing environment. The 1982 Particulate Matter and Oxides of Sulfur (PM-SO_x) AQCD summarized the concentration-response information available at the time ([U.S. EPA, 1982b](#)). Effects on growth and yield of vegetation were associated with increased SO₂ exposure concentration and time of exposure. However, that document concluded that more definitive concentration-response studies were needed before useable exposure metrics could be identified. Because ambient SO₂ concentrations declined and focus on O₃ vegetation effects research increased, relatively few studies have emerged to better

1 inform a metric and levels of concern for effects of SO₂ on growth and productivity of
2 vegetation.

3 SO₂ is considered to be the primary factor causing the death of lichens in many urban and
4 industrial areas, with fruticose lichens being more susceptible to SO₂ than many foliose
5 and crustose species ([Hutchinson et al., 1996](#)). Damage to lichens in response to SO₂
6 exposure includes reduced photosynthesis and respiration, damage to the algal
7 component of the lichen, leakage of electrolytes, inhibition of N fixation, reduced K⁺
8 absorption, and structural changes ([Hutchinson et al., 1996](#); [Belnap et al., 1993](#); [Farmer et
9 al., 1992](#)). Significant reductions in lichen photosynthesis have been measured at
10 concentrations as low as 91 ppb over 2–4 hours ([Sanz et al., 1992](#); [Huebert et al., 1985](#)).
11 Damage to the algal component of the thallus is evidenced by its discoloration. The entire
12 thallus dies soon after algal cells are damaged ([Hutchinson et al., 1996](#)). At higher
13 concentrations, SO₂ deactivates enzymes by chemical modification, leading to reduced
14 metabolic activity and loss of membrane integrity ([Nieboer et al., 1976](#); [Ziegler, 1973](#)). In
15 addition, SO₂ binds to the central metal atoms of enzymes, adversely affecting membrane
16 function and cell osmolality. SO₂ also competitively inhibits bicarbonate (HCO₃⁻) and
17 dihydrogen phosphate (H₂PO₄⁻) interactions with enzymes ([Hutchinson et al., 1996](#)).
18 Low pH increases the toxicity of SO₂ action ([Farmer et al., 1992](#)). The toxic effects of
19 atmospheric deposition of SO₂ are lessened when lichens are attached to a substrate,
20 typically bark or rock, that has high pH or superior buffering capacity ([Richardson and
21 Cameron, 2004](#)). [van Herk \(2001\)](#) evaluated relationships between bark pH and air
22 pollution levels as two significant variables affecting epiphytic lichen composition and
23 concluded that bark pH was the primary factor regulating the distribution of acidophilic
24 species in the Netherlands. In studies of unpolluted areas, differences in bark chemistry
25 also affect the presence and distribution of epiphytes ([Farmer et al., 1992](#)). Indirect
26 changes to bark pH, caused by acidification and high SO₂ concentrations, also affect
27 lichen distribution ([Farmer et al., 1992](#)). In a more recent, [Geiser and Neitlich \(2007\)](#)
28 reported that direct SO₂ damage to lichens in the Pacific Northwest may have been
29 confined to major urban areas such as Seattle, Portland, and Bellingham. However, lichen
30 monitoring plots were not colocated with SO₂ monitors and the authors were not able to
31 quantify SO₂ exposure. More information on the N effects reported in this study is found
32 in [Appendix 6.3.7](#) and [Appendix 6.5.2](#).

33 More recent research has been performed in areas of Europe where ambient SO₂
34 concentrations are generally higher than in the U.S. Since the 2008 ISA, several studies
35 in Germany and some eastern European countries have indicated that direct effects of
36 SO₂ caused growth reductions in trees during the last century ([Cavlovic et al., 2015](#);
37 [Hauck et al., 2012](#); [Rydval and Wilson, 2012](#); [Elling et al., 2009](#)). [Elling et al. \(2009\)](#)
38 evaluated a large database providing long-term growth records of 1,010 silver firs (*Abies*

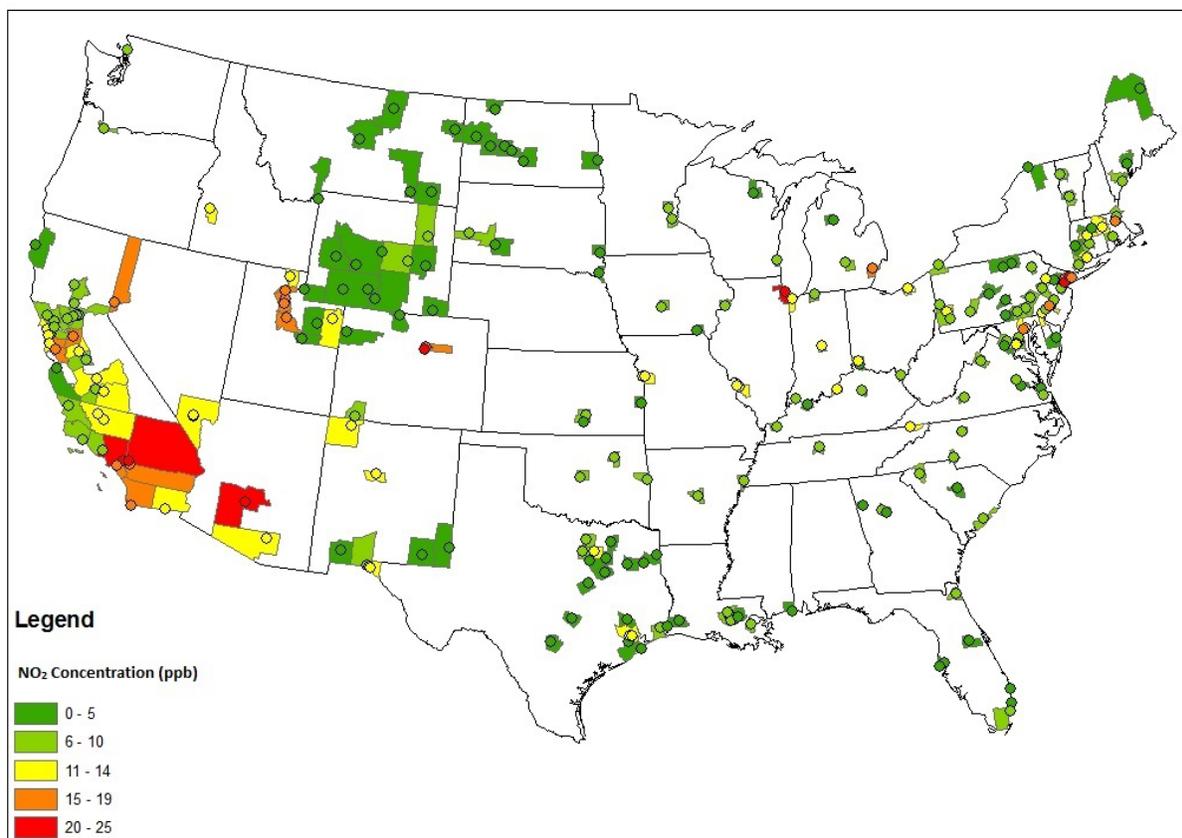

1 *alba*), long-term climate records, and long-term air pollution data from 51 sites in
2 southern Germany. In this analysis, silver fir growth was influenced by SO₂ pollution
3 more than any other factor in the second half of the last century. The study authors also
4 reported an almost immediate increase in growth in response to falling SO₂ emissions in
5 the 1980s. This rapid response indicates a direct effect of gaseous SO₂ rather than an
6 indirect effect of soil acidification, which would have a longer response time. Annual
7 average concentrations above 10 µg SO₂/m³ (approximately 4 ppb) appeared to reduce
8 growth of silver fir. (See [Figure 2-15](#) for recent concentrations in the continental U.S.). In
9 a later publication, [Bošela et al. \(2014\)](#) argued a combination of SO₂ and NO_x gas
10 emissions has historically reduced growth in silver fir in the western Carpathian
11 Mountains of the Czech Republic.

12 A similar gaseous SO₂ effect on tree growth may have been occurring in the eastern U.S.
13 Using tree ring analysis, [Thomas et al. \(2013\)](#) reported significant growth increases in
14 old-growth eastern red cedar (*Juniperus virginiana*) in West Virginia following decreases
15 in SO₂ emissions since 1980. Growth continued to increase as SO₂ emissions further
16 declined in the 1990s and 2000s. [Thomas et al. \(2013\)](#) also found evidence of
17 physiological changes in response to SO₂ emissions. The authors attributed the growth
18 response to an indirect effect of decreasing acidifying deposition, and thus, recovery from
19 soil acidification. However, a historical record of acidifying deposition was not available.
20 As in Europe, the trees studied in West Virginia also had a relatively rapid recovery in
21 response to declining SO₂ emissions that could indicate the effects were from direct
22 exposure to gases in the atmosphere rather than soil acidification. Further, a response to
23 this study from other researchers suggested that the eastern red cedars in the West
24 Virginia study were found on a limestone outcrop that could be well buffered from soil
25 acidification ([Schaberg et al., 2014](#)). This study may indicate that gaseous SO₂ alone or in
26 combination with other gases may have inhibited red cedar growth. See [Appendix 5.2.1.3](#)
27 for further discussion of this study.

3.3. Direct Phytotoxic Effects of Nitric Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate

28 In sufficient concentrations, nitric oxide (NO) and nitrogen dioxide (NO₂) can have
29 phytotoxic effects on plants by decreasing photosynthesis and inducing visible foliar
30 injury ([U.S. EPA, 1993](#)). The current secondary (welfare) and primary (human health)
31 standard for oxides of nitrogen is a NO₂ annual mean of 0.053 ppm. See [Figure 3-3](#) for
32 recent concentrations of NO₂. The 1993 Oxides of Nitrogen AQCD concluded that
33 concentrations of NO₂ or NO in the atmosphere are rarely high enough to have
34 phytotoxic effects on vegetation ([U.S. EPA, 1993](#)). Since the 1993 Oxides of Nitrogen

1 AQCD, very little new research has been done on these phytotoxic effects to alter this
2 conclusion ([Bender and Weigel, 2011](#)). However, it is known that these gases alter the N
3 cycle in some ecosystems, especially in the western U.S., and contribute to N saturation
4 ([Sparks, 2009](#); [Fenn et al., 2003a](#); [Bytnerowicz and Fenn, 1996](#)). See [Appendix 6.1](#) for a
5 discussion of the nutrient effects of N.

Note: NO₂ = nitrogen dioxide. Concentrations indicated are the highest concentration in the county and do not represent countywide concentrations.

Source: U.S. Environmental Protection Agency 2014 analysis of data from state and local air monitoring stations ([U.S. EPA, 2016f](#)).

Figure 3-3 Map of U.S. annual average nitrogen dioxide concentrations for 2013.

6 In general, NO and NO₂ enters leaves through the stomata ([Saxe, 1986](#)). However, the
7 leaf cuticle could be an important receptor for NO₂, and there is evidence of transport of
8 NO and NO₂ across isolated cuticles ([Lendzian and Kerstiens, 1988](#)). Several studies
9 have demonstrated that plant canopies can directly assimilate N in the form of NO₂, but

1 canopy uptake of NO₂ is generally small relative to total plant uptake ([Vallano and](#)
2 [Sparks, 2008](#); [Ammann et al., 1995](#); [Nussbaum et al., 1993](#); [Segschneider et al., 1993](#);
3 [von Ballmoos et al., 1993](#); [Hanson et al., 1989](#)). After entering the leaves, NO₂ dissolves
4 in the extracellular water of the substomatal cavity to form HNO₂ and HNO₃, which then
5 dissociate to form NO₂⁻, NO₃⁻, and H⁺ ([Bytnerowicz et al., 1998](#)). Both cell and tonoplast
6 membranes contain ATP-dependent H⁺ pumps, and the tonoplast pumps are strongly
7 inhibited by NO₃⁻ ([Bytnerowicz et al., 1998](#)). If extra protons are deposited in vacuoles of
8 the plant cells during normal cellular regulation, then additional acidity will occur in
9 combination with additional NO₃⁻. This combination can cause disruptions in cellular
10 control ([Taylor and MacLean, 1970](#)). NO₃⁻ and nitrite (NO₂⁻) are metabolized to amino
11 acids and proteins through a series of enzymatic reactions mainly involving NO₃⁻ and
12 nitrite reductases ([Amundson and MacLean, 1982](#)). The ability of plants to reduce NO₃⁻
13 and NO₂⁻ to amino acids and proteins determines the potential of the plant to detoxify
14 NO and NO₂ ([Wellburn, 1990](#)). Reduction of NO₃⁻ takes place outside of the chloroplast
15 while the reduction of NO₂⁻ is coupled with the light reactions of photosynthesis.
16 Therefore, when leaves are exposed to NO and NO₂ in the dark, highly phytotoxic levels
17 of NO₂⁻ accumulate and may lead to greater toxicity to NO and NO₂ at night ([Amundson](#)
18 [and MacLean, 1982](#)). Exposure to NO produces both NO₃⁻ and NO₂⁻ in the leaves, but
19 the rate of NO₃⁻ accumulation is much slower than NO₂⁻. Thus, plants exposed to high
20 NO could be at risk to elevated concentrations of NO₂⁻ ([Wellburn, 1990](#)). More detailed
21 information on the cellular effects of NO and NO₂ can be found in the 1993 Oxides of
22 Nitrogen AQCD.

23 The functional relationship between ambient concentrations of NO or NO₂ and a specific
24 plant response, such as foliar injury or growth, is complex. Factors such as inherent rates
25 of stomatal conductance and detoxification mechanisms and external factors, including
26 plant water status, light, temperature, humidity, and the particular pollutant exposure
27 regime, all affect the amount of a pollutant needed to cause symptoms of foliar injury.
28 Plant age and growing conditions and experimental exposure techniques also vary widely
29 among studies quantifying the response of plants to NO₂. An analysis conducted in the
30 1993 Oxides of Nitrogen AQCD of over 50 peer-reviewed reports on the effects of NO₂
31 on foliar injury indicated that plants are relatively resistant to NO₂, especially compared
32 to foliar injury caused by exposure to O₃ ([U.S. EPA, 1993](#)). With few exceptions, visible
33 injury has not been reported at concentrations below 0.20 ppm, and these exceptions
34 occurred when the cumulative duration of exposures extended to 100 hours or longer. At
35 0.25 ppm, increased leaf abscission was reported on navel orange trees (*Citrus sinensis*),
36 but only after exposures in excess of 1,000 hours ([Thompson et al., 1970](#)). Green bean
37 (*Phaseolus vulgaris*) plants used as bioindicators of NO₂ injury in Israel developed foliar
38 injury symptoms when ambient concentrations exceeded 0.5 ppm ([Donagi and Goren,](#)
39 [1979](#)). In most plants, injury occurred in less than 1 day only when concentrations

1 exceeded 1 ppm ([U.S. EPA, 1993](#)). In recent years (2011–2013), ambient hourly NO₂
2 concentrations in the U.S. have been well below the exposures in the above studies with
3 maximum highest 1-hour daily concentrations less than 0.075 ppm [see Section 2.5.2 of
4 [U.S. EPA \(2016f\)](#)].

5 Decreased rates of photosynthesis have been recorded in experimental exposures of
6 plants to both NO and NO₂, but usually at concentrations significantly higher than would
7 normally be encountered in ambient air. For example, [Sabaratnam et al. \(1988\)](#) reported
8 that soybeans (*Glycine max*) exposed 7 hours/day for 5 days showed an increase in
9 photosynthesis at a concentration of 0.2 ppm but a decrease in net photosynthesis at a
10 concentration of 0.5 ppm. Short-term exposures of soybean to 0.6 ppm NO₂ for 2 to
11 3 hours also had no effect on net photosynthesis ([Carlson, 1983](#)). Most plants appear to
12 be more susceptible to NO than to NO₂, as shown by [Saxe \(1986\)](#), who exposed a variety
13 of horticultural plants raised in greenhouses (species of *Hedera*, *Ficus*, *Hibiscus*,
14 *Nephrolepis*, and *Dieffenbachia*) to both NO and NO₂. [Saxe \(1986\)](#) reported that
15 decreases in net photosynthesis occurred at doses of NO that were 22 times less than that
16 for NO₂. However, these decreases in net photosynthesis required concentrations as high
17 as 1 ppm NO for 12 hours to elicit a response in these plants.

18 In the 1970s and 1980s, hundreds of studies were conducted on the effects of NO₂ on
19 growth and yield of plants. These studies varied widely in plant species, growing
20 conditions, exposure equipment, concentrations, durations, exposure regimes, and
21 environmental conditions during exposures. No clear dose-response relationships for
22 exposure to NO₂ and reductions in growth and/or yield of plants emerged from these
23 experiments. Readers are referred to the analysis of over 100 studies conducted in the
24 1993 Oxides of Nitrogen AQCD. A few key studies are highlighted in this section. The
25 growth of several plant species appears to be susceptible to concentrations of NO₂ less
26 than 0.2 ppm, particularly when exposure occurs during low-light conditions. For
27 example, nearly continuous exposure to 0.1 ppm NO₂ for 8 weeks significantly reduced
28 growth of Kentucky blue grass [*Poa pratensis*; ([Whitmore and Mansfield, 1983](#);
29 [Ashenden, 1979](#))]. Eight species of tree seedlings were exposed to 0.1 ppm NO₂ for
30 6 hours/day for 28 days, resulting in reduced shoot or root growth in two species, white
31 ash (*Fraxinus americana*) and sweetgum (*Liquidambar styraciflua*), reduced height
32 growth in two clones of loblolly pine (*Pinus taeda*), and no effects on the other species
33 ([Kress and Skelly, 1982](#)). No effects of NO₂ at 0.1 ppm or lower were observed on
34 numerous other species, including potato (*Solanum tuberosum*), black poplar (*Populus*
35 *nigra*), radish (*Raphanus sativus*), soybean, or peas (*Pisum sativum*) ([U.S. EPA, 1993](#)).
36 No effects of NO₂ were observed on soybeans grown in field plots subjected to a series of
37 10 episodic exposures averaging 0.4 ppm for 2.5 or 3 hours ([Irving et al., 1982](#)).
38 Numerous studies have reported negative effects on growth of a variety of plants exposed

1 to 0.5 ppm NO₂ and above ([U.S. EPA, 1993](#)), but these concentrations are very high
2 relative to current ambient levels of NO₂ (see [Appendix 2.6.1](#)).

3 The 1993 Oxides of Nitrogen AQCD reviewed the extensive literature on the effects of
4 NO₂ in combination with other gaseous air pollutants, particularly SO₂ and O₃, and
5 concluded that combinations of pollutants can cause foliar injury or decreases in
6 photosynthesis at concentrations lower than those associated with NO₂ acting alone.
7 However, the plant responses occur at concentrations much higher than typically found in
8 ambient air in the U.S. ([U.S. EPA, 1993](#)). In addition, the presence of NO₂ in studies
9 combining other gases did not produce symptoms different from those caused by the
10 dominant pollutant, either SO₂ or O₃, such that a plant response produced by
11 combinations of NO₂ with other air pollutants in the field would be difficult, if not
12 impossible, to distinguish from those of the other single pollutants ([U.S. EPA, 1993](#)).

13 Since the 1993 Oxides of Nitrogen AQCD was completed, most new research on NO₂
14 exposure to vegetation has taken place in Europe and other areas outside the U.S. For
15 example, foliar NO₃ reductase activity was increased in Norway spruce (*Picea abies*)
16 growing near a highway in Switzerland with average exposures of about 0.027 ppm
17 compared to trees growing 1,300 m away from the highway with NO₂ exposures less than
18 0.005 ppm ([Ammann et al., 1995](#)). This result was consistent with other studies on
19 Norway spruce in the field and laboratory ([von Ballmoos et al., 1993](#); [Thoene et al.,](#)
20 [1991](#)). [Muller et al. \(1996\)](#) found that the uptake rate of NO₃⁻ by roots of Norway spruce
21 seedlings was decreased by exposure to 0.1 ppm of NO₂ for 48 hours. Similarly, soybean
22 plants grown in Australia had decreased NO₃ uptake by roots and reduced growth of
23 plants exposed to 1.1 ppm of NO₂ for 7 days ([Qiao and Murray, 1998](#)). In a Swiss study,
24 poplar (*Populus ×euramericana*) cuttings exposed to 0.1 ppm of NO₂ for approximately
25 12 weeks resulted in decreased stomatal density and increased specific leaf weight, but
26 did not result in other effects such as leaf injury or a change in growth ([Günthardtgoerg et](#)
27 [al., 1996](#)). However, NO₂ enhanced negative effects of ozone on poplars, including leaf
28 injury, when the pollutants were applied in combination ([Günthardtgoerg et al., 1996](#)).

29 Since the 2008 ISA for Oxides of Nitrogen and Oxides of Sulfur-Ecological Criteria
30 [hereafter referred to as the 2008 ISA ([U.S. EPA, 2008a](#))], very few studies have been
31 published on the direct effects of NO and NO₂ on vegetation. [Hu et al. \(2015b\)](#) exposed
32 clonal hybrid poplar (*Populus alba* × *Populus berolinensis*) saplings to 4 ppm of NO₂.
33 The authors reported significant declines in photosynthesis and dark respiration with
34 exposures of 48 hours. They also reported stomatal dysfunction at this level of exposure
35 resulting in partial stomatal closure and a decline in stomatal conductance. However,
36 4 ppm of NO₂ is very high relative to current ambient levels of NO₂ in the U.S. (see

1 [Appendix 2.6.1](#)). These results are consistent with past studies of plants with relatively
2 high NO₂ exposure.

3 As part of a broad study of N deposition of a native serpentine grassland in California,
4 [Vallano et al. \(2012\)](#) exposed five native grasses and forbs (*Plantago erecta*, *Layia*
5 *gaillardoides*, *Lasthenia californica*, *Vulpia microstachys*, and *Cryptantha flaccida*) and
6 the most common invasive grass *Lolium multiflorum* to NO₂ and soil N addition. The
7 plants were exposed in a growth chamber to very low levels of NO₂ (0.03 ppm) to
8 simulate recent ambient air concentrations for this ecosystem. At this relatively low NO₂
9 exposure, no significant effects were found on shoot biomass, root biomass,
10 photosynthesis, or stomatal conductance. The authors reported that despite not finding
11 species responses to NO₂ exposure, the additive effects of NO₂ combined with soil N on
12 plant performance indicate that uptake of NO₂ may play a role in species responses to
13 increasing N deposition. The authors found that the combined NO₂ and N addition
14 resulted in a strong positive growth and competitive response in the invasive *Lolium*. This
15 result is consistent with previous findings that low levels of NO₂ that are not phytotoxic
16 to plants can add to the N load to an ecosystem from uptake through leaves ([Sparks,](#)
17 [2009](#)).

18 In a study in the Grand Canyon National Park, AZ, [Kenkel et al. \(2016\)](#) found that NO_x
19 concentrations measured by Ogawa passive samplers were about 52% higher along
20 roadsides than 30 m away from the road. The pattern of the amount of ¹⁵N in pinyon pine
21 (*Pinus edulis*) mirrored the concentration gradient of NO_x concentrations from the road,
22 indicating that the vegetation is taking up N from the vehicle traffic in the park. The
23 authors reported that sustained chronic N deposition on this arid environment could result
24 in deleterious effects for these ecosystems.

25 Peroxyacetyl nitrate (PAN) is a well-known photochemical oxidant that often co-occurs
26 with O₃ during high photochemical episodes and that has been shown to cause injury to
27 vegetation (See reviews by, [Cape, 2003](#); [Kleindienst, 1994](#); [Temple and Taylor, 1983](#)).
28 Acute foliar injury symptoms resulting from exposure to PAN are generally characterized
29 as a glazing, bronzing, or silvering of the underside of the leaf surface; some sensitive
30 plant species include spinach, Swiss chard, lettuces, and tomatoes ([Temple and Taylor,](#)
31 [1983](#)). Petunias (*Petunia hybrida*) have also been characterized as sensitive to PAN
32 exposures and have been used as bioindicators in areas of Japan ([Nouchi et al., 1984](#)).
33 Controlled experiments have also shown significant negative effects on the net
34 photosynthesis and growth of petunias and kidney beans (*Phaseolus vulgaris*) after
35 exposure of 30 ppb of PAN for 4 hours on each of 3 alternate days ([Cape, 2003](#); [Izuta et](#)
36 [al., 1993](#)). As mentioned previously, it is known that oxides of N, including PAN, could
37 be altering the N cycle in some ecosystems, especially in the western U.S., and

1 contributing to N saturation ([Fenn et al., 2003a](#); [Bytnerowicz and Fenn, 1996](#)). Although
2 PAN continues to persist as an important component of photochemical pollutant
3 episodes, there is little evidence in recent years to suggest that PAN poses a significant
4 risk to vegetation in the U.S.

3.4. Direct Phytotoxic Effects of Nitric Acid

5 Relatively little is known about the direct effects of HNO₃ vapor on vegetation. Recent
6 information on HNO₃ concentrations are given in [Appendix 2.6.3](#) The deposition velocity
7 of HNO₃ is very high compared to other pollutants (see [Table 2-2](#)) and HNO₃ may be an
8 important source of N for plants ([Hanson and Garten, 1992](#); [Hanson and Lindberg, 1991](#);
9 [Vose and Swank, 1990](#)). This deposition could contribute to N saturation of some
10 ecosystems close to sources of photochemical smog ([Fenn et al., 1998](#)). For example, in
11 mixed conifer forests of the Los Angeles basin mountain ranges, HNO₃ has been
12 estimated to provide 60% of all dry deposited N ([Bytnerowicz et al., 1998](#)). Since the
13 2008 ISA, a controlled exposure study ([Padgett et al., 2009a](#)) reported that 10 to 60% of
14 the HNO₃ retained by foliage was incorporated into the biologically active N pool. The
15 remainder of the HNO₃ was bound to foliar surfaces. This new study provides further
16 evidence for HNO₃ as a contributor of biologically available N to southern California
17 forests.

18 [Norby et al. \(1989\)](#) reported that exposure of 75 ppb of HNO₃ for 1 day increased nitrate
19 reductase activity in red spruce (*Picea rubens*) foliage. In another study, foliar nitrate
20 reductase activity was also increased in California black oak (*Quercus kelloggii*), canyon
21 live oak (*Quercus chrysolepis*), and ponderosa pine (*Pinus ponderosa*) seedlings with
22 exposure to 65 to 80 ppb of HNO₃ for 24 hours ([Krywult and Bytnerowicz, 1997](#)).
23 Because the induction of nitrate reductase activity is a step in a process leading to the
24 formation of organic N compounds (amino acids), the nitrate from HNO₃ could function
25 as an alternative source of N for vegetation ([Calanni et al., 1999](#)). However, in plants
26 under stress, the reduction of nitrate to amino acids consumes energy needed for other
27 metabolic processes.

28 At high ambient concentrations, HNO₃ can cause vegetation damage. Seedlings of
29 ponderosa pine and California black oak subjected to short-term exposures from
30 50–250 ppb of HNO₃ vapor for 12 hours showed deterioration of pine needle cuticle at
31 50 ppb in light ([Bytnerowicz et al., 1998](#)). Oak leaves, however, appeared to be more
32 resistant to HNO₃ vapor, with 12-hour exposures in the dark at 200 ppb producing
33 damage to the epicuticular wax structure ([Bytnerowicz et al., 1998](#)). The observed
34 changes in wax chemistry caused by HNO₃ and accompanying injury to the leaf cuticle

1 [\(Bytnerowicz et al., 1998\)](#) may predispose plants to various environmental stresses such
2 as drought, pathogens, and other air pollutants. Because elevated concentrations of HNO₃
3 and ozone co-occur in photochemical smog ([Solomon et al., 1988](#)), synergistic
4 interactions between the two pollutants are possible ([Bytnerowicz et al., 1998](#)). Note,
5 however, that the experiments described above were observed at relatively short-term
6 exposures at above ambient concentrations of HNO₃. Studies of long-term effects of
7 lower air concentrations that more closely approximate ambient HNO₃ are needed.

8 Since the 2008 ISA, [Padgett et al. \(2009b\)](#) investigated dry deposition of HNO₃ on the
9 foliage of ponderosa pine, white fir (*Abies concolor*), California black oak, and canyon
10 live oak in southern California. Using a chamber system within a greenhouse, leaves and
11 needles were exposed to control (0 µg/m³ HNO₃), moderate (30 to 60 µg/m³ peak HNO₃),
12 and high (95 to 160 µg/m³ peak HNO₃) concentrations. The high concentrations
13 represented a high ambient concentration that occurs periodically in California. The
14 experimental exposures resulted in a suite of damage symptoms that intensified with
15 increasing exposure. The exposures caused substantial perturbations to the epicuticular
16 surfaces of foliage of all four tree species studied. The damage caused by dry deposition
17 may leave foliage more vulnerable to other copollutants such as ozone.

18 It has been suspected that HNO₃ may have caused a dramatic decline in lichen species in
19 the Los Angeles basin ([Nash and Sigal, 1999](#)). The suggestion was strengthened by
20 transplant of *Ramalina* lichen species from clean air habitats (Mount Palomar and San
21 Nicolas Island) to analogous polluted habitats in the Los Angeles basin and observing
22 death of the lichens over a few weeks in the summer ([Boonpragob and Nash, 1991](#)).
23 Associated with this death was a massive accumulation of H⁺ and NO₃⁻ in the lichen
24 thalli ([Boonpragob et al., 1989](#)). [Riddell et al. \(2008\)](#) exposed healthy *R. menziesii* thalli
25 to moderate (8–10 ppb) and high (10–14 ppb) HNO₃ in month-long fumigations and
26 reported a significant decline in chlorophyll content and carbon exchange capacity
27 compared to thalli in control chambers. Thalli treated with HNO₃ showed visual signs of
28 bleaching and by Day 28 were clearly damaged and dead. The damage may have
29 occurred through several mechanisms, including acidification of pigments and cell
30 membrane damage ([Riddell et al., 2008](#)). The authors concluded that *R. menziesii* has an
31 unequivocally negative response to HNO₃ concentrations common to ambient summer
32 conditions in the Los Angeles air basin. They believed it was very likely that HNO₃
33 contributed to the disappearance of this sensitive lichen species from the Los Angeles air
34 basin, as well as other locations with arid conditions with high HNO₃ deposition loads
35 ([Riddell et al., 2008](#)).

36 Since the 2008 ISA, there have been more studies published on HNO₃ effects on lichen in
37 the Los Angeles basin. [Riddell et al. \(2012\)](#) studied six lichen species with differing

1 morphology and physiology that were collected near the Los Angeles basin. All were
2 found to be sensitive to HNO₃ exposures (daily peak levels near 50 ppb) in controlled
3 chambers. Measurements of effects included decreased chlorophyll content and
4 chlorophyll fluorescence, decreased photosynthesis and respiration, and increased
5 electrolyte leakage. The species showed differential sensitivity to the HNO₃ exposures
6 ([Riddell et al., 2012](#)). In the same study, lichens were not reported to be sensitive to
7 ozone exposure. This study adds to evidence that the main agent of decline of lichen in
8 the Los Angeles basin is HNO₃ exposure.

9 In another study, [Riddell et al. \(2011\)](#) resampled 18 plots from a 1976–1977 study in the
10 Los Angeles basin. The 1976–1977 study ([Sigal and Nash, 1983](#)) had documented an air
11 pollution-related 50% decline of lichens described and collected in the same region in the
12 early 1900s ([Hasse, 1913](#)). In the 2008 resampling, [Riddell et al. \(2011\)](#) found
13 community shifts, declines in the most pollutant-sensitive lichen species, and increases in
14 abundance of nitrogen-tolerant lichen species compared to 1976–1977. The authors also
15 reported that these lichen communities have not recovered from the damaged state of the
16 late 1970s, and the 2008 survey data suggest that lichen communities are further
17 degrading. This recent observational field study further supports the evidence air
18 pollutants such as HNO₃ may be causing declines in lichens in the Los Angeles basin.

3.5. Summary

3.5.1. Sulfur Dioxide

19 The current secondary standard for SO₂ is a 3-hour average of 0.50 ppm, which is
20 designed to protect against acute foliar injury in vegetation. There has been limited
21 research on acute foliar injury since the 1982 PM-SO_x AQCD, and there is no clear
22 evidence of acute foliar injury below the level of the current standard. The limited
23 research since 2008 adds more evidence on acute effects of SO₂ on vegetation, but does
24 not change conclusions from the 2008 ISA on the levels producing the effects.

25 Effects on growth and yield of vegetation are associated with increased SO₂ exposure
26 concentration and time of exposure. The 1982 PM-SO_x AQCD concluded that more
27 definitive concentration-response studies were needed before useable exposure metrics
28 could be identified. Very few studies have been reported on the effects of SO₂ on growth
29 of U.S. vegetation since the 1982 PM-SO_x AQCD. Recent studies from eastern Europe
30 indicate recovery of tree growth correlated to falling SO₂ concentrations since the 1980s.
31 [Elling et al. \(2009\)](#) reported that annual SO₂ concentrations of 4 ppb appeared to reduce
32 silver fir (*Abies alba*) growth. There may be similar effects of SO₂ emissions on trees in

1 West Virginia ([Thomas et al., 2013](#)), but more research is needed to further investigate
2 the mechanisms of the apparent recovery of tree growth to link this phenomenon with
3 declines in ambient SO₂ that have occurred since the 1980s.

4 Limited new evidence from 2008 to the present continue to support the causal findings of
5 the 2008 ISA. As a whole, **the body of evidence is sufficient to infer a causal**
6 **relationship between gas-phase SO₂ and injury to vegetation.**

3.5.2. Nitrogen Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate

7 It is well known that in sufficient concentrations, NO, NO₂, and PAN can have
8 phytotoxic effects on plants through decreasing photosynthesis and induction of visible
9 foliar injury ([U.S. EPA, 1993](#)). However, the 1993 Oxides of Nitrogen AQCD concluded
10 that concentrations of NO, NO₂, and PAN in the atmosphere are rarely high enough to
11 have phytotoxic effects on vegetation ([U.S. EPA, 1993](#)). Since the 1993 Oxides of
12 Nitrogen AQCD, very little new research has been performed on these phytotoxic effects
13 at concentrations currently observed in the U.S.

14 Since the 2008 ISA ([U.S. EPA, 2008a](#)), very few studies have been published on the
15 direct effects of NO, NO₂ and PAN on vegetation; thus, **the body of evidence is**
16 **sufficient to infer a causal relationship between gas-phase NO, NO₂, and PAN and**
17 **injury to vegetation.**

3.5.3. Nitric Acid

18 The 2008 ISA reported experimental exposure of HNO₃ resulted in damage to the leaf
19 cuticle of pine and oak seedlings, which could predispose those plants to other stressors
20 such as drought, pathogens, and other air pollutants ([U.S. EPA, 2008a](#)). Since the 2008
21 ISA, [Padgett et al. \(2009b\)](#) investigated dry deposition of HNO₃ on the foliage, with
22 findings that supported the earlier research. The 2008 ISA also reported several lines of
23 evidence in lichen studies, including transplant and controlled exposure studies,
24 indicating that past and current HNO₃ concentrations contributed to the decline in lichen
25 species in the Los Angeles basin ([U.S. EPA, 2008a](#)). Since the 2008 ISA, there have been
26 more exposure and field survey studies published on the effects of HNO₃ on lichen in the
27 Los Angeles basin ([Riddell et al., 2012](#); [Riddell et al., 2011](#)). These new studies continue
28 to support the causal findings of the 2008 ISA. As a whole, **the body of evidence is**
29 **sufficient to infer a causal relationship between gas-phase HNO₃ and changes to**
30 **vegetation.**

APPENDIX 4. SOIL BIOGEOCHEMISTRY

1 This appendix characterizes how nitrogen (N) and sulfur (S) deposition contribute to total
2 loading of N and S in the soils of nonagricultural terrestrial ecosystems ([Appendix 4.2](#))
3 and how this loading causes soil acidification and eutrophication by altering soil chemical
4 pools and processes ([Appendix 4.3](#)). Additional topics are discussed, including soil
5 monitoring and databases ([Appendix 4.4](#)), soil biogeochemistry models ([Appendix 4.5](#)),
6 national-scale soil sensitivity to N and S deposition ([Appendix 4.6](#)), climate modification
7 of soil response to N ([Appendix 4.7](#)), and a summary ([Appendix 4.8](#)). The effects of
8 altered soil biogeochemistry on terrestrial biota due to soil acidification and
9 eutrophication are discussed in [Appendix 5](#) and [Appendix 6](#), respectively. Soil
10 biogeochemistry that has been altered by N may also be linked to aquatic
11 biogeochemistry, which is discussed in [Appendix 7](#).

4.1. Introduction

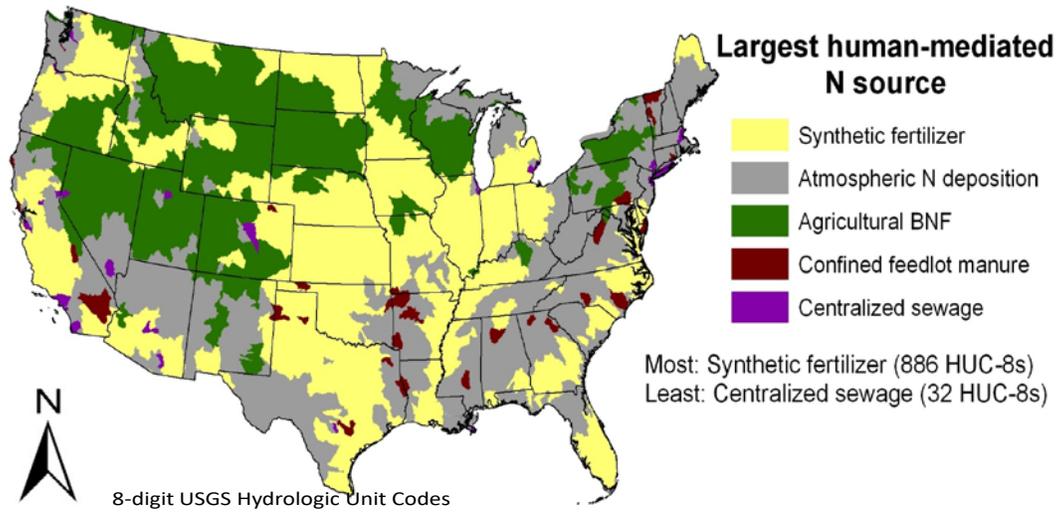

12 The *2008 ISA for Oxides of Nitrogen and Oxides of Sulfur—Ecological Criteria*
13 (hereafter referred to as the 2008 ISA) documented that the main effects of N and S
14 deposition on terrestrial soils were N enrichment and acidification. Since the 2008 ISA,
15 there is new evidence on how deposition contributes to total N and S loading in terrestrial
16 ecosystems, as well as the effects of deposition on soil chemical pools and processes.
17 This evidence is from addition, gradient, and time-series studies. Many of the new studies
18 focus on the effects of N deposition, with relatively little work focusing on S deposition.
19 There are improved models to evaluate ecosystem responses to deposition, most of which
20 are applicable at watershed scales. Some may be applied regionally. Soil N enrichment
21 and soil acidification occur in sensitive ecosystems across the U.S. at recent levels of
22 deposition. Decreasing emissions of S have led to early signs of recovery from soil
23 acidification in some northeastern watersheds; however, areas in the Southeast do not
24 show any appreciable recovery of soils. There are no signs of recovery of N enrichment
25 effects in soils. Critical loads (CL) determinations for soils have been made at the
26 ecoregion scale for NO_3^- leaching and some soil acidification indicators. **The body of
27 evidence is sufficient to infer a causal relationship between N and S deposition and
28 alteration of soil biogeochemistry in terrestrial ecosystems**, which is consistent with
29 the conclusions of the 2008 ISA.

4.2. Nitrogen and Sulfur Sources to Soil

1 The 2008 ISA documented that atmospheric deposition is the main source of
2 anthropogenic N to nonagricultural and nonurban terrestrial ecosystems and headwater
3 streams. In 2008 it was well known that the global pool of reactive N (N_r) had increased
4 over the previous century, largely due to three main causes: (1) widespread cultivation of
5 legumes, rice, and other crops that support bacteria capable of converting diatomic
6 nitrogen gas (N_2) to organic N through biological N fixation; (2) fossil fuel combustion
7 converting atmospheric N_2 and fossil N to total oxidized N (NO_y); and (3) the
8 Haber-Bosch process, which converts nonreactive N_2 to N_r for N fertilizer production and
9 some industrial activities ([Galloway et al., 2003](#); [Galloway and Cowling, 2002](#)). Food
10 production was known to account for much of the conversion of N_2 to N_r . N was shown
11 to be geographically redistributed through food shipment to meet human needs and often
12 returned to the environment via wastewater. N_r was known to accumulate in the
13 environment on local, regional, and global scales ([Galloway et al., 2003](#); [Galloway and](#)
14 [Cowling, 2002](#); [Galloway, 1998](#)) in the atmosphere, soil, and water ([Galloway and](#)
15 [Cowling, 2002](#)), with a multitude of effects on humans and ecosystems ([Townsend et al.,](#)
16 [2003](#); [Rabalais, 2002](#); [van Egmond et al., 2002](#); [Galloway, 1998](#)). The term the “N
17 cascade” was coined to refer to the sequence of transfers, transformations, and
18 environmental effects ([Galloway et al., 2003](#); [Galloway and Cowling, 2002](#)).

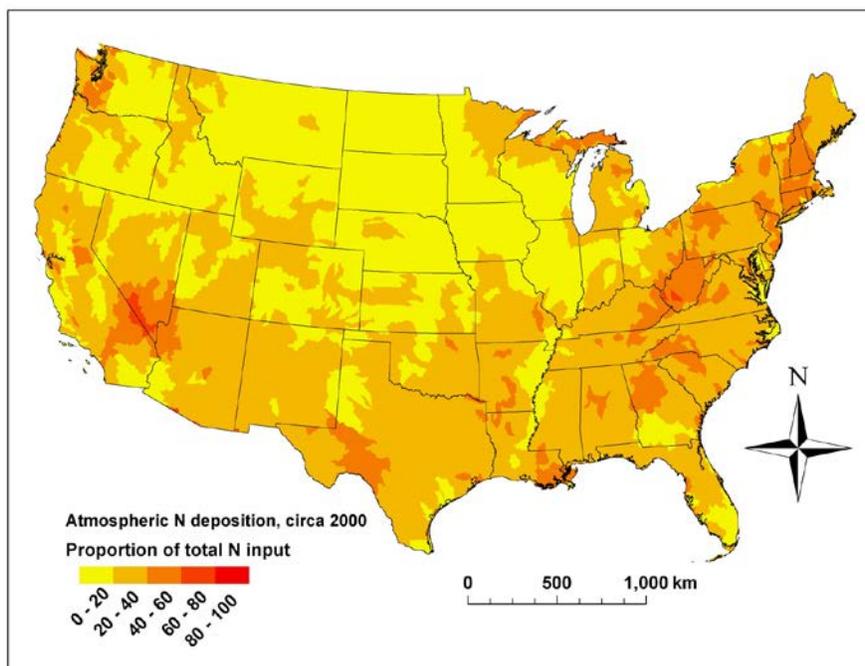

19 Since 2008, a number of estimates have been made of the relative contribution of sulfate,
20 oxidized N, and reduced N from atmospheric deposition. The most recent estimates are
21 summarized in [Appendix 2](#). Maps showing the geographic distribution of deposition are
22 presented for total acidifying (N + S) deposition ([Figure 2-12](#)), total N deposition
23 ([Figure 2-13](#)), and total S deposition ([Figure 2-31](#)). Maps depicting how the relative
24 contribution of oxidized and reduced N species varies across the U.S. are presented in
25 [Figure 2-14](#).

26 Several new studies have been published since the 2008 ISA on the source of N inputs to
27 ecosystems; however, no new studies on S sources to ecosystems have been identified.
28 [Sobota et al. \(2013\)](#) quantified sources and fluxes of reactive N inputs to U.S. lands and
29 waterways and found human-mediated N inputs are spatially heterogeneous across the
30 country, ranging up to 34.6-fold the background N input across all of the 8-digit
31 hydrologic unit codes (HUC-8s). Across the contiguous U.S. (CONUS), synthetic N
32 fertilizer and atmospheric N deposition are the largest and second-largest overall
33 human-mediated N inputs to ecosystems, and the single largest sources in 41 and 33% of
34 HUC-8s, respectively ([Figure 4-1](#) and [Figure 4-2](#)).

USGS = U.S. Geologic Survey; HUC-8 = 8-digit hydrologic unit code; N = nitrogen; BNF = biological nitrogen fixation.
Source: map presented in [Sobota et al. \(2013\)](#).

Figure 4-1 Dominant sources of nitrogen across the U.S. at 8-digit hydrologic unit codes.

N = nitrogen.
Source: modified from data presented in [Sobota et al. \(2013\)](#).

Figure 4-2 Percentage of nitrogen input from nitrogen deposition at 8-digit hydrologic unit codes.

1 At the global scale, ([Fowler et al., 2013](#)) estimated the relative contributions of five
2 sources of N that contribute to emissions and deposition, all of which are predicted to
3 change through the end of this century. Two new studies, both in the western U.S., have
4 confirmed that N from the weathering of sedimentary and metasedimentary rock can be a
5 source of N to some ecosystems ([Montross et al., 2013](#); [Morford et al., 2011](#)), although
6 [Sobota et al. \(2013\)](#) suggest that anthropogenic sources of N are more significant at the
7 landscape scale.

4.3. Soil Pools and Processes

8 Eutrophication and acidification are two biogeochemical processes that can occur in
9 response to the inputs of N and S deposition. These processes can alter the
10 biogeochemistry in terrestrial ecosystems and they may occur either in sequence or
11 simultaneously in a given geographic area. N driven eutrophication is typically indicated
12 by N accumulation (e.g., increased soil N concentrations or decreased C:N ratios). These
13 indicators of N accumulation are directly linked to biological effects in the soil, including
14 changes in microbial-mediated decomposition and nitrification. N added to terrestrial
15 ecosystems can also be lost through leaching from the soil, typically as nitrate (NO_3^-), or
16 through emissions to the atmosphere, primarily via denitrification ([Galloway et al., 2003](#);
17 [Galloway and Cowling, 2002](#)). Denitrification is a microbial process that reduces NO_3^- to
18 either unreactive N_2 gas, nitrogen oxide (NO), or the potent greenhouse gas nitrous oxide
19 (N_2O). S addition to an ecosystem typically causes S accumulation and variable amounts
20 of leaching from the soil, which in turn leads to acidification because demand for S as a
21 nutrient is low compared to human-caused soil stores of organic and inorganic S.

22 Soil acidification results from the accumulation of hydrogen ions (H^+). This occurs
23 naturally through the production of carbonic acid and organic acids, as well as through
24 plant cation uptake ([Charles and Christie, 1991](#); [Turner et al., 1991](#)). The rate of soil
25 acidification can increase as a result of soil acidification caused by the deposition of the
26 inorganic acids HNO_3 and H_2SO_4 . In addition, NH_x deposition contributes to soil
27 acidification by stimulating nitrifying bacteria that derive energy by oxidizing the NH_4^+
28 to NO_3^- . A byproduct of nitrification is the production of an H^+ ion, but whether there is a
29 net effect on soil acidity depends upon the fate of the NO_3^- . If the NO_3^- is leached with a
30 base cation, then the H^+ is left behind and the soil become more acidic. If, however, the
31 NO_3^- is denitrified, then the H^+ from nitrification is neutralized by OH^- generated by
32 denitrification. Likewise, if NO_3^- is taken up by a plant root, the root will exude an OH^-
33 in exchange.

1 Decreases in soil pH attributable to acid deposition have been documented throughout the
2 U.S. ([Sullivan et al., 2006b](#); [Bailey et al., 2005](#); [Johnson et al., 1994b](#); [Johnson et al.,
3 1994a](#)). Inorganic and organic acids can be neutralized by soil weathering or base cation
4 exchange, in addition to denitrification. However, because soils vary in their capacity to
5 neutralize incoming acidity, the effects of acidification have been heterogeneous across
6 the U.S. In addition, pollutant loadings vary across the U.S. The primary chemical effects
7 of acidification in soils that have biological effects include the loss of important base
8 cation nutrients such as Ca and Mg, as well as the mobilization of aluminum (Al) cations,
9 several of which are toxic to many organisms. The quantities of precipitation and runoff
10 are important determinant of base cation leaching and acidification. ([Van Breemen et al.,
11 1984](#)). The loss of base cations through leaching, decrease in base saturation, and
12 decreased in soil solution Ca:Al ratio all serve as indicators of soil acidification.

13 Studies published since the 2008 ISA augment our knowledge of previously identified
14 effects of N addition on soils. The following sections document the empirical evidence of
15 N effects on multiple pools, processes, and indicators associated with the general effects
16 of N enrichment and eutrophication ([Table 4-1](#)). These sections summarize the empirical
17 effects of N and S addition on soil biogeochemistry, often based on results of from
18 addition or gradient studies. The publications summarized here present information on
19 multiple processes and indicators; therefore individual papers are often discussed in more
20 than one section.

Table 4-1 Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N-Driven Nutrient Enrichment	Acidification	Section of ISA that Discusses Each Endpoint

4.3.1. Nitrogen Pathways and Pools

1 The 2008 ISA documented that N is stored primarily in the soil in forest ecosystems, and
 2 soil N often exceeds 85% of the total ecosystem N ([Cole and Rapp, 1981](#); [Bormann et al.,](#)

1 [1977](#)). Experimental ¹⁵N addition studies showed that trees typically take up only a small
2 fraction of added ¹⁵N; most is retained in the soil N pool ([Providoli et al., 2005](#); [Templer](#)
3 [et al., 2005](#); [Nadelhoffer et al., 1999a](#); [Tietema et al., 1998](#)). However, these experiments
4 were criticized for applying ¹⁵N directly to the soil surface, thereby precluding direct
5 canopy uptake of N from wet or dry deposition and limiting inference for N deposition
6 effects ([Sievering et al., 2000](#); [Sievering, 1999](#)). Forest canopies take up an average of
7 16% of total atmospheric N input ([Lovett, 1992](#)), but this uptake could be considerably
8 higher (up to 90%) in some N limited forests with large epiphyte loads ([Klopatek et al.,](#)
9 [2006](#)). It is unclear how much of the N from deposition retained by vegetation was used
10 in photosynthetic enzymes and would thus contribute to increased productivity ([Bauer et](#)
11 [al., 2004](#)).

12 Most soil N is contained in organic matter, typically bound in organo-mineral complexes
13 or large-molecular-weight organic compounds ([Schmidt et al., 2011](#); [Schimel and](#)
14 [Bennett, 2004](#)) These pools of N are not directly available for uptake by plants or
15 microbes, and the relative immobility of these compounds means they contribute little to
16 the leaching loss of N into ground or surface waters. To enter the actively cycling portion
17 of the ecosystem N pool, recalcitrant organic N must be converted into inorganic forms
18 (e.g., NO₃⁻, NH₄⁺) or small-molecular-weight organic compounds (e.g., amino acids,
19 amino sugars), typically through the activity of extracellular enzymes produced by soil
20 microorganisms. The size of this N pool often controls net primary productivity (NPP;
21 see [Appendix 6](#)), but plants compete with microorganisms for available N.

22 Since 2008 there is new research using ¹⁵N to trace pathways and pools in ecosystems
23 ([Table 4-2](#)), including a new paper confirming the previous conclusion that ecosystem N
24 is primarily stored in forest mineral soil ([Perakis et al., 2011](#)). There is also new evidence
25 that litter is the largest sink for added N in grasslands, shrublands, and wetlands ([Templer](#)
26 [et al., 2012](#)).

27 New studies have also been conducted tracing pathways of N in ecosystems through time.
28 In Swiss grasslands, N addition increased ecosystem N storage in plant biomass, both in
29 living plant biomass as well as litter, but did not affect soil N ([Bassin et al., 2015](#)). In a
30 temperate forest ecosystem in Switzerland, application of ¹⁵N tracer in a solution to
31 simulate wet deposition showed increased dissolved organic N and enrichment of soil
32 microbes and plant roots within the first day. When plots were resampled a year later,
33 litter and soil pools, particularly soil organic matter, were enriched with the N tracer
34 ([Morier et al., 2008](#)). These results confirm that deposited N is incorporated rapidly into
35 ecosystem pools and is stored primarily in litter and recalcitrant organic matter in the soil.

Table 4-2 Pathways and pools.

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference HERO ID
Mineralization	Semiarid	Southern California	Up to 35–45 for N	Two applications per yr of 30 kg N	N fertilizer additions resulted in faster gross N cycling rates. Greater net release or greater net immobilization of N was observed at different sampling times and likely related to seasonality of C availability.	Sirulnik et al. (2007b)
N pools	Temperate hardwood forest	Swiss Prealps	16		The litter layer retained approximately 19–28% of the ¹⁵ N tracer after 1 day. The authors concluded that the processes relevant for the fate of atmospherically deposited N take place rapidly and that N recycling within the microbe-plant-soil organic matter system prevents further losses in the long term.	Morier et al. (2008)
N turnover times	Semiarid grassland	Not specified	Not specified	5 as NH ₄ NO ₃	Model for N cycling was developed using observations of ¹⁵ N. The temporal dynamics of ¹⁵ N fractions (labeled-N fractions) in plant and microbial biomass are closely tied to the turnover time of these N pools	Dijkstra (2009)
N pathway	Spruce plantation	Höglwald, Bavaria, Germany	45		After two to three decades of high loads of N deposition, a new equilibrium was reached, characterized by substantial losses of N to the groundwater (approximately 20 kg NO ₃ ⁻) and to the atmosphere (16 kg N in form of N ₂ O, NO, and N ₂). Ecosystem N retention is dominated by microbial immobilization, which was about a factor of three higher than plant N uptake.	Kreutzer et al. (2009)
N pathway	Simulated northern hardwood forest	Michigan, Great Lakes region	7 to 12	30	Tracing ¹⁵ NO ₃ ⁻ revealed that N accumulated in soil organic matter by first flowing through soil microorganisms and plants, and that the shedding of ¹⁵ N-labeled leaf litter enriched soil organic matter.	Zak et al. (2008)

Table 4–2 (Continued): Pathways and pools.

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference HERO ID
N pools	Temperate forest	Oregon coast range	2.0	None	Mineral soil accounted for 96–98% of total ecosystem N. Soil water $^{15}\text{NO}_3^-$ patterns suggested a shift in relative N losses from denitrification to NO_3^- leaching as N accumulated, and simulations identified NO_3^- leaching as the primary N loss pathway that constrains maximum N accumulation.	Perakis et al. (2011)
N pools	Soil ^{15}N	Global	Varied across 48 studies	Varied across 48 studies	A meta-analysis of studies at 48 sites across four continents shows the largest sinks for ^{15}N tracers among ecosystem types were organic soil in forests (35.5%, n = 31) and foliage in tundra (12.1%, n = 3). Litter was the largest sink in grasslands (25.5%, n = 9), shrublands (33.8%, n = 6), and wetlands (34.1%, n = 2).	Templer et al. (2012)
N pools	Common garden experiment, five broadleaved tree species	Denmark	13 to 19 for broadleaf forest 18 to 26 for Norway Spruce		Tree species influenced N cycling and ^{15}N patterns through multiple species-specific traits. The type of mycorrhiza association, light regime, and ground vegetation differed between ash and sycamore and beech, lime, oak, and Norway spruce.	Callesen et al. (2013)
Pools and pathway N uptake	Subalpine (seminatural) pasture	Alp Flix, a high plateau near Sur, Grosos, Switzerland	4	0, 5, 10, 25, and 50 as NH_4NO_3	Plant N pools increased by 30–40% after N addition, while soil pools remained unaffected.	Bassin et al. (2015)
N cycling	All	Global	Not specified	None	Synthesis of recent literature that did not include new quantitative analysis.	Niu et al. (2016)

Table 4–2 (Continued): Pathways and pools.

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference HERO ID
Throughfall NH ₄ ⁺ , NO ₃ ⁻ , and SO ₄ ²⁻ Base cations Dry N deposition	<i>Quercus ilex</i> forests ranging from Mediterranean climate to a drier, more seasonal climate		Not specified	None	Rainfall and net NH ₄ ⁺ throughfall were negatively correlated at all sites. Rainfall and net NO ₃ ⁻ -N throughfall correlation varied between negative and positive. Rainfall and net SO ₄ ²⁻ throughfall were positively correlated at wet sites and negatively correlated at the drier site.	Aguillaume et al. (2017)

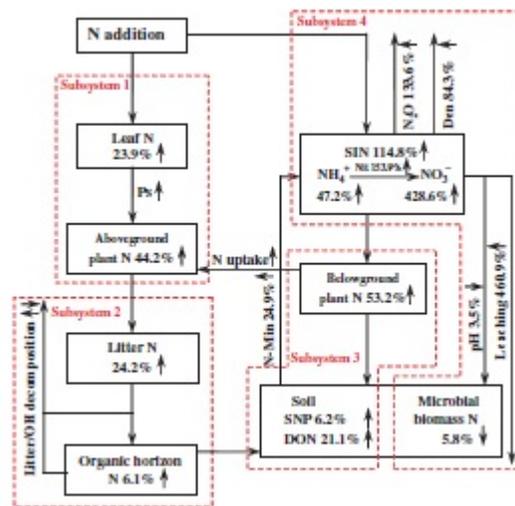

¹⁵N = Nitrogen-15; N = nitrogen; NO = nitric oxide; N₂O = nitrous oxide; NO₂ = nitrogen dioxide; NO₃⁻ = nitrate; ¹⁵NO₃⁻ = Nitrogen-15-labeled nitrate; NH₄NO₃ = ammonium nitrate; yr = year.

4.3.2. Nitrogen Accumulation, Saturation, and Leaching

1 In the 2008 ISA, a documented indicator of terrestrial N driven eutrophication was the
2 accumulation of N in soil. Atmospherically deposited N can accumulate in soil as
3 inorganic N or by incorporating N into organic matter. The ability of atmospheric N
4 pollution to cause an accumulation of N in soil is indicated by a positive correlation
5 between the atmospheric deposition rate and total N concentration in the Oa horizon
6 observed at sites in New York, Vermont, New Hampshire, and Maine ([Driscoll et al.,
7 2001b](#)). Accumulation of soil N as a result of N deposition has been either documented or
8 suggested to occur across large areas of the U.S. ([Aber et al., 2003](#)) including semiarid
9 ecosystems ([Padgett et al., 1999](#)). There is also evidence for soil N accumulation from
10 mass-balance studies of experimental N additions ([Campbell et al., 2004b](#)). Further
11 evidence that atmospheric deposition increased the availability of N in soil is provided by
12 the strong negative correlation between atmospheric N deposition and the decreasing C:N
13 ratio of the Oa soil horizon across the northeastern U.S. ([Aber et al., 2003](#)). Soil N
14 accumulation is linked to increased N leaching.

15 New studies ([Table 4-3](#)) confirm that, across terrestrial ecosystem types, N addition
16 increases soil N concentrations. In semiarid shrublands in southern California, [Vourlitis
17 and Fernandez \(2012\)](#) observed that N additions increased soil N. [Lu et al. \(2011a\)](#)
18 conducted a meta-analysis of N cycle responses to N additions using data from
19 206 peer-reviewed studies. They observed mean increases in N leaching, soil inorganic
20 N, soil total N pool, as well as increases in the litter N, organic horizon N, and mineral
21 soil N; the only pool that decreased was microbial N ([Figure 4-3](#)).

22 Thresholds of N deposition associated with the onset of elevated NO_3^- leaching have
23 been previously identified. Atmospheric deposition of 8 to 10 kg N/ha/yr resulted in the
24 onset of NO_3^- leaching to surface waters throughout the eastern U.S. Slightly lower N
25 deposition levels (5–10 kg N/ha/yr) led to NO_3^- leaching in the Rocky Mountains, and
26 this was attributable to colder temperatures, shorter growing season, slow soil
27 development, extensive exposed bedrock, and rapid melting of large snowpacks
28 ([Williams and Tonnessen, 2000](#); [Williams et al., 1996c](#); [Baron et al., 1994](#)). Lastly,
29 deposition loads of 17 kg N/ha/yr led to the onset of NO_3^- leaching in the Sierra Nevada
30 and San Bernardino mountains ([Fenn et al., 2008](#)).

N = nitrogen; Ps = photosynthesis; SIN = soil inorganic N; N-min = net N mineralization; Nit = nitrification; Den = denitrification; SNP = soil N pool; DON = dissolved organic N.

Source: [Lu et al. \(2011a\)](#).

Figure 4-3 A conceptual framework for the responses of the ecosystem nitrogen (N) cycle to nitrogen (N) addition.

1
2 The 2008 ISA documented that N saturation occurred when the input of N to the
3 terrestrial ecosystem exceeded the uptake capacity of the soils and biota, causing a large
4 fraction of the incoming N to leach from soils to surface waters ([Stoddard, 1994](#); [Aber et
5 al., 1989](#)). N saturation had been observed or suggested to occur across large areas of the
6 U.S. ([Adams et al., 2000](#); [Aber et al., 1998](#); [Adams et al., 1997](#); [Peterjohn et al., 1996](#);
7 [Cook et al., 1994](#); [Edwards and Helvey, 1991](#); [Aber et al., 1989](#)).

8 New evidence ([Table 4-3](#)) from an N tracer study confirms that N retention varies across
9 ecosystem types and is highest in shrublands (89.5%) and wetlands (84.8%), followed by
10 forests (74.9%), and grasslands [51.8%; ([Templer et al., 2012](#))]. Other significant factors
11 affecting long-term ¹⁵N recovery (a proxy for N retention in N tracer studies) were
12 mycorrhizal association (ericoid > ecto > arbuscular), plant growth form, and site history
13 (less retention on former agricultural sites). The influence of biotic processes on N
14 retention is evident at smaller scales. Among nine forested sites along an urban-to-rural
15 landscape gradient in the Boston, MA area, throughfall inorganic N deposition increased
16 with proximity to the urban core, with inorganic N deposition rates positively correlated
17 with rates of soil inorganic N leaching across the sites ([Rao et al., 2014](#)). Measurements
18 of δ¹⁵N and δ¹⁸O in soil NO₃⁻ leachate indicated no clear relationship between microbial
19 nitrification and proximity to the urban core—evidence that factors other than N

1 availability influenced N processing. Overall, it is clear from recent research that N
2 retention is strongly influenced by biotic factors (e.g., mycorrhizae, plant growth form)
3 and environmental conditions (e.g., precipitation).

4 Leaching of N tends to increase with increasing N addition. Where ¹⁵N tracer studies
5 were conducted as part of N addition experiments, the N additions decreased ¹⁵N
6 retention. In ¹⁵N studies with multiple N addition treatments, a negative correlation
7 between retention and the rate of N additions was observed ([Templer et al., 2012](#)). In
8 Europe, [Dise et al. \(2009\)](#) documented approximately 95% of forests receiving less than
9 8 kg N/ha/yr still had leaching, typically less than 1 kg N/ha/yr. Additional work on
10 monitoring data in Sweden by [Khalili et al. \(2010\)](#) showed a clear sudden increase in
11 NO₃⁻ leaching in regions where N deposition exceeded 7.5 kg/ha/yr ([Appendix 4.4](#)). In
12 the U.S. there are new studies modeling N leaching in eastern U.S. forests ([Fakhraei et](#)
13 [al., 2016](#); [Phelan et al., 2016](#)).

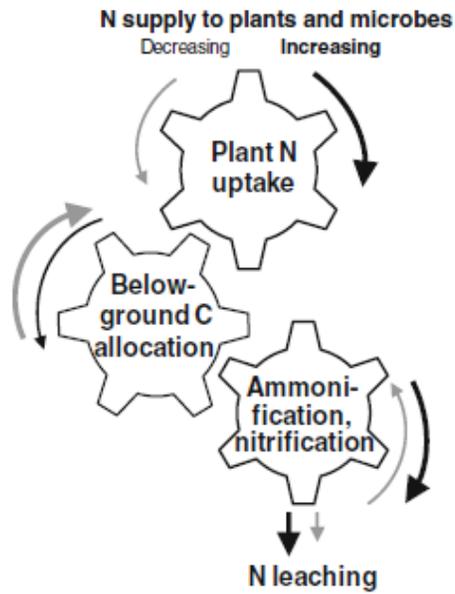

14 N leaching is an indicator of ecosystem N saturation. New studies ([Table 4-3](#)) suggest the
15 N saturation concept ([Aber et al., 1998](#)) may need revision in response to observations of
16 N cycling in temperate forests ([Lovett and Goodale, 2011](#)) and chaparral ([Homyak et al.,](#)
17 [2014](#)). [Lovett and Goodale \(2011\)](#) proposed a new model of N saturation that
18 distinguished capacity N saturation, in which the vegetation and soil sinks for N have
19 been filled, from kinetic N saturation, in which the plant and soil sinks are accumulating
20 N, but the rate of N accumulation is slower than the N input rate. One implication of this
21 new model is that NO₃⁻ leaching can occur even if the ecosystem N retention capacity
22 has not yet been saturated, as is observed at many sites (e.g., [Homyak et al., 2014](#);
23 [Talhelm et al., 2012](#); [Lovett and Goodale, 2011](#)). New information confirms the
24 applicability of the capacity N saturation concept in northwest forests ([Perakis and](#)
25 [Sinkhorn, 2011](#)), although the new idea of kinetic N saturation is particularly useful in
26 describing N cycling processes in California chaparral ([Homyak et al., 2014](#)). At
27 chaparral sites, N added during the dry season is lost from the ecosystem, while N added
28 during the growing season is retained in plant biomass ([Vourlitis and Pasquini, 2009](#);
29 [Grulke et al., 2005](#)). In these systems, water scarcity limits plant productivity, microbial
30 C availability, and denitrification, all of which cause NO₃⁻ to be flushed from surface
31 soils during large precipitation events ([Menon et al., 2010](#)). Large leaching losses of N in
32 arid ecosystems—where N demand is not indicated by biota—are evidence for kinetic
33 saturation.

34 New research highlights the importance of deposition of N from mobile sources along
35 roadsides ([Bettez et al., 2013](#)). The higher deposition along roadsides in Cape Cod, MA
36 was associated with a two to four-fold greater rate of nitrate leaching from the soils.
37 Approximately 15% less N from deposition was retained 10 m from the road than sites

1 more distant removed from the road. N deposition contribution to N in the watershed may
2 be underestimated by 13–25% when roadside deposition and the associated leaching are
3 not included.

4 New research highlights the role of the microbial community in N saturation. [Kopáček et](#)
5 [al. \(2013\)](#) developed a conceptual model in which N saturation is associated with shifts in
6 the microbial community, namely a decrease in the fungi-to-bacteria ratio, and a
7 transition from N to C limitation. In N enriched systems, three mechanisms could lead to
8 lower amounts of bioavailable dissolved organic C (DOC) for the microbial community
9 and to C limitation: (1) lower plant allocation of nutrients to roots in response to
10 increased nutrient availability, leading to a decrease in plant exudates; (2) chemical
11 suppression of DOC solubility by soil acidification; and (3) enhanced bacterial
12 mineralization of DOC due to increased abundance of electron acceptors in the form of
13 NO_3^- in anoxic soil. In support of this model, recent studies indicate that N retention in
14 semiarid shrublands is driven more by spatial and temporal variations in labile C
15 availability than exceedance of N storage capacity ([Vourlitis and Fernandez, 2015](#)).
16 Furthermore, [Högberg et al. \(2013\)](#) found that forest soils with low concentrations of
17 NO_3^- and AI had a higher fungi:bacteria ratio compared with stands having with higher
18 concentrations of NO_3^- and AI (negative correlation, $r = -0.857$). Fungi:bacteria ratio, and
19 a second indicator, stem growth, explained 70% of the variation in N and AI leaching
20 (see broader discussion of N effects on microbial community composition in
21 [Appendix 6](#)).

22 [Högberg et al. \(2013\)](#) proposed a hypothetical model to account for the effects of N
23 supply on plant N uptake and belowground C allocation, microbial production of
24 inorganic N, and N leaching ([Figure 4-4](#)). Shifts in N mineralization, nitrification, and
25 leaching from forests might occur in response to N loading as a result of decreasing tree
26 allocation of C to belowground roots, and ultimately, to ectomycorrhizal fungi and other
27 C limited soil microbes. When N supply increases, ectomycorrhizal fungi and other
28 rhizosphere microbes become progressively more C limited, and their abundance and
29 activity decline. Microbial assimilation of N diminishes, and N mineralization increases,
30 whereas the fungi:bacteria ratio decreases. Increasing NH_4^+ levels and decreasing organic
31 C supply stimulate leaching, and denitrification. Increasing N loading can alter plant C
32 allocation, causing shifts in microbial activity and community composition that in turn
33 increase NO_3^- leaching from the ecosystem ([Figure 4-4](#)).

C = carbon; N = nitrogen.

Thick arrows indicate an increasing rate whereas thin arrows mean decreasing rate. Nitrogen supply increases are indicated by black arrows.

Source: [Högberg et al. \(2013\)](#).

Figure 4-4 A hypothetical model to account for the effects of nitrogen supply on plant nitrogen uptake and belowground carbon allocation, microbial production of inorganic nitrogen, and nitrogen leaching.

Table 4-3 Nitrogen accumulation, saturation, and leaching.

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference HERO ID
N leaching	Forest	248 sites (plot and catchment scale) from 15 countries in Europe	Varied	Not reported	Gradient: The most consistent indicators of N leaching were throughfall N deposition, organic horizon C:N ratio, and mean annual temperature. Sites receiving low levels of N deposition (8 kg N/ha/yr) showed very low output fluxes of N. In general, the models successfully predicted N leaching (mean of ± 5 kg N/ha/yr between observed and predicted) from forests at early to intermediate stages of N saturation but not from N saturated sites.	Dise et al. (2009)
N accumulation N leaching	Mesic desert	Spanish Spring Valley, NV	Not specified	None	Field Experiment: Concluded that vadose soil resources (water and organic C) are rare. Unused NO_3^- from low biological demand is transported and accumulated in the deeper vadose zone with occasional deep leaching events.	Menon et al. (2010)
N saturation	Oak forest	Southeastern New York State	9	100 NH_4NO_3 (1996–1999) 50 NH_4NO_3 (2000–2006)	Conceptual Model: New N saturation model based on an N addition study of an oak forest in southeastern New York State.	Lovett and Goodale (2011)
N accumulation	meta-analysis		Varied	Varied	Meta-Analysis: N cycle responses to N additions using data from 206 peer-reviewed studies and observed a mean increase in N soil pools except microbial biomass N (Figure 4-12).	Lu et al. (2011a)

Table 4-3 (Continued): Nitrogen accumulation, saturation, and leaching.

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference HERO ID
N saturation N accumulation N mineralization nitrification	Douglas-fir forest	Oregon coast range	2.0	None	Gradient: This is a test of the N saturation theory along a natural N gradient. Higher N content of surface (0–10 cm) soil was linearly related to higher net N mineralization. Lower pH was related to lower nitrification. The ratio of net:gross N mineralization to higher nitrification increased along the gradient, indicating progressive saturation of microbial N demand.	Perakis and Sinkhorn (2011)
N leaching	Douglas-fir forest	Oregon coast range	2.0	None	Gradient: Hydrologic N losses were dominated by dissolved organic N at low N sites, with increased nitrate loss causing a shift to dominance by nitrate at high N sites, particularly where net nitrification exceeded plant N demands.	Perakis and Sinkhorn (2011)
N leaching	48 sites across four continents Grassland, forest, wetland, shrubland	Global	Varied across 48 studies	Varied across 48 studies	Meta-Analysis: The greatest recoveries of ecosystem ¹⁵ N tracer occurred in shrublands (mean, 89.5%) and wetlands (84.8%) followed by forests (74.9%) and grasslands (51.8%).	Templer et al. (2012)
Soil N, C:N	Chaparral and coastal sage scrub (CSS)	Southern California	6–8.1	56 to 58	Addition: In this 6-yr field experiment, chaparral and CSS vegetation communities were found to have the capacity to immobilize 6.2 and 11.9 g N/m ² /yr, respectively. Soil extractable N increased significantly after 7–10 g/m ² of cumulative N exposure, resulting in a simultaneous increase in the N concentration and a decline in the C:N ratio of shrub tissue. Similar results were observed for the surface litter pool and litter production but at a higher cumulative N exposure.	Vourlitis and Fernandez (2012)

Table 4-3 (Continued): Nitrogen accumulation, saturation, and leaching.

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference HERO ID
NO ³⁻ leaching	Forest	Cape Cod, MA	Annual throughfall deposition was 8.7 (±0.4) and 6.8 (±0.5) TDN at sites 10 and 150 m away from the road	None	Roadside Gradient: 25 to 30% higher N deposition to forests 10 m away from roads on Cape Cod, compared to hundreds of meters away from the road; the higher deposition was associated with a two to four-fold greater rate of nitrate leaching from the soils. 73% of the deposition was retained in the forest away from roads, compared to 58% retention at 10 from the road. Results scaled to the entire watershed indicate an underestimate of the amount of N deposition to the watershed by 13–25% by not including roadside deposition and leaching.	Bettez et al. (2013)
Soil [NO ₃ ⁻] Soil [Al] Fungi:bacteria ratio	19 <i>Picea abies</i> (L.) Karst. Stands	South Sweden	Throughfall N includes wet and dry inputs and ranged from 2.7 to 19	Ammonium NO ₃ ⁻ at 20	Addition: Microbial community composition in the organic horizon and soil solution chemistry below the rooting zone were highly correlated. Stands with low concentrations of NO ₃ ⁻ and Al had higher fungi:bacteria ratio compared with stands with higher concentrations of NO ₃ ⁻ and Al. Microbial community composition in the soil was more closely related to the soil solution than to the soil chemistry. The study found a significant negative correlation between the fungi:bacteria ratio in the soil and NO ₃ ⁻ and Al in soil solution ($r = -0.533$ and -0.857 , respectively).	Högberg et al. (2013)
N saturation	None (theoretical)	None (theoretical)	Not specified	None	Conceptual Model: N addition alleviates N limitation, and together with SO ₄ ²⁻ deposition, causes soil acidification and increases availability of electron acceptors for soil microbial processes. Increasing N and SO ₄ ²⁻ decreases fungal biomass, increases bacterial DOC mineralization, and decreases DOC leaching.	Kopáček et al. (2013)
Decomposition	Deciduous forests	Catskills Mountains of southeastern New York	9.0	50 (NH ₄ NO ₃)	Addition: NO ₃ ⁻ leaching increased markedly in response to the N addition in all species, indicating that the addition rate of N exceeded the N retention capacity of vegetation and soils in these plots.	Lovett et al. (2013)

Table 4-3 (Continued): Nitrogen accumulation, saturation, and leaching.

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference HERO ID
NO ₃ ⁻ leaching	Alpine	Rocky Mountain National Park (Niwot Ridge)	Not specified	Variable	Review: Nitrate leaching increases above 10 kg N/ha/yr deposition.	Bowman et al. (2014)
Rate of soil N cycling	Alpine	Rocky Mountain National Park (Niwot Ridge)	Not specified	Variable	Review: the rate of soil N cycling increases above 15 kg/ha/yr deposition.	Bowman et al. (2014)
Soil acidification and soluble Al	Alpine	Rocky Mountain National Park (Niwot Ridge)	Not specified	Variable	Review: soil acidification and soluble aluminum increases above 25 kg/ha/yr deposition.	Bowman et al. (2014)
N export	Forest	Ontario, Canada	Not reported	Not applicable	Isotope: Rain on snow, as it passes through the ecosystem, has a higher concentration of NO ₃ ⁻ (throughfall/snowmelt average = 498 µg/L) compared with baseflow (average = 7.3 µg/L; average = 41 µg/L) and as a result, throughfall and snowmelt contribute the majority of NO ₃ ⁻ export (average = 62%) during rain on snow events.	Casson et al. (2014b)
NO ₃ ⁻ leaching	Urban gradient		Urban sites 12.3 and nonurban 5.7		Gradient: The source of N leaching from five of nine sites was almost entirely from nitrification, indicating that the NO ₃ ⁻ in leachate came from biological processes rather than directly passing through the soil. A significant proportion (17–100%) of NO ₃ ⁻ leached from the other four sites came directly from the atmosphere.	Rao et al. (2014)
N saturation/NH ₄ ⁺ , NO ₃ ⁻ , total inorganic N, and SO ₄ ²⁻ -S	Forest	White Mountains National Forest, Crawford Notch, NH; Lye Brook, VT in southern Green Mountain National Forest	6.6 to 6.7 N 8.1 to 8.5 SO ₄ ²⁻	Not applicable	Isotope: There was no significant biological production of NO ₃ ⁻ via nitrification in the canopy. NO ₃ ⁻ concentrations in streams were low and had natural ¹⁸ O abundances consistent with microbial production, demonstrating that atmospheric N is being biologically transformed while moving through these watersheds and that these forested watersheds are unlikely to be N saturated.	Templer et al. (2015b)

Table 4-3 (Continued): Nitrogen accumulation, saturation, and leaching.

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference HERO ID
N accumulation	Semiarid chaparral and CSS	Santa Margarita Ecological Reserve and the Sky Oaks Field Station	6 to 8	50	Addition: N enrichment significantly increased N accumulation but not microbial respiration.	Vourlitis and Fernandez (2015)
N retention	Beech and Norway spruce forests	Solling, Germany	Direct total deposition not specified	None	Field Time Series: Two study plots observed that N retention decreased from 40 to 0–20 kg/ha/yr (from 1970s to current), indicating increasing N saturation.	Meesenburg et al. (2016)
NO ₃ ⁻ leaching, and N availability	Eastern U.S. forests	Hubbard Brook Experimental Forest, NH, and Bear Brook Watershed, ME	Four modeling scenarios ranging from 7.4 to 103.9 keq/ha N and 7.8 to 149.1 keq/ha S from 1850–2100 with 0–95% decrease from 2010 to 2100	28.8 kg/hr/yr S and 25.2 kg/ha/yr (NH ₄) ₂ SO ₄	Model: Modeled scenarios at Hubbard Brook, NH received twice the N and S at Bear Brook, ME and resulted in the largest changes in soil base saturation, ANC, NO ₃ ⁻ leaching and N availability. Modeled recovery of soil chemistry and understory plant communities at both forests only occurred when N and S deposition were modeled at preindustrial levels.	Phelan et al. (2016)
NO ₃ ⁻ leaching	Mixed beech-pine forest	Neuglobsow Integrated Monitoring (IM) site, Germany	Total N wet deposition: 13.26 ± 2.01 kg N/ha/yr (1998–2013)	None	Field Observation: Seepage water (120 cm) is estimated to contain at 2.38 kg N/ha/yr (96% as NO ₃ ⁻).	Schulte-Bisping and Beese (2016)
N immobilization	Restored tallgrass prairie	Prairie invasion and Climate Experiment (PRICLE) Loveland, CO	~1/3 of N added	5 g N/m ² /yr urea. “Seasonal maximum 5-day cumulative rainfall” increased by 33% (2012) and 9% (2013)	N Addition: Nitrogen addition during plant growth accelerated subsequent mass loss of <i>Schizachyrium scoparium</i> litter and litter produced with N addition had a 65% greater N loss than ambient N litter in <i>Solidago Canadensis</i> plots, indicating N addition accelerates N cycling.	Schuster (2016)

Table 4-3 (Continued): Nitrogen accumulation, saturation, and leaching.

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference HERO ID
N soil retention	Forest	Great Smoky Mountains National Park	5.1 kg N/ha/yr (36.5 mmolc /m ² /yr), respectively.	None	Model: PnET-BGC was used to model 30 stream watersheds characterized by decreased SO ₄ ²⁻ and NO ₃ ⁻ deposition during 1981–2014 (81 and 53%) and predict stream recovery. Spruce-fir forests at higher elevations have limited N retention and exhibit N saturation due to elevated N deposition.	Fakhraei et al. (2016)

1

4.3.3. Sulfate Accumulation, Adsorption, and Leaching

1 The 2008 ISA showed that SO_x deposition may be assimilated by vegetation or microbes,
2 accumulate in the soil, or act as a mobile ion and leach out of the soil to aquatic
3 ecosystems. Plant demand for S is typically low, particularly in comparison to the large
4 pools of S stored in the soil in recalcitrant organic compounds; consequently almost all S
5 deposited in terrestrial ecosystems enters soil rather than plant pools. At many locations
6 in the U.S. that receive high levels of S deposition, notably the glaciated Northeast and
7 upper Midwest, much of the deposited S leaches through soils into streams and lakes. The
8 physical process of charge balance pairs sulfate (SO₄²⁻) leaching with leaching of
9 countercharged cations from the soil matrix, and this process contributes to acidification
10 of soil, soil water, and surface water. As the base cations become depleted in the soil
11 matrix, charge balance in the soil is maintained by an increase in acidic cations (H⁺ and
12 inorganic Al), sometimes resulting in toxic conditions for plant roots and aquatic
13 organisms ([Charles and Christie, 1991](#); [Turner et al., 1991](#)).

14 In the 2008 ISA, regional trends of SO₄²⁻ soil accumulation and leaching were identified
15 in the U.S. In the Southeast, accumulation of atmospherically deposited S in soil resulted
16 from SO₄²⁻ adsorption to soil particles as well as incorporation of S into soil organic
17 matter through biological assimilation. Accumulated S is slowly released from soil pools
18 into drainage water, and this process can temporarily delay ecosystem recovery in
19 response to decreases in S deposition ([Sullivan et al., 2004](#); [Elwood et al., 1991](#); [Turner
20 et al., 1991](#)). In the Northeast, there was a demonstrated accumulation of S in soil
21 ([Driscoll et al., 2001a](#)). Two new studies on SO₄²⁻ accumulation, leaching, and
22 adsorption are described below ([Table 4-4](#)).

23 The net loss of S from soils is occurring in a number of northeastern watersheds in
24 response to decreased levels of atmospheric S deposition. In a new study evaluating
25 watersheds in the Northeast, [Mitchell and Likens \(2011\)](#) calculated that annual
26 discrepancies in the watershed S budgets (SO₄²⁻ flux in drainage waters minus total
27 atmospheric S deposition) have become more negative, indicating the increasing
28 importance of the release of S from internal ecosystem sources. The release of S from
29 forest soils is controlled (57%) by water flux and soil moisture ([Mitchell and Likens,
30 2011](#)).

31 In the southeastern U.S., [Rice et al. \(2014\)](#) calculated SO₄²⁻ mass balances for
32 27 forested, unglaciated watersheds from Pennsylvania to Georgia by using total
33 atmospheric deposition (wet plus dry) as input. Unlike their counterparts in the
34 northeastern U.S. and southern Canada, many of these watersheds still retain SO₄²⁻. [Rice](#)

1 [et al. \(2014\)](#) predicted that many of the watersheds in the study will begin releasing SO_4^{2-}
2 over the next two decades. The specific years when the watersheds cross over from
3 retaining to releasing SO_4^{2-} correspond to a general geographical pattern from north to
4 south of later net watershed release. For instance, the three watersheds in West Virginia
5 have crossover years that ranged from 2006 to 2011, and crossover years for five of the
6 watersheds in Virginia range from 2012 to 2021. The runoff ratio, computed as the ratio
7 of annual mean discharge to annual mean precipitation, was the single best
8 watershed-scale predictor of the crossover year ($r^2 = 0.72$). Watersheds with higher
9 runoff ratios tend to convert sooner from net retention to net release of SO_4^{2-} ([Rice et al.,](#)
10 [2014](#)). More recently, [Fakhraei et al. \(2016\)](#) used PnET-BGC to model 30 stream
11 watersheds during 1981–2014 in the Great Smoky Mountains National Park. Hindcast
12 modeling (beginning ca. 1850) to 2014 showed that the soil SO_4^{2-} pools increased from
13 20.2 g/m² (preindustrial) to 145.6 g/m² (ambient median). Soils with high SO_4^{2-}
14 adsorption capacity also had a faster rate of base cation depletion.

Table 4-4 Sulfate adsorption, accumulation and leaching.

Process/Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Sulfate adsorption and cation leaching	Upland forests, low-lying areas and wetlands	Athabasca oil sands region (AOSR) in Alberta, Canada	Not specified	None	Field Comparison: SO_4^{2-} adsorption capacity was relatively low (50 to 500 mg SO_4^{2-} /kg) in both watersheds as compared to other acid-sensitive soils in eastern North America.	Jung et al. (2011)
S budget	Varied	15 sites southeastern Canada and northeastern U.S.	~0.1 to 14		Long-Term Deposition: The net annual fluxes of SO_4^{2-} showed a strong relationship with hydrology; the sensitivity of S budgets is likely greatest in watersheds with the greatest wetland area, which are particularly sensitive to drying and wetting cycles.	Mitchell et al. (2011)
Sulfate accumulation and leaching	Forest	HBEF in the White Mountains of New Hampshire	~7 to 20	None	Long-term Deposition: S released from internal sources is increasing over time. Watershed wetness, as a function of \log_{10} annual water flux explained 57% ($n = 157$) of the annual variation for four watersheds. The biogeochemical control of annual SO_4^{2-} export in streamwater draining from forested watersheds has shifted from control by atmospheric S deposition to soil moisture driven by climate.	Mitchell and Likens (2011)

Table 4-4 (Continued): Sulfate adsorption, accumulation and leaching.

Process/Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
SO ₄ ²⁻ leaching	Watersheds ranging from Pennsylvania to Georgia	27 forested, unglaciated watersheds	Not specified	None	Long-term Deposition: Calculated SO ₄ ²⁻ -mass balances for 27 watersheds showed that over the next two decades, many of the study's watersheds will begin releasing SO ₄ ²⁻ . The single most important variable that explained the crossover year was the runoff ratio, defined as the ratio of annual mean stream discharge to precipitation.	Rice et al. (2014)
Soil SO ₄ ²⁻	Forest	Great Smoky Mountains National Park	3.1 kg S/ha/yr (19.3 mmolc/m ² /yr)	None	Model: PnET-BGC used to model 30 stream watersheds during 1981–2014 when SO ₄ ²⁻ and NO ₃ ⁻ deposition decreased (81 and 53%, resp.). Hindcast modeling (beginning ca. 1850) increased soil pools of SO ₄ ²⁻ from 20.2 g/m ² (preindustrial) to 145.6 g/m ² (current median).	Fakhraei et al. (2016)
Base saturation	Forest	Great Smoky Mountains National Park, U.S.	5.1 kg N/ha/yr (36.5 mmolc/m ² /yr)	None	Model: PnET-BGC used to model 30 stream watersheds during 1981–2014 when SO ₄ ²⁻ and NO ₃ ⁻ deposition decreased (81 and 53%, resp.). High capacity SO ₄ ²⁻ adsorbing soils depleted base saturation faster.	Fakhraei et al. (2016)
Soil SO ₄ ²⁻	Boreal forest	Sweden	Not specified	None	Time Series: In an analysis of 10 yr of data, riparian zone soil SO ₄ ²⁻ was observed to decrease from 2003–2012.	Ledezma et al. (2016)

Table 4-4 (Continued): Sulfate adsorption, accumulation and leaching.

Process/Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Soil SO ₄ ²⁻	Maritime pine forest plantation	Northwest Spain	Not specified	None	Field Experiment: The soil parent material (slate, biotitic schist, mica schist, and granite) did not significantly affect soil solution SO ₄ ²⁻ ($p = 0.39$).	Eimil-Fraga et al. (2016)

AOSR = Athabasca oil sands region; SO₄²⁻ = sulfate; kg = kilogram; HBEF = Hubbard Brook Experimental Forest; S = sulfur; yr = year.

4.3.4. Base Cation Leaching and Exchange

1 In the 2008 ISA, it was known that acidifying deposition changes concentrations of
2 exchangeable base cations in soil by accelerating natural rates of base cation leaching
3 until stores become depleted ([Lawrence et al., 1999](#); [Cronan et al., 1978](#)). Base cations
4 include the essential plant nutrients (e.g., Ca, Mg, and K), and the loss of exchangeable
5 base cations from the soil may have adverse effects on flora. When SO_4^{2-} and NO_3^-
6 leaching occur in equal magnitude to base cation leaching, the drainage water is not
7 acidified. However, in the process of neutralizing the acidity of drainage water, base
8 cation release from soil eventually can cause decrease of the base saturation of the soil.
9 Soil base saturation expresses the concentration of exchangeable bases (Ca, Mg,
10 potassium [K], sodium [Na]) as a percentage of the total cation exchange capacity (which
11 includes exchangeable H^+ and inorganic Al).

12 Under conditions of low soil base saturation (approximately <20%) and elevated
13 concentrations of strong acid anions, Al is mobilized from soil to drainage water ([Cronan
14 and Schofield, 1990](#); [Reuss, 1983](#)), with potentially harmful consequences for sensitive
15 terrestrial plants and aquatic organisms ([Appendix 7](#)) throughout the food web
16 ([Appendix 4.3.6](#)).

17 Leaching of base cations by acidifying deposition has been documented in sensitive
18 regions in the U.S., including the Adirondack Mountains, New England, the Catskill
19 Mountains, and northwestern Pennsylvania ([U.S. EPA, 2008a](#)). Base cation loss increases
20 the sensitivity of the watershed to further acidifying deposition. Watersheds that were
21 capable of fully neutralizing a particular level of acidifying deposition in the past may no
22 longer be capable of fully neutralizing that level today or in the future due to the
23 cumulative effect of acidifying deposition on soil base saturation.

24 Base saturation values less than 10% predominate in the soil B-horizon in the areas in the
25 U.S. where soil and surface water acidification from acidifying deposition have been
26 most pronounced, including conifer and hardwood forests in the Adirondack Mountains
27 ([Sullivan et al., 2006b](#)), red spruce forests throughout the Northeast ([David and
28 Lawrence, 1996](#)), hardwood forests in the Allegheny Plateau ([Bailey et al., 2004](#)), and
29 conifer and hardwood forests in the southern Appalachian Mountains ([Sullivan et al.,
30 2003](#)). In a study of sugar maple decline throughout the Northeast, [Bailey et al. \(2004\)](#)
31 found threshold relationships between base cation availability in the upper B soil horizon
32 and sugar maple mortality at Ca saturation less than 2%, and Mg saturation less than
33 0.5% ([Bailey et al., 2004](#)). The authors concluded that base saturation varied as a function
34 of topography, geologic parent material, and acidifying deposition.

1 New publications further support findings from the 2008 ISA that N and S deposition
2 cause base cation depletion from soils ([Table 4-5](#)). In the Rocky Mountains, [Lieb et al.](#)
3 ([2011](#)) observed that soil acid buffering capacity decreased as N inputs increased (40%
4 decrease at highest N input). An acidification threshold was calculated for significant loss
5 of soil acid buffering capacity of around 28 kg N/ha/yr. In another U.S. study, long-term
6 trends in base cation depletion at Bear Brook watershed, ME, showed N and S addition
7 over a 17-year time period (while ambient S deposition was simultaneously decreasing)
8 resulted in little evidence of continued soil exchangeable base cation depletion or
9 recovery [expected because of decreasing S deposition ([SanClements et al., 2010](#))]. A
10 study of the forest understory herb community in West Virginia found that N addition
11 lowered plant-available Ca and, to a lesser degree, Mg, but not K, illustrating how
12 biogeochemical cycling of forest ecosystems is altered ([Gilliam et al., 2016a](#)).

13 A meta-analysis of 107 studies found N addition alters the availability of base cations in
14 terrestrial and aquatic ecosystems ([Lucas et al., 2011](#)): although short-term N and S
15 deposition cause base cation depletion, long-term trends across all studies are unclear and
16 may be affected by confounding disturbances. Evaluating the strength of these results is
17 difficult because they are based on averages from various biome types and there are few
18 long-term studies.

19 Field studies in forests in Europe confirm that N deposition and N addition lower soil pH
20 and decreases base cations ([Chen et al., 2015](#); [Ferretti et al., 2014](#)). As acidifying
21 deposition decreased, base cation concentration in the soil increased ([Berger et al., 2016](#)).
22 Two studies from grasslands in Asia report mixed results, with N addition causing Bc
23 levels to decrease in one study ([Chen et al., 2015](#)) and increase in another ([Tian et al.,](#)
24 [2016b](#)). A study of European grasslands found that base cation depletion increased with
25 N addition over a 10-year period, leading to a loss of 23 to 35% of total available bases
26 (Ca^{2+} , Mg^{2+} , K^{+} , and Na^{+}) from the soil and acidifying it by 0.2 to 0.4 pH units ([Horswill](#)
27 [et al., 2008](#)).

28 Base cation weathering rates are uncertain, but substantial advancements have been made
29 in this field since the 2008 ISA ([Appendix 4.5.1.1](#)). New model estimates have been
30 published to two forested areas in Canada ([Williston et al., 2016](#); [Watmough et al., 2014](#)).

31 Major sources of sources of Bc to ecosystems are either from atmospheric deposition or
32 weathering from soils. Two additional studies from Spain considered the sources of Bc in
33 ecosystems from deposition ([Aguillaume et al., 2017](#)) or as compared with sources from
34 different types of soil parent material([Eimil-Fraga et al., 2016](#)).

35 Additional literature that evaluates how base cation depletion from acidification may
36 recover in response to the addition of base cations to the soil is also noted here; however,

1 this literature does not describe the effects of N and S deposition, but rather a method for
2 recovering ecosystems to a more natural state. This literature includes several
3 publications from a 15-year Ca addition study at Hubbard Brook Experimental Forest,
4 NH ([Shao et al., 2016](#); [Johnson et al., 2014](#); [Green et al., 2013](#); [Nezat et al., 2010](#)).

Table 4-5 Base cation leaching and exchange.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Base cation depletion Soil pH Soil [Al], [Fe], [Mg]	Grasslands	Peak District National Park, England	Not specified	Plots treated for 8 to 10 yr with 0, 35, or 140 N as NH ₄ NO ₃	Addition: Treatments caused grassland soils to lose 23 to 35% of their total available bases (Ca ²⁺ , Mg ²⁺ , K ⁺ , and Na ⁺), and they became acidified by 0.2 to 0.4 pH units. Al, Fe, and Mn were mobilized and taken up by limestone grassland forbs and were translocated down the acid grassland soil. Mineral N availability increased in both grasslands and many species showed foliar N enrichment. N deposition depletes base cations from grassland soils.	Horswill et al. (2008)
Base cation depletion	Hardwood forest	Eastern U.S., Bear Book watershed, ME		28.8 S and 25.2 N as (NH ₄) ₂ SO ₄	Addition: Compared treated and untreated watersheds after N and S manipulation over a 17-yr time period. Found little evidence of continued soil exchangeable base cation concentration depletion or recovery, possibly because a 1998 ice storm increased litterfall and accelerated mineralization, obscuring temporal trends in soil chemistry.	SanClements et al. (2010)
Base cation depletion Critical load	Forest stands with mature white ash	Niwot Ridge in southern Rocky Mountains	8	20, 40, 60 N	Addition: Soil acid buffering capacity decreased with increasing N inputs (40% decrease at highest input), and was associated with a decrease in pH, loss of extractable Mg ²⁺ and increases in Mn and Al ³⁺ . The threshold at which acidification occurred was around 28 kg N/ha/yr.	Lieb et al. (2011)
Base cation depletion	Boreal forest, temperate forest, tropical forest, and grassland	107 sites globally	Not specified	Median N addition across the studies was 38, and 71% of the studies added 70 or less	Meta-analysis: Evaluation of 107 independent studies to determine whether N fertilization alters the availability of base cations (Bc) in terrestrial and stream ecosystems. Results suggest N fertilization may accelerate Bc loss from terrestrial ecosystems over time periods less than 5 yr.	Lucas et al. (2011)

Table 4–5 (Continued): Base cation leaching and exchange.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Base cation leaching	Jack pine (<i>Pinus banksiana</i>) and aspen (<i>Populus tremuloides</i>) in upland forests and black spruce (<i>Picea mariana</i>) in low-lying areas and wetlands.	Athabasca oil sands region (AOSR), Alberta, Canada	Not specified for AOSR	30 N, 30 S (2006 through 2009)	Addition: No evidence of N saturation in the studied forest ecosystem after 4 yr of N and S additions. No long-term increase of inorganic N concentrations in the soil; leaching of N beyond the main rooting zone in the soil profile was minimal, and tree growth was increased by N addition, all indications of N limitation in the studied forest stand. However, exchangeable Ca ²⁺ and Mg ²⁺ concentrations in the surface mineral soil layer were reduced by N and S additions because of increased cation leaching associated with increased SO ₄ ²⁻ leaching caused by S addition and increased nutrient uptake associated with increased tree growth resulting from N addition.	Jung and Chang (2012)
Hydrologic flowpath	Forest	Hubbard Brook Experimental Forest, NH	Not specified	41 metric tons of the mineral wollastonite (CaSiO ₃) was applied to an 11.8 hectare watershed	Addition: The flow path of the added Ca was followed through time. The deepest flowpaths to the streams were penetrated by 3–9 yr after application. It was estimated that only ~360 kg out of 19 metric tons of Ca applied as wollastonite had been exported from the watershed in stream flow 9 yr after its application and it would take 1,000 yr for all of the added Ca to be transported from the watershed.	(Nezat et al. (2010)
Evapotranspiration	Forest	Hubbard Brook Experimental Forest, NH	Not specified	1,028 kg Ca/ha (as wollastonite) in 1999	Field Observation: 25, 18, and 19%, evapotranspiration, increased in Years 1–3 after addition and then returned to pretreatment levels. Watershed soil retained Ca from the wollastonite, indicating a watershed-scale fertilization effect on transpiration. That response is unique in being a measured manipulation of watershed runoff attributable to fertilization.	Green et al. (2013)

Table 4–5 (Continued): Base cation leaching and exchange.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Total Ca, exchangeable Ca, cation exchange capacity, base saturation	Forest	Hubbard Brook Experimental Forest, NH	Not specified	1,028 kg Ca/ha (as wallastonite) in 1999	Field observation: Compared to conditions before the 1999 Ca addition, total Ca increased 596% in the Oie-horizon in 2000, 81% in the Oa-horizon in 2002, and 146% in the 0–10 cm mineral soil in 2006. Oie-horizon exchangeable Ca tripled in 2000 and remained significantly higher through 2010. Significant increases occurred in 2002 in Oa; modest increases measured in upper mineral soil in 2006 and 2010. Total Ca pool in O-horizon and mineral soils was 250 kg/ha greater than pretreatment. In total, 92.4% of Ca added was estimated to dissolve and enter the ecosystem as labile Ca. Cation exchange capacity CEC increased by 106% in the Oie-horizon in 2010 but decreased 52 and 32% in the Oa and mineral soil. Oie, Oa, and mineral soil base saturation rose 69, 84, and 58%, resp. by 2010.	Johnson et al. (2014)
pH Base cations	Forest soils	Italy	4.5 to 28.8 throughfall N (NO ₃ ⁻ + NH ₄ ⁺)	Not applicable	Gradient: Exchangeable base cations and pH decreased with increasing N deposition, and foliar nutrient N ratios (especially N:P and N:K) increased. Comparison between bulk openfield and throughfall data suggested possible canopy uptake of N, levelling out for bulk deposition >4–6 kg/ha/yr.	Ferretti et al. (2014)
Bc weathering rate	Boreal plains	NE Alberta, Canada	S = 118, NH ₄ ⁺ = 93, NO ₃ ⁻ = 49 in units of mmolc m ² /yr	Not applicable	Modeling: base cation weathering rate estimated for 63 sites using PROFILE was 17 mmolc m ² /yr, however acidification was not expected because base cations from fugitive dust sources were a comparatively high 250 mmolc m ² /yr, offsetting much of the acidifying input of N and S deposition.	Watmough et al. (2014)
pH Soil N Base cations Fungi:bacteria ratio Belowground biomass Microbial community Structure	Semiarid grassland	Mongolia	Not specified	0, 17.5, 52.5, 105.0, 175, and 280 NH ₄ NO ₃ fertilizer	Addition: Soil pH decreased across the N addition gradient by 0.3–1.8 units in 2010 and by 0.1–1.7 units in 2011. Decreased concentrations of mineral cations Ca ²⁺ , Mg ²⁺ , and Na ⁺ were observed. The observed increases in above- and belowground biomass and changes in plant community structure were mainly (57–69%) attributed to the increase in soil N availability and changes in soil base cations. N addition increased the fungi:bacteria ratio by 5–18% in 2010 and by 2–10% in 2011.	Chen et al. (2015)

Table 4–5 (Continued): Base cation leaching and exchange.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Base saturation		Adirondack Mtns. region, NY	SO ₄ ²⁻ = 290.3–365.7 eq/ha/yr; NO ₃ ⁻ = 172.5 –233.5 eq/ha/yr	None	Model: PnET-BGC was used to evaluate biophysical factors that affect CLs of acidity. Model simulations included a range of future scenarios of decreases in atmospheric nitrate, ammonium, and sulfate deposition from the present to 2,200; historical forest harvesting; supply of naturally occurring organic acids; and variations in lake hydraulic residence time. Assuming the current soil base saturation of 6.4%, a decrease in SO ₄ ²⁻ deposition from 0 to 100% resulted in a soil percentage BS range of 6.2 to 15.3%, respectively, after 200 yr. (Preindustrial soil percentage BS ~22%).	Zhou et al. (2015c)
Bc	Predominantly beech	Vienna Woods, Austria	Not specified locally	None	Time Series: In 1984 and 2012, soil samples were taken from 20 cm downhill and 3 m away from the base of a beech tree stem. Exchangeable Ca ²⁺ , Mg ²⁺ , and pH increased in 0–5 cm soil from 1984 to 2012. Recovery appeared delayed in deeper soils. Foliar base cations Ca, Mg, and K decreased. (Foliar K declined the most at 48%).	Berger et al. (2016)
Bc	Maritime pine forest	Northwest Spain	Not specified	None	Field observation: The soil parent material (slate, biotitic schist, mica schist, and granite) significantly affected base cation concentrations.	Eimil-Fraga et al. (2016)
Foliar base cation	Eastern U.S. temperate, hardwood forest herbaceous layer (<i>Viola rotundifolia</i> , <i>Rubus allegheniensis</i>)	Fernow Experimental Forest, WV	~10 kg N/ha/yr (wet)	35 kg N/ha/yr (NH ₄) ₂ SO ₄	N Addition: Foliar measurements were used as a proxy for soil micronutrient availability under N addition. Excess N lowered plant-available Ca and, to a lesser degree, Mg, but not K. N addition significantly affected Ca:Al ratios in <i>Viola</i> sp and <i>Rubus</i> sp.	Gilliam et al. (2016a)

Table 4–5 (Continued): Base cation leaching and exchange.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Soil solution Bc	Forest	Hubbard Brook Experimental Forest, NH	Not specified	1,028 kg Ca/ha (as wallastonite) in 1999	Field Observation: Significant increase in soil Ca concentrations. Increases in pH and ANC and decreases in inorganic Al in the Oa, Bh, and Bs soil horizons. Ca:Al ratios ranging from 1 to 5.3 in the Oa-, Bh-, and Bs-horizons before treatment increased significantly after Ca addition, with the greatest increase occurring in the Oa-horizon. Average 2000–2011 Ca fluxes in soil solution across the study area’s three subwatersheds ranged from 26.4 + 3.2 mmol/m ² /yr to 29.9 + 4.2 mmol/m ² /yr. The weighted average percentage increase in Ca fluxes for the three subwatersheds from 1999–2011 were 139, 91, and 97% for Oa-, Bh-, and Bs-horizons, respectively.	Shao et al. (2016)
Soil Bc	Temperate grassland	Mongolia, China	1.6 mg N/m ² /yr (not specified if wet or total)	1, 2, 4, 8, 16, 32, 64 g N/m ² /yr (urea)	N Addition: Soil exchangeable Mn ²⁺ , Fe ³⁺ , and Al ³⁺ concentrations increased linearly with N addition.	Tian et al. (2016b)
Bc weathering	Forest	NW British Columbia, CAN (Kitmat and Prince Rupert	0–80 meq SO ₄ ²⁻ /m ² /yr and 0–30 meq N/m ² /yr	None	Model: Weathering rates were modeled by PROFILE and A2M solver using empirical soil data to parameterize the models. Rates ranged between 19 and 393 meq/m ² /yr (average: 76) in the top 50 cm of soil in Prince Rupert and between 24 and 118 meq/m ² /yr (average: 57 meq/m ² /yr) in Kitimat.	Williston et al. (2016)
Bc deposition	Mediterranean holm-oak (<i>Quercus ilex</i>) forests ranging from the typical Mediterranean climate to a drier, more seasonal climate	Spain	Not specified	None	Field Observation: In wetter forest sites, 55–65% of total base cation deposition was wet deposition. Rainfall and net throughfall were positively correlated for leaching for K ⁺ and uptake for NH ₄ ⁺ at all sites. Variable response between sites was found for Na ⁺ , Ca ²⁺ , SO ₄ ²⁻ and Cl ⁻ . The authors suggest that the interplay of dry deposition, leaching, and uptake at the canopy was different depending on site climate and air quality characteristics.	Aguillaume et al. (2017)

Al = aluminum; AOSR = Athabasca oil sands region; Bc = base cations; BCE = exchangeable base cations; Ca²⁺ = calcium ion; Fe = iron; g = gram; ha = hectare; K⁺ = potassium ion; kg = kilogram; m = meter; Mg²⁺ = magnesium ion; N = nitrogen; Na⁺ = sodium ion; NH₄⁺ = ammonium; NH₄NO₃ = ammonium nitrate; (NH₄)₂SO₄ = ammonium sulfate; NO₃⁻ = nitrate; S = sulfur; SO₄²⁻ = sulfate; yr = year.

4.3.5. Aluminum Mobilization

1 The 2008 ISA documented that when soil base saturation is 15 to 20% or lower,
2 acidifying deposition can mobilize inorganic Al, which can lead to its leaching into soil
3 solution and into surface waters ([Cronan and Schofield, 1990](#); [Reuss and Johnson, 1985](#);
4 [Reuss, 1983](#)). Leaching of inorganic Al is an extremely important effect of acidifying
5 deposition because some forms of inorganic monomeric Al, including Al³⁺ and various
6 hydroxide species, are toxic to tree roots, fish, algae, and aquatic invertebrates
7 ([Appendix 5](#) and [Appendix 8](#)). Increased concentrations of exchangeable inorganic Al in
8 the soil have been identified through repeated sampling in the U.S. and Europe over
9 periods ranging from 17 to 41 years in studies by [Billett et al. \(1990\)](#), [Falkengren-Grerup](#)
10 [and Eriksson \(1990\)](#), [Bailey et al. \(2005\)](#), and [Lawrence et al. \(1995\)](#).

11 The negative biological effects of Al mobilization are discussed in [Appendix 5](#); in
12 general, Al disrupts Ca uptake by tree roots ([Shortle and Smith, 1988](#)). Substantial
13 evidence of this relationship has been provided through field studies ([Kobe et al., 2002](#);
14 [Minocha et al., 1997](#); [Shortle et al., 1997](#); [McLaughlin and Tjoelker, 1992](#); [Schlegel et](#)
15 [al., 1992](#)) and laboratory studies ([Cronan and Grigal, 1995](#); [Sverdrup and Warfvinge,](#)
16 [1993](#)). These studies make clear that high inorganic Al concentration in soil water can be
17 toxic to plant roots. The toxic response is often related to the concentration of inorganic
18 Al relative to the concentration of Ca, expressed as the molar ratio of Ca to inorganic Al
19 in soil solution. From an exhaustive literature review, [Cronan and Grigal \(1995\)](#)
20 estimated a 50% risk of adverse effects on tree growth if the molar ratio of Ca to Al in
21 soil solution was as low as 1.0. They estimated a 100% risk for adverse effects on growth
22 at a molar ratio value Ca:Al <0.2 in soil solution and minimal to no risk is thought to
23 occur at Ca:Al >10.

24 New studies on Al in soils are summarized in [Table 4-6](#) and include an investigation of
25 long-term soil solution chemistry trends in Hubbard Brook Experimental Forest ([Fuss et](#)
26 [al., 2015](#)), an investigation of the influence of increasing dissolved organic
27 matter (DOM) on toxic inorganic Al (Al_i) concentration in 52 Adirondack and Hubbard
28 Brook watersheds ([Fakhraei and Driscoll, 2015](#)), an investigation of the effects of soil
29 parent material on Al ([Eimil-Fraga et al., 2016](#)), a model comparison of three models'
30 predictions of soil solution Al concentrations in three monitored Swiss and German
31 forests ([Bonten et al., 2015](#)), and a study showing that N addition increased Al
32 mobilization on grasslands in England ([Horswill et al., 2008](#)).

33 [Fakhraei and Driscoll \(2015\)](#) evaluated the influence of increasing DOM on Al_i
34 concentration in the Adirondacks and Hubbard Brook. The authors linked a PnET-BGC

1 model chemical equilibrium subroutine with an optimization algorithm. They determined
2 that accounting for the increasing concentration of DOM (as acid deposition decreases
3 and ANC increases) and its binding capacity for Al_i is necessary in the model to avoid
4 substantial overestimation of available toxic Al_i in waters. In an empirical study, [Fuss et](#)
5 [al. \(2015\)](#) found that Al_i in soil water solution in the mineral horizon decreased over the
6 period of 1984–2011 (also discussed in the recovery [Appendix 4.6.1](#)).

Table 4-6 Aluminum mobilization.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Base cation depletion Soil pH Soil [Al], [Fe], [Mg]	Grasslands	Peak District National Park, England,	Not specified	Plots treated for 8 to 10 yr with 0, 35, or 140 N as NH ₄ NO ₃	Addition: Treatments caused the grassland soils to lose 23 to 35% of their total available bases and acidify by 0.2 to 0.4 pH units. Al, Fe, and Mn were mobilized and taken up by limestone grassland forbs and were translocated down the acid grassland soil.	Horswill et al. (2008)
Al _i , DOM, DOC	Lakes	Adirondack Long-Term Monitoring (ATLM) Program lakes	Variable	None	Model: A PnET-BGC chemical equilibrium subroutine was linked with an optimization algorithm. Accounting for the increasing concentration of dissolved organic matter (DOM) as acid deposition decreases and ANC increases, DOM's binding capacity for Al is necessary to avoid substantial overestimation of toxic Al _i in waters.	Fakhraei and Driscoll (2015)
Al _i	Forest and streams	Hubbard Brook Experimental Forest, NH	Variable	None	Field observation/elevation gradient: Al _i in soil solution in the mineral horizon decreased over the period of 1984–2011.	Fuss et al. (2015)
Al	Forest	Three Swiss forest monitoring sites	Not specified	None	Model: VSD modeled soil solution Al concentrations are substantially smaller than measured ones. However, VSD only calculates free Al ³⁺ , whereas measurements also include other Al species as Al hydroxides, Al fluorides, and Al complexed by DOM.	Bonten et al. (2015)
Al	Spruce forest	Bechtel, Switzerland	Not specified	None	Model: ForSAFE-modeled Al ³⁺ was in the range of the measured soil solution values at 20 cm depth (1990–2005)	Bonten et al. (2015)

Table 4-6 (Continued): Aluminum mobilization.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Al, Ca and protons	Norway spruce forest	Long-term monitoring site in Germany	Not specified	None	Model: SMARTml results showed that modeled Al ³⁺ , Ca ²⁺ , and H ⁺ agree with measured values in soil solution (1990-2005).	Bonten et al. (2015)
Total Al, reactive Al	Maritime pine forest	Northwest Spain	Not specified	None	Field Observation: The soil parent material (slate, biotitic schist, mica schist, and granite) significantly affected total and reactive Al in soil solution. Total Al ranged from 17.2 to 64.2 µmol/L. (<i>p</i> = 0.0006). The concentration was significantly higher for soil developed from mica schist developed soil than granite and biotitic schist.	Eimil-Fraga et al. (2016)

Al = aluminum; Al_i = toxic inorganic Al; AOSR = Athabasca oil sands region; Bc = base cations; BCE = exchangeable base cations; Ca²⁺ = calcium ion; Fe = iron; g = gram; H⁺ = hydrogen ion; ha = hectare; K⁺ = potassium ion; kg = kilogram; m = meter; Mg²⁺ = magnesium; N = nitrogen; Na⁺ = sodium ion; NH₄⁺ = ammonium; NH₄NO₃ = ammonium nitrate; (NH₄)₂SO₄ = ammonium sulfate; NO₃⁻ = nitrate; S = sulfur; SO₄²⁻ = sulfate; yr = year.

4.3.6. Nitrification and Denitrification

1 Nitrification is the microbial oxidation of ammonia or ammonium to form nitrite
2 followed by the oxidation of the nitrite to form NO_3^- . The 2008 ISA documented that
3 oxidation of ammonia into nitrite is performed by two groups of organisms,
4 ammonia-oxidizing bacteria and ammonia-oxidizing archaea. The rate of nitrification is
5 controlled by numerous factors, including substrate availability (presence of NH_4^+),
6 aeration (availability of O_2 , often as well-drained soils with <60% soil moisture), and
7 acidity (pH). N addition may increase nitrification, which is often stimulated in soils with
8 a C:N ratio below about 20 to 25 ([Ross et al., 2004](#); [Aber et al., 2003](#)). The microbial
9 process of autotrophic nitrification is an acidifying process, releasing 2 moles of
10 hydrogen ion (H^+) per mole of NH_4^+ converted to NO_3^- ([Reuss and Johnson, 1986](#)). As
11 the N cycle becomes enriched through cumulative N addition, N becomes more abundant,
12 competition among organisms for N decreases, net nitrification rates often increase, and
13 NO_3^- can leach from the soil ([Aber et al., 2003](#); [Aber et al., 1989](#)).

14 Soils with a C:N ratio below about 20 to 25 are associated with stimulated mineralization,
15 nitrification, and cation leaching ([Ross et al., 2004](#); [Aber et al., 2003](#)). This observation
16 makes the C:N ratio an especially useful field measurement that provides a relative index
17 rather than a quantitative rate of N leaching ([Ross et al., 2004](#)). C:N ratios in the forest
18 floor are generally inversely related to acidifying deposition levels, although the
19 relationship is stronger for hardwood stands than conifer stands ([Aber et al., 2003](#)). The
20 C:N ratio is a reliable and relatively straightforward measure for identifying forest
21 ecosystems that may be experiencing soil acidification and base leaching as a result of N
22 input and increased nitrification.

23 Denitrification is the microbial process that transforms NO_3^- by anaerobically reducing it
24 to nitrite (NO_2^-), nitric oxide (NO), the greenhouse gas nitrous oxide (N_2O) and N_2 . The
25 2008 ISA documented that in terrestrial ecosystems, denitrification mainly occurs in
26 oxygen-depleted soils (e.g., during periods of water saturation), groundwater, and
27 riparian zones. Soil pH has a marked effect on denitrification, with lower rates in acidic
28 as compared with alkaline conditions ([Yamulki et al., 1997](#)). Soil denitrification and N_2O
29 production and consumption are extremely variable in time and space ([McClain et al.,](#)
30 [2003](#)).

31 New information published since 2008 is summarized in [Table 4-7](#). New empirical work
32 along an N deposition gradient in Oregon found that nitrification increased with
33 increasing N deposition ([Perakis and Sinkhorn, 2011](#)); likewise, denitrification increased
34 with N deposition in northeastern forests ([Morse et al., 2015a](#)). In a deposition exclusion

1 study in Europe, after two decades of deposition exclusion, net nitrification and NO_3^-
2 concentration in soils were not detectable, and in fact, the soil switched from a net source
3 of NO_y to a net sink ([Eickenscheidt and Brumme, 2012](#)).

4 A growing body of information indicates that increased N deposition also alters the soil
5 microbial community ([Freedman et al., 2013](#)). Discussion of this is provided in
6 [Appendix 6. Marusenko et al. \(2013\)](#) explored the role of fungi in NO_3^- and N_2O
7 production in soils from regions across the southwestern U.S. and found that fungi are
8 significant sources of N_2O production in soils in semiarid grasslands and deserts. High
9 soil organic matter is associated with increased rates of nitrification in forest watersheds
10 in North America, Europe, and Japan ([Mitchell, 2011](#)). However, [Russow et al. \(2008\)](#)
11 found that soils with high soil organic matter adsorbed added NH_4^+ , making it difficult to
12 determine microbial activity.

13 Several new syntheses evaluated N addition effects on denitrification and nitrification in
14 terrestrial ecosystems ([Yang et al., 2017](#); [Bouwman et al., 2013](#); [Lu et al., 2011a](#); [Liu and](#)
15 [Greaver, 2009](#)). Globally, the amount of N removed from ecosystems by denitrification
16 may be higher in terrestrial ecosystems than from groundwater or riparian zones
17 ([Bouwman et al., 2013](#)); however, other older estimates have indicated more
18 denitrification may occur in riparian wetlands and in first-order streams than in terrestrial
19 ecosystems ([Van Breemen et al., 2002](#)), although the authors acknowledged this estimate
20 likely underestimated terrestrial N. [Liu and Greaver \(2009\)](#) showed that N addition
21 significantly increased denitrification from all ecosystems tested (coniferous forest,
22 deciduous forest, tropical forest, wetland, grassland) except heathland. Among the five
23 chemical forms of N fertilizer added to ecosystems in studies, NO_3^- showed the strongest
24 stimulation of N_2O emission ([Figure 4-5](#)). [Lu et al. \(2011a\)](#) further confirmed that N
25 addition stimulates nitrification and denitrification ([Figure 4-6](#)). Using data extracted
26 from 206 peer-reviewed papers, the meta-analysis showed that the largest changes caused
27 by N addition in the ecosystem N cycle were increased nitrification (154%), nitrous oxide
28 emission (134%), and denitrification (84%). In addition, [Yang et al. \(2017\)](#) evaluated N
29 cycling in five biomes in California and found a strong ($r^2 = 0.34$) significant linear
30 correlation between NO_3^- and nitrification rates. They also found a strong negative
31 relationship between gross nitrification and soil C:N in forests that had soil C:N ratios
32 greater than 20. However, the authors noted that not all forests have such high soil C:N
33 ratios as those in their study that were dominated by coniferous trees. Coniferous forest
34 generally have higher litter C:N ratios than deciduous forests, and deciduous forests with
35 lower C:N ratio may also have negative relationship with C:N and nitrification.

Table 4-7 Nitrification and denitrification.

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Nitrification and denitrification	Agricultural black earth soils (haplic chernozem); two sites: high and normal SOM	Central Germany	Not specified	81.3 (KNO ₃ , Ca[NO ₃] ₂); 80 kg (NH ₄) ₂ SO ₄	Isotopic Tracer: Addition of ¹⁵ N revealed denitrification of NO ₃ ⁻ represents the main pathway of soil N ₂ O release. On average, 76 and 54% of N ₂ O was emitted during denitrification from soils with high and normal SOM content, respectively. Denitrification contributed, on average, only 17 and 12% of released NO from soil with high and normal SOM content, respectively.	Russow et al. (2008)
Nitrification	Spruce plantation	Höglwald, Bavaria, Germany	30 (two decades)	None	Time series: Dynamic internal N cycle within the soil, driven by growth and death of the microbial biomass, which turns over approximately seven-fold each year.	Kreutzer et al. (2009)
Denitrification	Agricultural crop, forest, grassland, wetland, tundra, heathland, and desert	Global	Not specified	10 to 562	Meta-analysis: Analysis of 313 observations across all ecosystems show N addition increased N ₂ O emission by 216%.	Liu and Greaver (2009)
Nitrification Denitrification	Agriculture and nonagriculture	Not specified	Mean = 105 Tg N/yr	0 to >100	Meta-analysis of 206 papers on responses of ecosystem N cycle in response to N addition. Increases in nitrification (154%), N ₂ O emission (134%), and denitrification (84%) were found. Increased N ₂ O emissions and N leaching under N addition tended to export the N out of the systems rather than benefit plant uptake over the long term, suggesting a leaky terrestrial N system.	Lu et al. (2011a)

Table 4–7 (Continued): Nitrification and denitrification.

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Nitrification and denitrification Microbial N demand	Temperate hardwood and conifer forests (unfertilized)	Nine sites in the north-central Oregon coast range, U.S.	Not specified	None	Soil and Foliar N Gradient: As future reductions in N deposition to polluted sites occurs, symptoms of N saturation are most likely to persist where soil N content remains elevated. Temperate and hardwood forests of the north-central Oregon coast range showed the ratio of net:gross N mineralization and nitrification increased along the gradient, indicating progressive saturation of microbial N demands at high soil N.	Perakis and Sinkhorn (2011)
Nitrification	Common garden experiment, five broadleaved tree species	Denmark	13 to 19 for broadleaf forest; 18 to 26 for Norway spruce		Isotopic Tracer: Litter $\delta^{15}\text{N}$ was positively correlated with N status based on nitrification, as well as other factors. A linear relationship was found between fungal mycelia production and net nitrification rate in lab incubations of soils collected in the field.	(Callesen et al., 2013)
Denitrification	Forested watershed	Pond Branch in Maryland, U.S.	10 ± 4	None	Isotopic Tracer: Spatial and temporal extrapolations of measured rates suggest that a minimum of 16–27% of atmospheric N deposition is lost to denitrification.	Duncan et al. (2013)
Fungal nitrification and denitrification	Semiarid grasslands	Arizona and New Mexico	Not specified	10 g soil to a 100 mL solution of 50 mmol/L $(\text{NH}_4)_2\text{SO}_4$, 0.2 mol/L K_2HPO_4 , and 0.2 mol/L KH_2PO_4 , with a pH of 7.2.	Moisture X Biocide: Fungi are significant sources of N_2O production in soils from semiarid grasslands and deserts, expanding evidence that fungi play a vital role in the N cycle of arid lands.	Marusenko et al. (2013)

Table 4–7 (Continued): Nitrification and denitrification.

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Denitrification	Agricultural land and natural ecosystems	Global	24 to 46 Tg N/yr from 1900–2050	Not applicable	Model: N ₂ production from denitrification increased from 52 to 96 Tg/yr between 1900 and 2000, and N ₂ O emissions increased from 10 to 12 Tg N/yr. The scenarios suggest a further increase to 142 Tg N ₂ and 16 Tg N ₂ O–N/yr by 2050. Riparian buffer zones are an important source of N ₂ O, contributing an estimated 0.9 Tg N ₂ O–N/yr in 2000.	Bouwman et al. (2013)
Nitrification and denitrification Microbial community	Sugar maple dominated northern hardwood forest	Upper Michigan	15 to 20	30 kg N in the form of NaNO ₃ pellets delivered to the forest floor over the growing season	Addition: NO ₃ ⁻ addition to forest stands across a 500-km climatic gradient decreased the abundance and richness of key protein-coding genes in archaea and bacteria responsible for N fixation, ammonification, denitrification, and assimilatory NO ₃ ⁻ reduction; the same was true for bacterial genes mediating nitrification and dissimilatory NO ₃ ⁻ reduction.	Freedman et al. (2013)
Denitrification	Northern hardwood forest	HBEF, White Mountain National Forest, NH	6 to 8	None	Method Comparison: Both the isotopic tracer and gas-flow soil core method indicate that denitrification is higher and N ₂ O:N ₂ ratios are lower (<0.02) than previously thought in the northern hardwood forest and that short-term abiotic and biotic transformations of atmospheric N deposition to gas are significant in this ecosystem.	Kulkarni et al. (2014)

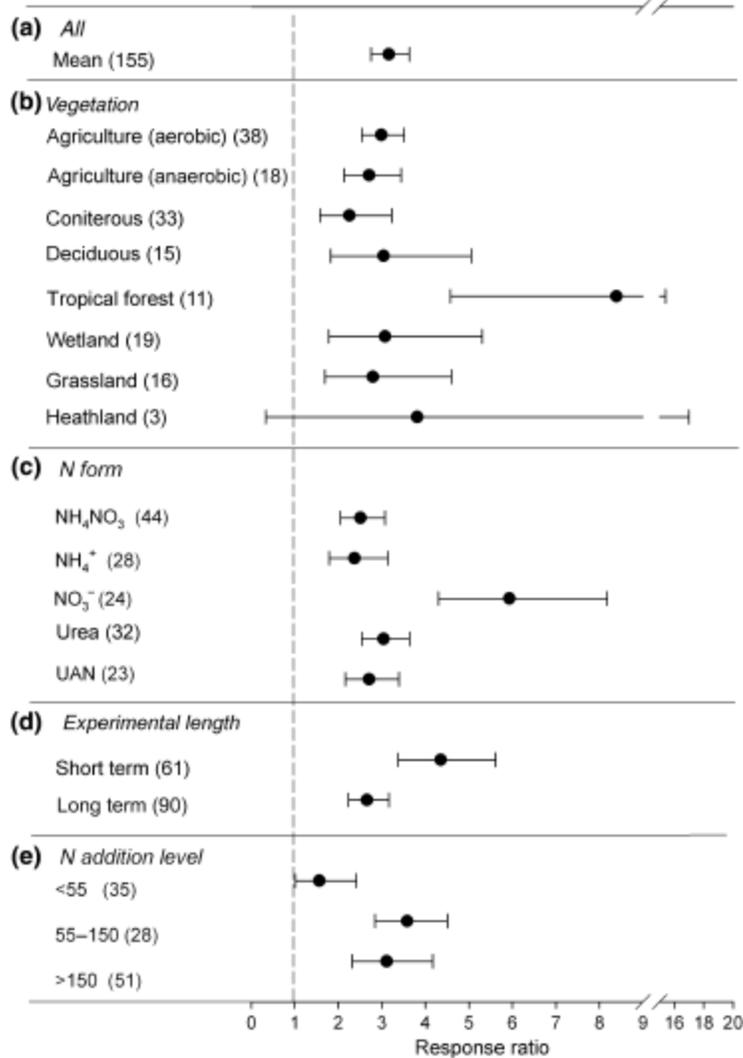

Table 4–7 (Continued): Nitrification and denitrification.

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Nitrification	Mixed hardwood forested headwater catchments	South-central Ontario, Canada	Average NO ₃ ⁻ N deposition 2.78 ± 1.22; average NH ₄ ⁺ N deposition 3.90 ± 1.39	Not applicable	<p>Time Series: Seasonal differences in nitrification were largely driven by temperature, soil moisture, and inorganic N concentration in soil.</p> <p>Annual nitrification fluxes were almost two orders of magnitude greater than N deposition or NO₃⁻ leaching. Nitrification rates scaled up to annual catchment-scale production of NO₃⁻; the resulting fluxes are 64.9 ± 8.7 and 59.7 ± 3.1 kg N/ha/yr, which greatly exceed seasonal inputs in deposition.</p> <p>Rates of nitrification and mineralization were similar, indicating that almost all mineralized N is converted to NO₃⁻ (ranging from 71 to 99%).</p>	Casson et al. (2014a)
Nitrification denitrification	Deciduous and coniferous forests	Ontario, Canada; New Hampshire; and Maine	Three sites along a gradient: 4.5, 7, and 11	Not applicable	<p>Gradient: N gas flux increased systematically with natural N enrichment from soils with high nitrification rates.</p> <p>N gas fluxes were linked to patterns of N availability in forests; results do not suggest that these fluxes respond to increases in atmospheric N deposition at the study sites.</p>	Morse et al. (2015a)

Table 4–7 (Continued): Nitrification and denitrification.

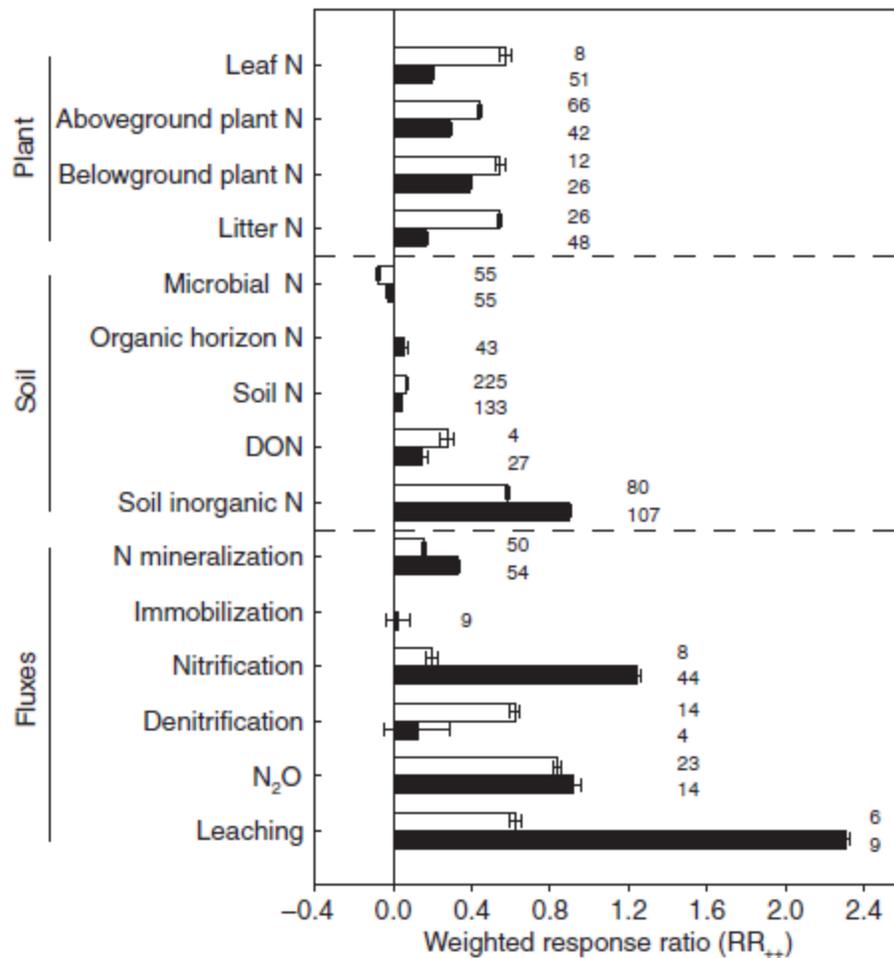

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Nitrification C:N	Five biome classes in California: desert, grassland, shrubland, forest, wetland	California	0.6–18.4 kg N/ha/yr	Grassland soil: 76.4 kg N/ha/yr as NPK (29:3:4); desert soil: 60 kg N/ha/yr as NH ₄ NO ₃ ; shrubland soil: 60 kg N/ha/yr as NH ₄ NO ₃	N Addition: Across biomes, a positive correlation of gross nitrification to soil NO ₃ ⁻ (<i>r</i> ² = 0.34) and a negative correlation to soil C:N (<i>r</i> ² = 0.31) was observed. No correlation was found between gross N mineralization and nitrification. Deserts had the lowest gross N mineralization rates and exhibited similar nitrification rates to the shrublands and grasslands. Only 15% of NH ₄ ⁺ produced was nitrified in the forests compared to 47 to 86% in the other biomes. This suggests that NH ₄ ⁺ production rates did not limit nitrifiers in the forests, but rather, that another factor limited nitrifier activity.	Yang et al. (2017)

4.3.7. Decomposition

2
3
4

Decomposition is a general term that refers to the breakdown of organic matter. ([Schlesinger, 1997](#)). Decomposition is an important part of N and C cycling that can be altered by N deposition. Decomposition rates correlate with ratios of C:N, lignin:N, and

1 lignin:cellulose in litter, all which may be altered by N deposition. The addition of N can
2 stimulate the decomposition of labile compounds that degrade during the initial stages of
3 decomposition, but added N can suppress the decomposition of more recalcitrant
4 material. Evidence for this is widespread in forests, but has not yet been well documented
5 in grasslands and other ecosystems. Since 2008, there are new addition studies and
6 meta-analyses to better understand the mechanisms and response trends.

7 The 2008 ISA documented that the soil microbial community (bacteria and fungi) are the
8 main decomposers of organic matter. Both the microbial community composition and
9 microbial enzyme activity can dynamically respond to shifts in inorganic nutrient and
10 substrate availability ([Compton et al., 2004](#); [Carreiro et al., 2000](#)); the shift reflects the
11 nutrient and energy limitation of the microbial community. Litter decay rates are also
12 well established to correlate with ratios of C:N, lignin:N, or lignin:cellulose in litter
13 ([Hobbie, 2008](#); [Aerts, 1997](#); [Melillo et al., 1982](#)). These chemical traits are strong
14 predictors of litter decay, accounting for over 73% of the variation in litter decomposition
15 rates worldwide ([Zhang et al., 2008](#)).

16 Traditionally, carbon dioxide (CO₂) is measured as an indication of soil respiration and a
17 proxy for decomposition. Since the 2008 ISA, analysis of microbial enzymes and genes
18 in the soil have been used to identify microbial activity. Litter decomposition is an
19 enzymatically complex process mediated by a diverse assemblage of microorganisms that
20 includes decomposition from both autotrophic (root) biomass and heterotrophic
21 (microbial) activity. More information is necessary to attribute the autotrophic or
22 heterotrophic source apportionment. Numerous studies have been published since 2008
23 describing how N addition affects the decomposition of organic C and N ([Table 4-8](#)).

Table 4-8 Decomposition.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Decomposition	Sugar maple hardwood forest	Bear Brook Watershed in eastern Maine		1,800 eq/ha/yr of (NH ₄) ₂ SO ₄	N + S Addition: Caused increased N concentration in leaves and faster short-term decomposition.	Hunt et al. (2008)
Enzyme activity Decomposition	Eight annual herb species	Controlled ecosystem (litter bags placed in annual herb-based microcosm ecosystems)	2.0 and 44.0		Growth Chamber: N deposition increased soil enzyme activity known to breakdown cellulose (cellobiosidase, β-glucosidase and β-xylosidase).	Manning et al. (2008)
Enzyme activity Decomposition	Northern hardwood forest	Michigan	6.8 to 11.8	30 NO ₃ ⁻	N Addition: N addition altered rates of organic matter decomposition by suppressing the soil enzymes responsible for litter degradation when litter has a higher N concentration. This causes an increase in surface soil C storage.	Pregitzer et al. (2008)
Enzyme activity Decomposition	Forests grasslands	Central Minnesota	Not specified	100 (NH ₄ NO ₃)	N Addition: Generally stimulated activities of cellulose degrading enzymes in litter and soil, but had no effect on lignin degrading enzyme activity. N addition had a negative or neutral effect on litter and SOM decomposition in the same sites, with no correspondence between effects of N on enzyme activity and decomposition across sites.	Keeler et al. (2009)
Enzyme activity	Northern hardwood forest	Catskill Mountains of New York, U.S.		50 (NH ₄ NO ₃)	N Addition: Identified that patterns in microbial community structure and function were more strongly influenced by tree species than by fertilization.	Weand et al. (2010)
Soil respiration Decomposition	Forest	Global		Varied	Meta-Analysis: N additions decreased root respiration, heterotrophic respiration, and soil CO ₂ but had no effect on litter decomposition.	Janssens et al. (2010)

Table 4–8 (Continued): Decomposition.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Soil respiration	Temperate broadleaf and mixed forest, temperate conifer forest, boreal forest, tropical forest, grassland, wetland, tundra, desert, and arctic	Global		Varied	Meta-Analysis: N additions decreased heterotrophic respiration but had no effect on total soil respiration.	Liu and Greaver (2010)
Enzyme activity Decomposition	Forest and grasslands	U.S.	None	None	Synthesis: Data from 28 ecosystems show resources to produce the enzymes phenol oxidase and β -1,4-glucosidase are uncoupled. This indicates that the increasing recalcitrance of organic matter decreases C and nutrient availability and slows microbial growth.	Sinsabaugh and Shah (2011)
Enzyme activity Decomposition	Mature black spruce forest in upland boreal ecosystem	Central Alaska	Not specified	Years 2009 = 200 (NH ₄ NO ₃) Years 2010 = 100 (NH ₄ NO ₃)	N Addition: N fertilization may alter decomposer community structure by favoring a shift toward cellulose- and mineral-N users. Cellulose degrading microbes (decomposers) were competitively dominant under N fertilization.	Talbot and Treseder (2012)
Enzyme activity Decomposition	Sugar maple forests	Michigan	Not specified	30	Meta-Analysis: N addition increased cellulose decomposition by 9% and decreases lignin decomposition rates by 30%. Overall, N increases the amount of litter mass entering the humus pool and leads to increases in soil C storage under experimental N deposition.	Whittinghill et al. (2012)
Enzyme activity Decomposition	Northern hardwood forest	Minnesota			N Addition: Accelerated the initial decomposition rate. Faster initial decomposition rates corresponded to higher activity of polysaccharide-degrading enzymes and greater relative abundances of Gram-negative and Gram-positive bacteria. Later in decomposition, externally supplied N slowed decomposition, increasing the fraction of slowly decomposing litter, reducing lignin-degrading enzyme activity, and relative abundances of Gram-negative and Gram-positive bacteria.	Hobbie et al. (2012)

Table 4–8 (Continued): Decomposition.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Decomposition	Deciduous forests	Catskill Mountains of southeastern New York, U.S.	9.0	50 mg N/ha/yr N (NH ₄ NO ₃)	N Addition: N addition caused decrease in mineralization and nitrification and an increase in forest floor C pools and C:N, indicating that N addition increased C sequestration in the organic horizons of the soil, most significantly in hemlock plots.	Lovett et al. (2013)
Enzymes Decomposition	Northern hardwood forest	Upper Michigan	15 to 20	30	N Addition: Caused slower organic matter decay and altered microbial community composition and function. Observed a decrease in the abundance and richness of key protein-coding genes in archaea and bacteria responsible for N fixation, ammonification, denitrification, and assimilatory NO ₃ ⁻ reduction; the same was true for bacterial genes mediating nitrification and dissimilatory NO ₃ ⁻ reduction.	Freedman et al. (2013)
Enzymes Decomposition	Sugar maple forests	Michigan	5.8 to 7.3	30	N Addition: (1) significantly altered the composition of actinobacterial and fungal genes mediating plant and fungal cell wall depolymerization; (2) significantly decreased the richness and diversity of genes involved in the depolymerization of starch (~12%), hemicellulose (~16%), cellulose (~16%), chitin (~15%), and lignin (~16%); and (3) resulted in small changes in community composition (25% difference in fungi; 18% in actinobacteria).	Eisenlord et al. (2013)
Enzymes Decomposition	Northern hardwood forest	Upper Michigan	15 to 20	30 as six equal applications of NaNO ₃ pellets delivered to the forest floor over the growing season	N Addition: Observed that atmospheric N deposition increases saprotrophic bacterial laccase-like multicopper oxidases (LMCOs). These results suggest a plausible mechanism by which anthropogenic N deposition has reduced decomposition, increased soil C storage, and accelerated phenolic DOC production.	Freedman and Zak (2014)
Decomposition fungal residue	Forest	Switzerland	Not specified	7 (NH ₄ NO ₃) 70 (NH ₄ NO ₃)	N Addition: Promoted the production of new fungal residues but slowed the decomposition of old residues in forest soil fractions. Preservation of old microbial residues could be due to decreased N limitation of microorganisms and therefore a reduced dependence on organic N sources.	Griepentrog et al. (2014)

Table 4–8 (Continued): Decomposition.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Enzyme activity	Northern hardwood and softwood forest	Bear Brook Watershed (BBWM), ME, U.S.		25.5	N Addition: After 22 yr of N addition, N enrichment had little effect on microbial enzyme activity in terrestrial compartments, even across varying degrees of organic matter recalcitrance.	Mineau et al. (2014)
Soil respiration	Multiple biomes	Global		Varied	Meta-Analysis: N addition significantly increased soil respiration by 2.0% across all biomes but decreased respiration by 1.44% in forests and increased it by 7.84 and 12.4% in grasslands and croplands, respectively ($p < 0.05$). The response ratios of soil respiration to N addition were positively correlated with mean annual temperature (MAT), most significant when MAT was less than 15°C. N addition largely altered root and microbial biomass and soil C content, which are likely the mechanisms behind the altered soil respiration.	Zhou et al. (2014a)
Decomposition	Grassland	Minnesota, Nebraska, Iowa, Kansas; Colorado	3.1 to 18	100	N Addition: Decreased microbial respiration of OM by as much as 29% relative to control plots, and consequently, decreased C loss from this pool.	Riggs et al. (2015)
Decomposition	Forest	Great Lakes region	6.8 to 11.8	30 as NaNO ₃	N Addition Fine root biochemistry was less responsive than leaf litter to long-term simulated N deposition. Fine roots were the dominant source of difficult-to-decompose plant C fractions entering the soil. When combined with litter production, simulated N deposition increased N flux through leaf litter by an average of 29%, but did not affect fine root N flux.	Xia et al. (2015)
Enzyme activity	Subalpine forest	Loch Vale watershed (LVWS) is located in Rocky Mountain National Park (RMNP) on the eastern edge of the Colorado Front Range.	3–4 kg N/ha/yr (wet)	25 kg NH ₄ NO ₃ /ha/yr (1996–present)	N Addition: There were no changes in the C degrading enzyme activity in response to fertilization, while the N degrading enzyme activity was enhanced with elevated activity of leucine aminopeptidase (LAP) and marginally significant increase in N-acetyl-β-glucosaminidase (NAG) with N fertilization.	Boot et al. (2016)

Table 4–8 (Continued): Decomposition.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Enzyme activity	Northern hardwood forest	Michigan	5.9–7.4 kg N/ha/yr (not specified if wet, dry, or total)	30 kg NaNO ₃ /ha/yr (beginning in 1994)	N Addition: This long-term experiment found N deposition decreased the activity reduced the activity of extracellular enzymes mediating plant cell wall decay.	Freedman et al. (2016)
Soil respiration	Northern hardwood forest	White Mountain National Forest, NH; Bartlett, Hubbard Brook, and Jeffers Brook Forests	8 kg N/ha/yr (wet + dry) (20th century average at HBEF)	30 kg N/ ha/yr (NH ₄ NO ₃), 10 kg P/ha/yr (NaH ₂ PO ₄), or N + P (treatments in Year 2011)	N Addition: The greatest reduction in soil respiration on N and N + P fertilized plots occurred on the sites with lowest pretreatment soil N mineralization and litterfall N flux. Nutrient additions did not significantly affect either fine root turnover (minirhizotrons) or microbial respiration (laboratory incubations).	Kang et al. (2016)
Decomposition	Restored tallgrass prairie	Prairie Invasion and Climate Experiment (PRICLE) Loveland, CO	~1/3 of N added	5 g N/m ² /yr urea. “Seasonal maximum 5-day cumulative rainfall” increased by 33 (2012) and 9% (2013)	N Addition: Increasing rainfall variability and N addition can stimulate litter decomposition in tall grass prairie.	Schuster (2016)
Decomposition	All ecosystems	Global	Not specified	Not specified	Meta-Analysis: 198 peer-reviewed journal articles found N addition did not significantly alter litter decomposition, soil respiration (except for wetlands, +28.26%), and microbial respiration (except for forests, +9.08).	Yue et al. (2016)

Table 4–8 (Continued): Decomposition.

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Decomposition	Mixed hardwood forest dominated by black and red oak (<i>Quercus velutina</i> and <i>Q. rubra</i>)	Chronic Nitrogen Amendment Study (CNAS) located at the Harvard Forest Long-Term 57 Ecological Research (LTER) site in Petersham, MA, USA		50–150	Changes in litter decay by was generally lower in the N treatment microbes compared to control microbes for the same species, a response not readily reversed when N microbial isolates were grown in low N environments. Changes in fungal behaviors accompany and perhaps drive previously observed N induced shifts in fungal diversity, community composition, and litter decay dynamics.	van Diepen et al. (2017)
Decomposition	Forest	Scotland	14–16 kg N/ha/yr	1.18 g 15N in 4m plot	Litter decomposition is a larger source of N for trees than simulated N deposition.	Nair et al. (2017)

BBWM = Bear Brook Watershed; C = carbon; DOC = dissolved organic carbon; ha = hectare; kg = kilograms; LMCO = Laccase-like multicopper oxidase; mg = milligrams; N = nitrogen; ¹⁵N = nitrogen-15; NaNO₃ = sodium nitrate; NH₄NO₃ = ammonium nitrate; (NH₄)₂SO₄ = ammonium sulfate; NO₃⁻ = nitrate; ¹⁵NO₃⁻ = nitrogen-15-labeled nitrate; OM = organic matter; S = sulfur; SOM = soil organic matter; yr = year.

1 The body of knowledge published since the 2008 ISA indicates the effects of N on
2 decomposition rates are inconsistent among studies. New field work supported the
3 concept that N deposition suppresses decomposition ([Riggs et al., 2015](#); [Zak et al., 2008](#)).
4 Likewise, [Kang et al. \(2016\)](#), in a large-scale N addition study of 13 northern hardwood
5 forests in the U.S., supported the findings that N addition decreases forest respiration and
6 further identified the greatest reduction in soil respiration on N fertilized plots occurred
7 on the sites with lowest pretreatment soil N mineralization and litterfall N flux ([Kang et
8 al., 2016](#)). In contrast, meta-analysis that evaluated the central tendencies of N addition
9 on total soil respiration in forest biomes reported inconsistent results, including an
10 increase ([Yue et al., 2016](#)), decrease ([Zhou et al., 2014a](#)), and no effect ([Liu and Greaver,
11 2010](#)). Meta-analyses that looked for the central tendencies of terrestrial soil respiration
12 to N addition also have inconsistent results; two meta-analyses found that N did not alter
13 total soil respiration in terrestrial soils ([Yue et al., 2016](#); [Liu and Greaver, 2010](#)), another
14 identified an increase ([Zhou et al., 2014a](#)), and only one identified a decrease ([Janssens et
15 al., 2010](#)). The different results in the meta-analyses reflect slightly different selection
16 criteria the authors used to determine which studies to include in the analyses. Among
17 biomes, differences in soil respiration may result largely from stimulation of autotrophic
18 respiration by N addition to croplands and grasslands compared with no significant
19 change for forests, and a simultaneous decline in heterotrophic/microbial respiration in
20 most biomes [[Zhou et al., 2014a](#); [Liu and Greaver, 2010](#)], with the exception of
21 croplands, tropical forests, and boreal forests].

22 One proposed mechanism for reduced microbial decay under increased N deposition is a
23 shift in the species composition of the microbial community with the consequence of
24 decreased lignin decomposition. Lignin is an organic polymer, particularly important in
25 cell wall formation of vascular plants. Under N addition, the microbial community would
26 shift from basidiomycete fungal activity, some of which oxidize lignin in plant detritus
27 and polyphenols in SOM to CO₂, to more metabolism by bacteria and ascomycete fungi
28 (cellulose degraders), which only partially oxidize these organic substrates ([Freedman
29 and Zak, 2014](#); [Zak et al., 2011](#)). There is new evidence to support this theory in
30 northeastern hardwood forest in the U.S. where N enrichment increases the species
31 richness and diversity of ascomycetes generally (cellulose degraders) ([Morrison et al.,
32 2016](#)), with evidence that observed changes in decay abilities were not readily reversed
33 when N isolates were grown in control environments, indicating that the fungal
34 community may not recover quickly following the cessation of N enrichment ([van
35 Diepen et al., 2017](#)) (see [Appendix 6](#)).

36 There is new evidence to support that lignolytic enzyme activity decreases under N
37 addition ([Freedman et al., 2016](#); [Keeler et al., 2009](#); [Manning et al., 2008](#)). This trend is
38 also supported by a meta-analysis by [Whittinghill et al. \(2012\)](#), who found that N

1 addition decreased lignin decomposition rates by 30% and increased cellulose
2 decomposition by 9%. Fine roots are likely the dominant source of
3 difficult-to-decompose plant carbon fractions entering the soil, and this pattern appears to
4 be widespread in boreal and temperate forests ([Xia et al., 2015](#)).

5 There are cases in which N addition causes no change in enzyme activity of microbes; for
6 example, the hardwood and softwood forests growing in the Bear Brook Watershed in
7 Maine ([Mineau et al., 2014](#)) and C degrading enzymes in a subalpine forest ([Boot et al.,
8 2016](#)). Another study in the Catskill Mountains of New York State found that patterns in
9 microbial community structure and function (detected by enzyme activity) were more
10 strongly influenced by the tree species present than by fertilization ([Weand et al., 2010](#)).

11 Microbial decomposition response to N addition may also change through time. The 2008
12 ISA documented an N addition study lasting longer than 2 years that indicated that a shift
13 can occur from stimulation to depression of decomposition over time ([Knorr et al., 2005](#)).
14 In a study looking at changes through time of the organic layer, [Hobbie et al. \(2012\)](#)
15 suggest N deposition in forest ecosystems may decrease mean residence times of active
16 fractions in fresh litter, while increasing those of more slowly decomposing fractions,
17 including more processed litter. In boreal forests, [Talbot and Treseder \(2012\)](#) found a
18 transition over time from competition among decomposers to high cellulase activity and
19 suppressed lignin loss under N fertilization. The trend suggests that, in N limited systems,
20 N fertilization may alter decomposer community structure by favoring a shift toward
21 cellulose- and mineral-N users.

22 There is also new evidence that experimental N deposition significantly decreased the
23 richness and diversity of microbial genes involved in the depolymerization of starch
24 (12%), hemicellulose (16%), cellulose (16%), chitin (15%), and lignin (16%). ([Eisenlord
25 et al., 2013](#)).

4.3.8. Nitrogen Mineralization

26 Mineralization refers to processes that release carbon as CO₂ and nutrients in inorganic
27 form. Nitrogen mineralization is the process by which organic N is converted to
28 plant-available inorganic forms. The 2008 ISA documented that the rate of mineralization
29 may be influenced by numerous factors including C:N of soil organic matter, soil pH, and
30 the microbial community. N mineralization has been shown to increase with increasing N
31 addition ([Aber et al., 1998](#)), often up to 1.6 times the control ([Gundersen et al., 1998](#)).

32 New publications ([Table 4-9](#)) support that soil N mineralization increases with N addition
33 across terrestrial ecosystems ([Lu et al., 2011a](#)), specifically in temperate forests ([Nave et](#)

1 [al., 2009a](#)), likely due to increases in dissolved organic nitrogen (DON), the size of the N
2 pool in the soil, and decreases in C:N ratios. The forest floor responds differently than the
3 deeper mineral soil layer [[Figure 4-7](#); ([Lovett et al., 2013](#); [Nave et al., 2009a](#))].

4 In two forested headwater catchments in Ontario, [Casson et al. \(2014a\)](#) found that N
5 mineralization and nitrification rates are similar, indicating that almost all mineralized N
6 is converted to NO_3^- (ranging from 71 to 99%) in catchments they studied. While [Bade et](#)
7 [al. \(2015\)](#) found in old-growth spruce forest, lower N mineralization occurred in the more
8 open patches than the closed ones. Possible reasons were reduced litter supply and lower
9 canopy N interception in gaps in this forest under exposure to high N deposition. Further
10 studies in other old-growth forests are needed to better understand the mechanisms
11 causing long-term change in N cycling with forest development.

12 In desert shrublands, [Rao et al. \(2009\)](#) found that N deposition may increase production
13 and/or alter litter C:N ratios that increase soil C. There was an inverse relationship
14 between the C:N ratio and total N mineralized, yet a positive relationship between
15 organic C and total N with mineralization. These results indicate that microbial activity in
16 low productivity arid land soils is primarily limited by C and secondarily limited by N.

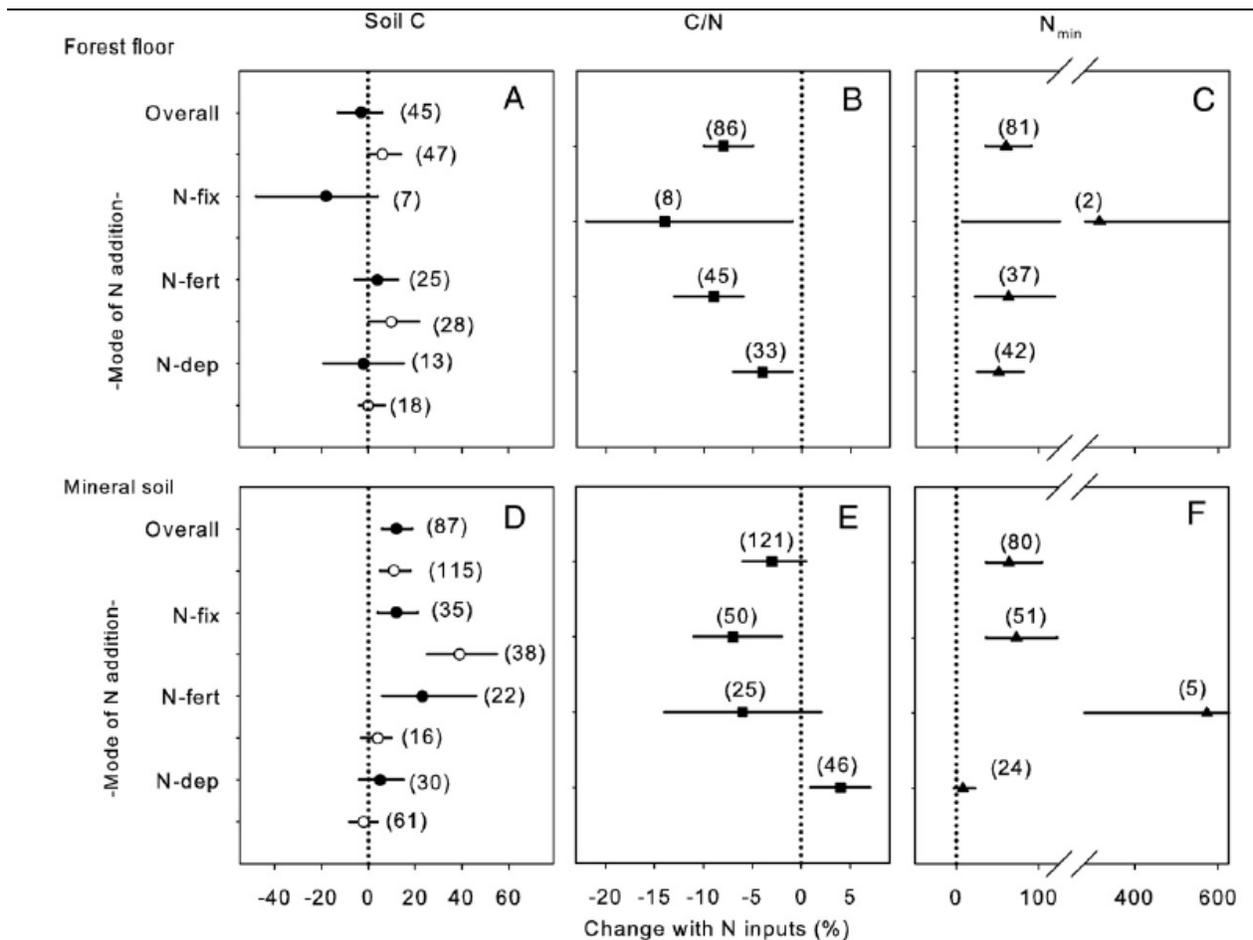

Table 4-9 Nitrogen mineralization.

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Mineralization	Semiarid	Southern California, U.S.	Up to 35–45 for N	Two applications per year of 30 kg N	N is mineralized at a faster rate from grass litter enriched in N as a result of N deposition	Sirulnik et al. (2007a)
Mineralization	Semiarid	Southern California, U.S.	Up to 35–45 for N	Two applications per year of 30 kg N	When significantly lower microbial N was reported in fertilized plots it corresponded to faster net N mineralization. When higher microbial N was observed in fertilized plots it corresponded to net immobilization (though not significantly faster), thus corroborating evidence that the microbial community was taking up more N in fertilized plots. These rates may have corresponded to C availability, which was not measured.	Sirulnik et al. (2007b)
Mineralization soil [N] soil [Ca]	Mixed hardwood stands	Adirondack Mountains, NY, U.S.	Not specified	None	Ca Gradient: The exchangeable Ca coupled with soil moisture, soil organic matter, and ambient temperature accounted for 61% of the variability in extractable inorganic N across 11 sites. The influence of Ca on soil inorganic N may be through interactions between soil Ca concentrations and species composition, which in turn affect the quality of litter available for N mineralization.	Page and Mitchell (2008)
Decomposition Enzyme activities	Spruce forest	Germany	8.5		N Exclusion: Some N cycling enzymes increased activities, whereas others decreased under reduced N treatment.	Enowashu et al. (2009)
N mineralization	Desert	Joshua Tree National Park	2.7 to 14.4		Calculated soil N from deposition was directly correlated with measured soil C and N and decreasing C:N ratios.	Rao et al. (2009)

Table 4–9 (Continued): Nitrogen mineralization.

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
N mineralization	Temperate forests.	Northeastern U.S.	Varies	Varies	Meta-Analysis: Overall, N inputs increased soil C (+7.7%) and N mineralization (+62%), while decreasing C:N (-4.9%).	Nave et al. (2009a)
N mineralization	Forest			50 (6 yr of N addition)	N Addition: There was a significant decline in potential N mineralization and nitrification rates in the mineral horizon but not in the forest floor.	Lovett et al. (2013)
N mineralization	Terrestrial ecosystems		Varies	Varies	Meta-Analysis: of 206 papers on responses of ecosystem N cycle caused by N addition. N addition increased mineralization rates.	Lu et al. (2011a)
N mineralization	Douglas fir forest	Oregon coast range	2.0	None	Aboveground N uptake by plants increased with net N mineralization, peaking at 35 kg N/ha/yr.	Perakis and Sinkhorn (2011)
Net N mineralization and nitrification rates/NH ₄ ⁺ N, soil NO ₃ ⁻ , stream NO ₃ ⁻	Mixed hardwood forested headwater catchments	Muskoka-Haliburton district of south-central Ontario, Canada	NO ₃ ⁻ deposition 2.78 ± 1.22; NH ₄ ⁺ deposition 3.90 ± 1.39	Not applicable	In all seasons, rates of nitrification were similar to rates of total mineralization, indicating that almost all mineralized N is converted to NO ₃ ⁻ in both soil types (ranging from 71 to 99%).	Casson et al. (2014a)
N mineralization, ammonification, nitrification/NO ₃ ⁻	Natural (unmanaged) old-growth Norway spruce forest	Harz National Park in central Germany	27 (open areas) 47 (closed forest)	Not applicable	Net N mineralization (and ammonification) rates were higher in the closed stands of the optimum and overmature stages than in the more open decay and regeneration stages. Only a small proportion of NH ₄ ⁺ was oxidized to NO ₃ ⁻ in the acidic soils.	Bade et al. (2015)
Net litter mineralization	Forest	Scotland	14–16 kg N/ha/yr	1.18 g ¹⁵ N per 4m plot	Three times as much ¹⁵ N was retained in the O and A soil layers when N was derived from litter decomposition than from mineral N additions.	Nair et al. (2017)

C = carbon; Ca = calcium; ha = hectare; kg = kilogram; N = nitrogen; NH₄⁺ = ammonium; NO₃⁻ = nitrate; yr = year.

C = carbon; C/N = carbon-to-nitrogen ratio; N-dep = nitrogen deposition; N-fert = nitrogen-fertilization; N-fix = nitrogen-fixing vegetation; N_{min} = nitrogen mineralization.

Points are means ± bootstrapped 95% confidence intervals, with number of studies in parentheses. Groups with confidence intervals overlapping the dotted reference line (0% change) show no significant effects of N addition. Soil carbon responses to nitrogen inputs are shown separately for pool sizes (filled symbols) and concentrations (open symbols). For each response parameter, the effects of nitrogen inputs are shown overall, and for individual modes of nitrogen addition, including the establishment of nitrogen-fixing vegetation, large-dose nitrogen-fertilization, and simulated chronic nitrogen deposition. Note that points plotted in panels C and F have 95% confidence intervals with upper-bounds beyond the x-axis maximum.

4.3.9. Dissolved Organic Carbon Leaching

1 The acid-base characteristics of dissolved organic matter (DOM) are an important part of
2 understanding the recovery potential for soils, lakes, and streams impaired by acid
3 deposition. The composition of DOM includes fulvic and humic acids, carboxylic acids,
4 and amino acids; dissolved organic carbon (DOC) includes these organic acids. Here we
5 focus on the DOC component of DOM. The many carboxylic groups of DOC make it
6 chemically interact like a weak acid; therefore, DOC content may affect pH levels. In
7 addition, [Fakhraei and Driscoll \(2015\)](#) emphasize the importance of predicting accurately
8 the acid-base properties of recovering surface waters because, for example, the acidic
9 components of DOC act as hosts for binding trace metals like toxic Al_i (for additional
10 discussion on Al_i and DOM see [Appendix 4.3.5](#)).

11 In recent years, the DOC of many lakes and streams has risen, with the likely source
12 being the soils in the adjacent terrestrial watershed. However, the mechanism causing the
13 observed increase is unclear. The increase may be due to a combination of soil recovery
14 from acidification, changes in climate (e.g., temperature and precipitation), and N
15 deposition, among other mechanisms (for reviews see [\(Evans et al., 2005; Kalbitz et al.,](#)
16 [2000\)](#). New studies in the literature have investigated soil DOC response to acidification
17 (N + S deposition) and/or looked at the effects of N addition; these studies will be the
18 focus of the following discussion ([Table 4-10](#)). For a discussion of DOC in surface water
19 see [Appendix 7](#).

Table 4-10 Terrestrial dissolved organic carbon (DOC) leaching.

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
DOC	Bog, heathland, grassland, broadleaf and coniferous forest	Synthesis of 17 addition experiments in the northeastern U.S. and northern Europe	Ranged from 5–16 N dep	Ranged from 10 to 150 N (chemical forms for N varied)	Synthesis: N had inconsistent effect on DOC; however, the form of N applied indicates nonacidifying forms of N tend to increase DOC concentrations.	Evans et al. (2008)
DOC	Temperate mixed and conifer forests, boreal forests, grasslands, tropical forests, arctic, wetlands, desert, and tundra	410 observations globally	Not specified	10 to 650	Meta-Analysis: N addition increases short-term belowground C storage by increasing C content of the organic layer. N addition; increased DOC concentration (+18%); and increased C content of the organic soil layer (+17%) but not the mineral soil layer.	Liu and Greaver (2010)
DOC	Norway spruce (<i>Picea abies</i>) forests	Southern Sweden	Not specified	Not specified	Model: The Stockholm Humic Model was used to model DOC solubility in soil water and predicted that DOC trends could vary between positive and negative depending on changes in pH, ionic strength, and soil Al pools.	Lofgren et al. (2010)

Table 4-10 (Continued): Terrestrial dissolved organic carbon (DOC) leaching.

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
DOC	Beech forest stands on calcareous soils	Swiss Jura mountain range	Not specified	5.5 (NH ₄ NO ₃)	N Addition: Leaching of DOC from the litter layer was not affected by N additions, but DOC fluxes from the mineral soils at 5- and 10-cm depth were significantly reduced by 17%. ¹³ C indicated that litter-derived C contributed less than 15% of the DOC flux from the mineral soil, with N additions not affecting this fraction. Hence, the suppressed DOC fluxes from the mineral soil at higher N inputs can be attributed to reduced mobilization of nonlitter derived “older” DOC.	Hagedorn et al. (2012)
DOC	None— theoretical	None— theoretical	Not specified	Not specified	N Addition: Increases mineralization causing the pool of bioavailable DOC to decrease. Consequently, relatively less bioavailable DOC remains for NH ₄ ⁺ assimilation and immobilization in microbial biomass, leaving more NH ₄ ⁺ for nitrifiers. As a result, internal NO ₃ ⁻ production increased. The higher bacterial demand for DOC under elevated availability of N and electron acceptors comes into conflict with increasing chemical suppression of DOC solubility and bioavailability in the progressively acidifying soils and finally results in the C limitation of microbial metabolism.	Kopáček et al. (2013)
DOC	Northern hardwood forest	Upper Michigan	15 to 20 kg N/ha/yr	30 (as six equal applications of NaNO ₃ pellets delivered to the forest floor over the growing season)	N Addition: N addition accelerated phenolic DOC production.	Freedman and Zak (2014)

Table 4-10 (Continued): Terrestrial dissolved organic carbon (DOC) leaching.

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
DOC	Forest and streams	Hubbard Brook Experimental Forest, NH	Variable	None	Field Observation: Concentrations of DOC showed statistically significant declines in the Oa soil solutions of all three elevation zones, and a subset of the Bs soil solutions over the period of 1984–2011.	Fuss et al. (2015)
DCO	Lakes	Adirondack Long-Term Monitoring (ATLM) Program lakes at Huntington Forest and Whiteface Mountain, Adirondack Mountains, NY	Variable	None	Field observation: increasing DOC in 29 of 48 lakes as lake pH increased.	Driscoll et al. (2016)
DOC	Forest and grassland	U.K.	Mean 1993 to 2010 gradients of deposition: S: 44 to 86 meq/m ² /yr; N: 40 to 90 meq/m ² /yr; Cl: 94 to 306 meq/m ² /yr	None	Modeling: Using the MADOC model, the acidifying effect of S deposition was the predominant control on the observed soil water DOC trends. The relative importance of S and N loading depended on soil sensitivity to acidification, and on N limitation.	Sawicka et al. (2017)

¹³C = carbon-13; C = carbon; DOC = dissolved organic carbon; ha = hectare; kg = kilogram; N = nitrogen; NaNO₃ = sodium nitrate; NH₄⁺ = ammonium; NH₄NO₃ = ammonium nitrate; NO₃⁻ = nitrate; S = sulfur; yr = year.

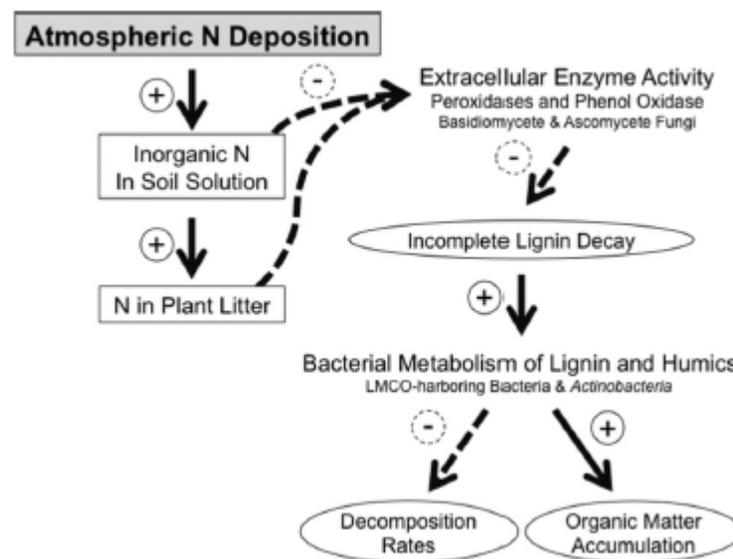

1 A number of studies suggest that recovery from acidification is driving the elevated
2 levels of DOC. An inverse relationship between mineral and organic acid export to
3 surface waters from soils was first proposed in the 1980s ([Krug and Frink, 1983](#)). Support
4 for this theory is found in a range of laboratory experiments in which increases in both
5 acidity and ionic strength (associated with a high SO_4^{2-} loading) have been shown to
6 reduce soil solution DOC ([Kalbitz et al., 2000](#)). [Evans et al. \(2008\)](#) addressed whether
7 elevated N deposition or recovery from acidification associated with decreasing S cause
8 increased DOC loss from upland soil. Their analysis of a large experimental data set
9 including 12 sites in the U.S. and northern Europe showed that although the response to
10 N addition is inconsistent, DOC concentrations responded predictably to the chemical
11 form of N added. DOC concentrations increased with NaNO_3 additions or gaseous NH_3
12 exposure, and decreased with most NH_4^+ salt additions. The authors cite the effect of the
13 chemical form of N on acidity as a plausible mechanism and further conclude that their
14 evaluation does not provide clear support for the role of N deposition as the sole driver of
15 rising DOC, but is consistent with an acidity-change mechanism. [Evans et al. \(2008\)](#) also
16 state their finding is consistent with findings based on long-term monitoring data, that
17 DOC increases in northern European and North American surface waters are
18 substantially attributable to regional decreases in acidifying, primarily S, deposition
19 ([Monteith et al., 2007](#); [Evans et al., 2005](#)). New studies also report that N addition has
20 caused inconsistent changes to DOC, with N addition causing both increases ([Driscoll et
21 al., 2016](#); [Liu and Greaver, 2010](#)) and decreases ([Fuss et al., 2015](#); [Hagedorn et al.,
22 2012](#)).

23 In the Adirondack Long-term Monitoring Program, [Driscoll et al. \(2016\)](#) measured
24 increasing DOC in 29 of 48 monitored lakes as lake pH increased. In contrast, increases
25 in DOC concentrations in a soil solution and streamwater studies were observed with
26 recovery from acidification in the Hubbard Brook Experimental Forest, NH ([Fuss et al.,
27 2015](#)). [Fuss et al. \(2015\)](#) reviewed European and U.S. research literature, found studies
28 with similar observed trends, and identified a number of potential factors leading to this
29 difference. While surface water DOC generally emanates from soil water DOC (with the
30 possible exception of snowmelt), soil ionic strength and soil Al pools, as well as soil
31 depth, may also influence DOC in soil solution ([Lofgren et al., 2010](#)). Decreasing ionic
32 strength can decrease DOC; higher levels of organic aluminum complexes in soil can
33 increase DOC solubility; and DOC in forest floor soil water may decrease at a faster rate
34 than in mineral soil water. The authors did note that Hubbard Brook's rate of decreasing
35 DOC concentrations appeared to be diminishing in the later 15 years of reporting.

36 Although most studies are on forests, [Sawicka et al. \(2017\)](#) used the MADOC model for
37 three forested and three grassland and heath sites and observed that the acidifying effect
38 of S deposition was the predominant control on the observed soil water DOC trends

1 ([Sawicka et al., 2017](#)). The relative importance of S and N loading depended on soil
2 sensitivity to acidification and on N limitation. In all N limited soils investigated, the
3 modeled DOC increases over the monitoring period were dominated by the effects of
4 recovery from acidification (higher DOC solubility), but the effects of N enrichment
5 driving higher DOC production may have been important in the longer term. In contrast,
6 reductions in nonmarine chloride deposition and the effects of long-term warming
7 appeared to have been relatively unimportant.

8 Other recent work has further explored the mechanisms for how N addition (including
9 nutrient as well as acidification effects) affects DOC ([Freedman and Zak, 2014](#); [Kopáček
10 et al., 2013](#)). [Freedman and Zak \(2014\)](#) reported that atmospheric N deposition led to less
11 microbial biodiversity and favored bacterial species in the forest floor that caused lead to
12 reduced decomposition, increased soil C storage, and accelerated phenolic DOC
13 production ([Figure 4-8](#)). [Kopáček et al. \(2013\)](#) observed that N addition, together with
14 SO_4^{2-} deposition, increases the availability of electron acceptors for soil microbial
15 processes. The chemical and microbial responses include an increase in bacterial
16 mineralization creating DOC, increased N mineralization where N availability increases
17 (with an increase in bacterial uptake of DOC), chemical suppression of DOC solubility
18 and bioavailability in the progressively acidifying soils, and finally, the C limitation of
19 microbial metabolism. Bacterial assimilation of NO_3^- , which depends on the
20 stoichiometric NO_3^- to DOC ratio in the substrate, may initially increase with increasing
21 NO_3^- concentrations, but then decrease due to a lower pool of bioavailable DOC.

N = nitrogen; LMCO = Laccase-like multicopper oxidase.

1

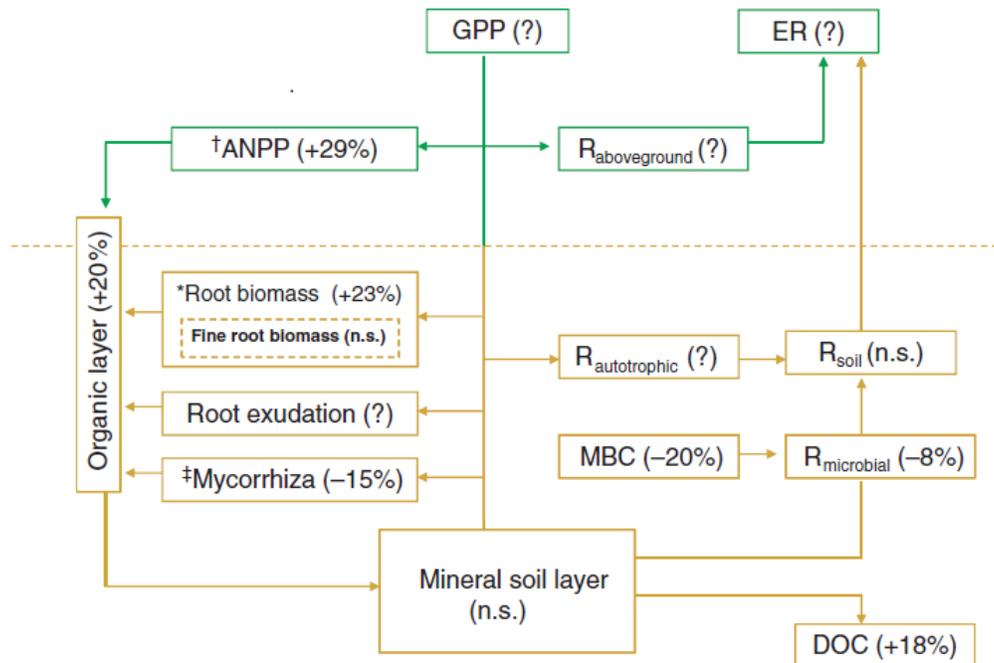

4.3.10. Belowground Carbon Pools

2 In general, N enrichment influences C flux, C partitioning, and the amount of C
3 sequestered by ecosystems. A number of studies have suggested that C sequestration
4 increases with increasing N supply based on the changes in aboveground net primary
5 production [ANPP; ([LeBauer and Treseder, 2008](#); [Xia and Wan, 2008](#))]. However, about
6 half of the C fixed annually by terrestrial vegetation is allocated to belowground pools.
7 Many studies have shown that the belowground C cycle does not always mirror the
8 aboveground cycle. For example, elevated CO₂ and N both have been shown to increase
9 aboveground biomass production ([LeBauer and Treseder, 2008](#)). However, increases in
10 aboveground plant production and greater aboveground litter inputs do not necessarily
11 increase mineral soil C storage ([Talhelm et al., 2009](#); [Gielen et al., 2005](#); [Lichter et al.,
12 2005](#)), and increases in soil C do not necessarily result from greater aboveground litter
13 inputs ([Pregitzer et al., 2008](#)). This disparity indicates that it is inappropriate to
14 extrapolate from aboveground responses to belowground processes. Aboveground plant
15 biomass, once dropped from the canopy, is one of the major contributors to soil organic
16 matter accumulation ([Sullivan et al., 2007a](#)). ANPP generally increases with increasing N
17 supply ([LeBauer and Treseder, 2008](#); [Xia and Wan, 2008](#)). However, this increase in C
18 input may not cause an increase in belowground ecosystem C storage. This is because the
19 output of C from the soil may be stimulated by N induced alteration of plant tissue
20 chemistry or the ratio of root:shoot, each of which will change the rate of decomposition
21 (see [Appendix 4.3.7](#)). Since the 2008 ISA was published there have been several new
22 meta-analyses on the effects of N addition on belowground carbon pools ([Janssens et al.,
23 2010](#); [Liu and Greaver, 2010](#)), each integrating information from numerous pools to
24 improve the understanding of how N addition alters the carbon cycle belowground.
25 Additional studies are summarized in [Table 4-11](#).

26 [Liu and Greaver \(2010\)](#) synthesized data from multiple terrestrial ecosystems to quantify
27 the response of belowground C cycling under N addition ([Figure 4-9](#)). N addition
28 increased aboveground litter inputs (+20%), but fine roots litter inputs were unchanged.
29 N addition inhibited microbial activity, as indicated by a reduction in microbial
30 respiration (-8%) and microbial biomass carbon (-20%). Although soil respiration was

1 not altered by N addition, dissolved organic carbon concentration increased (+18%),
2 suggesting C leaching loss may increase. N addition increased the C content of the soil
3 organic horizon (+17%) but not the mineral soil. The increase in organic horizon C was
4 attributed to both increased litter input and decreased decomposition [inferred from the
5 lower microbial respiration rates ([Liu and Greaver, 2010](#))].

6 Field studies provide additional support for the finding that soil carbon responds
7 differently to N addition depending on the organic (vs. mineral) content of the soil, with
8 organic content tending to decrease with increasing soil depth. In four northern hardwood
9 forests spread across Michigan that received experimental N deposition (additional
10 30 kg N/ha/yr) for 10 years, [Pregitzer et al. \(2008\)](#) and [Zak et al. \(2008\)](#) reported
11 significant increases in soil C, particularly within the soil organic horizon. These
12 increases occurred despite no increase in aboveground litter production or root turnover.
13 A $^{15}\text{NO}_3^-$ -labeling experiment revealed that N accumulated in SOM by first flowing
14 through soil microorganisms to plants, which then shed the leaves back to the detrital
15 layer. In a meta-analysis including data from 72 north temperate forests, ([Nave et al.,
16 2009a](#)) found N addition increased soil C (+7.7%). The forest floor responded differently
17 than the deeper mineral soil layer (5- to 100-cm depth) as increased soil C storage
18 occurred only in the mineral soil (+12.2%), in contrast to the findings of [Liu and Greaver
19 \(2010\)](#) and [Pregitzer et al. \(2008\)](#).

ANPP = aboveground net primary production; DOC = dissolved organic carbon; ER = ecosystem respiration; GPP = gross primary productivity; MBC = microbial biomass carbon; n.s. = nonsignificant; $R_{aboveground}$ = aboveground respiration; $R_{autotrophic}$ = soil autotrophic respiration; $R_{microbial}$ = microbial respiration; R_{soil} = total soil respiration.

A new study has evaluated the consistency of N cycling in different ecosystems by synthesizing data across five biomes in California. The results indicated that, across biomes, N concentration in soil has a strong positive correlation to SOC ([Yang et al., 2017](#)). There are also new studies indicating N deposition increases SOM accumulation without altering the biochemical composition ([Zak et al., 2017](#)). New studies on how the response of belowground soil C to N is modified by temperature and precipitation has been published since the 2008 ISA ([Ni et al., 2017](#); [Greaver et al., 2016](#)) and is summarized in [Appendix 4.7](#).

Table 4-11 Belowground carbon pools.

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
SOC	Soil	Great Britain	0–2 g N/m ² /yr	None	Model: Using model N ¹⁴ CP for data from ~2,000 N limited field sites, it was predicted that, N deposition increased NPP between the Years 1750 and 2010, increasing via detritus SOC by 1.2 kg C/m ² (~10%). (The authors assumed ~30% error of estimated values.)	Tipping et al. (2017)
SOC	Five biome classes in California: desert, grassland, shrubland, forest, wetland	California	0.6–18.4 kg N/ha/yr	Grassland soil: 76.4 kg N/ha/yr as NPK (29:3:4); desert soil: 60 kg N/ha/yr as NH ₄ NO ₃ ; shrubland soil: 60 kg N/ha/yr as NH ₄ NO ₃	Synthesis: Across biomes, total N concentration was strongly correlated to SOC ($R^2 = 0.88$; $\log(y) = [0.81 \times \log(x)] - 1.10$).	Yang et al. (2017)
SOC	Hardwood forest birch (<i>Betula platyphylla</i>) and aspen (<i>Populus davidiana</i>)	Jilin province, China	23 kg N/ha/yr	0 kg N/ha/yr, 25 kg N/ha/yr, and 50 kg N/ha/yr	N Addition: This was a 6-yr fertilization study. The authors observed that fertilization decreased the fraction of macroaggregates (2–8 mm) and increased the fraction of 0.053–2 mm aggregates. ($P = 0.01$). They concluded that N deposition (as simulated with fertilization) can increase formation of micro- and macroaggregates within macroaggregate soil and thus stabilize C.	Chen et al. (2017)

Table 4-11 (Continued): Belowground carbon pools.

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference HERO ID
Soil organic matter	Sugar maple (<i>Acer saccharum</i>)-dominated northern hardwood forests	North-south geographic range of sugar maple-dominated upper Great Lakes and eastern North America	6.8–11.8 kg N/ha/yr (wet + dry) across sites	30 kg NO ₃ ⁻ -N/ha/yr (NaNO ₃)	N Addition: SOM accumulated as soil particulate organic matter occlusion at N addition sites.	Zak et al. (2017)
Abundance of carboxyl, aryl, O/N-alkyl, and alkyl C in mineral soil (biochemical composition of forest floor [Oe/Oi-horizon ~4 cm] and organic matter)	Sugar maple (<i>Acer saccharum</i>)-dominated northern hardwood forests	North-south geographic range of sugar maple-dominated upper Great Lakes and eastern North America	6.8–11.8 kg N/ha/yr (wet + dry) across sites	30 kg NO ₃ ⁻ -N/ha/yr (NaNO ₃)	N Addition: Abundance of carboxyl and aryl C in forest floor differed across sites but the abundance of O/N-alkyl and alkyl C did not (<i>P</i> = 0.10–0.80). No difference was observed in the proportion of aryl, O/N-alkyl, or alkyl C in mineral soil between ambient deposition and N addition sites. (Particulate organic matter's increased occlusion of organics may shift fungal and bacterial activity toward partial oxidation of organics without changing biochemistry of organic matter.)	Zak et al. (2017)

1

4.3.11. New Biogeochemical Indicators

1 In this section, we report on new biogeochemical indicators reported in the literature
2 since the 2008 ISA. Recent literature offering potential new indicators of biogeochemical
3 change due to N and/or S deposition included fungal-to-bacterial ratio ([Högberg et al.,
4 2013](#)) and syntaxonomic associations [([Wamelink et al., 2011](#)) [Table 4-12](#)].

5 [Högberg et al. \(2013\)](#) proposed soil microbial community indices as predictors of soil
6 solution chemistry and N leaching in *Picea abies* spruce forests in southern Sweden.
7 Stands with low concentrations of NO_3^- and Al^{3+} had higher fungi:bacteria ratios
8 compared with stands with higher concentrations of NO_3^- and Al. They identified three
9 promising microbial community indices as indicators of N leaching from forests; the soil
10 fungi:bacteria ratio was the most important.

11 In a study in the Netherlands, [Wamelink et al. \(2011\)](#) examined whether the abiotic
12 ranges of syntaxonomic units (associations) in terms of pH and NO_3^- concentration can
13 be estimated and then, in principle, used to estimate critical loads for acid and N
14 deposition. They used splines to estimate abiotic ranges of syntaxonomic units on the
15 basis of measured soil pH and NO_3^- concentration and vegetation relevés. They
16 acknowledge it is not yet possible to directly estimate ranges for syntaxa for pH and NO_3^-
17 on a large scale using this approach; however, indirectly estimated soil pH and NO_3^-
18 concentrations are sufficiently available to derive ranges for many associations.

Table 4-12 New biogeochemistry indicators.

Endpoint	Nutrient Enrichment Indicator	Acidification Indicator	Deposition kg/ha/yr	Addition kg/ha/yr	Description/Direct Effect of Soil/Water Endpoint On Biological Effect	Reference HERO ID
N leaching		X	Throughfall N includes wet and dry inputs and ranged from 2.7 to 19	20 (NH ₄ NO ₃)	Microbial community composition in the mor layer of spruce forests and soil solution chemistry below the rooting zone was highly correlated. Stands with low concentrations of NO ₃ ⁻ and Al were fungi dominated and had a higher fungi:bacteria ratio compared with stands with high concentrations of these leachates. Leaching stands had higher abundance of Gram-positive bacteria.	Högberg et al. (2013)
Vegetation health	X	X	Not specified	None	Acknowledge the approach is not yet possible to directly estimate ranges for syntaxa for pH and NO ₃ ⁻ on a large scale; however, indirectly estimated soil pH and NO ₃ ⁻ concentrations are sufficiently available to derive ranges for many associations.	Wamelink et al. (2011)

Al = aluminum; ha = hectare; kg = kilogram; N = nitrogen; NH₄NO₃ = ammonium nitrate; NO₃⁻ = nitrate; yr = year.

4.3.12. Differential Effects of Reduced and Oxidized nitrogen (N)

1 Some biogeochemical process responses to N deposition have the potential to vary
2 depending on whether the dominant form of deposited N was oxidized or reduced. We
3 have focused on presenting meta-analyses as they synthesize the central tendencies of
4 many studies. In some cases, the results for a given endpoint are not consistent among
5 meta-analyses. [Table 4-13](#) summarize the studies that look at the most common forms of
6 N.

7 Additional studies include the observation by [Evans et al. \(2008\)](#) that DOC
8 concentrations responded predictably to the chemical form of N used for manipulation,
9 increasing with NaNO_3 additions or gaseous NH_3^+ exposure, and decreasing with most
10 NH_4^+ salt additions ([Appendix 4.3.9](#)). The authors cite the effect of the chemical form N
11 on acidity as a plausible mechanism. [Ramirez et al. \(2010a\)](#) investigated whether soil
12 microbes in three distinct soils (from aspen, pine, and grassland ecosystems) respond
13 differently six different reduced and oxidized N species, including NH_4NO_3 , $(\text{NH}_2)_2\text{CO}$
14 (urea), KNO_3 , NH_4Cl , $(\text{NH}_4)_2\text{SO}_4$, and $\text{Ca}(\text{NO}_3)_2$ (also discussed in [Appendix 6](#)). The
15 authors found that all inorganic forms of N fertilizer significantly decreased microbial
16 CO_2 production but that organic N (urea) decreased the respiration rate in forest soil only
17 by 27% (aspen) and 11% (pine) and increased the grassland microbial respiration rate by
18 20%. They added that the soil pH change resulting from N addition did not appear to
19 influence the observed decrease in the soils' microbial respiration rate.

20 [Jovan et al. \(2012\)](#) monitored tree trunk pH during their research on eutrophic lichen
21 abundance in the Los Angeles air basin, oxidized forms of N (particularly HNO_3)
22 dominate dry deposition. They noted that NH_3 deposition would normally raise bark pH
23 but in the arid, hot Mediterranean climate of the study area, high trunk pH dust raises
24 bark pH.

Table 4-13 The effects of different forms of inorganic nitrogen on biogeochemical processes and indicators according to meta-analyses. See [Table 6-1](#) for the effects of different forms of inorganic nitrogen on biological endpoints.

4.4. Soil Monitoring and Databases

1 There are several new studies using long-term monitoring data sets in the U.S. and
2 Europe ([Table 4-14](#)). New studies in the U.S. include an analysis of 45 years of
3 biogeochemical monitoring data ([Yanai et al., 2013](#)) and sulfur accumulation ([Mitchell
4 and Likens, 2011](#)) at the Hubbard Brook Experimental Forest LTER, NH. At the Niwot
5 Ridge LTER site, CO ([Lieb et al., 2011](#)), identify the effects of a decade of simulated N
6 deposition in the southern Rocky Mountains.

7 [Yanai et al. \(2013\)](#) evaluated 45 years of biogeochemical monitoring data at the Hubbard
8 Brook Experimental Forest LTER site, New Hampshire. Since 1992, the ecosystem
9 shifted to a net N sink ~8 kg N/ha/yr. There are several possible explanations: (1) gaseous
10 N fluxes from the ecosystem in response to denitrification, (2) a budget discrepancy in
11 the net error of the other measured and estimated stocks and fluxes, and/or (3) N
12 accumulation in an unidentified ecosystem compartment.

13 As discussed in [Appendix 4.3.3](#), [Mitchell and Likens \(2011\)](#) examined the sulfur
14 accumulation observed in over four decades of continuous long-term records for four
15 watersheds in Hubbard Brook Experimental Forest, NH and found that as S deposition
16 declined, soil moisture became a more powerful control on S release from soils than did
17 deposition.

18 At the southern Rocky Mountains Niwot Ridge LTER site, CO, U.S., [Lieb et al. \(2011\)](#)
19 found a decade of simulated N deposition to alpine ecosystems caused ongoing changes
20 in diversity and soil biogeochemistry, including lower soil acid buffering capacity,
21 decreased concentrations of exchangeable Mg²⁺, and increased concentrations of the
22 potentially toxic cations Mn²⁺ and Al³⁺. Their results suggested an N deposition threshold
23 for the onset of acidification at this site of 28 kg N/ha/yr.

Table 4-14 Biogeochemistry monitoring and databases.

Process/ Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effects	Reference HERO ID
Base cation (Bc) release soil [Al] soil [Mn] soil pH	Alpine soils	Niwot Ridge in the southern Rocky Mountains, CO, U.S.	6 to 8 (10 yr)	8, 28, 48, and 68 (NH ₄ NO ₃)	Addition: Changes in diversity, lower soil acid buffering capacity, decreased concentrations of Mg ²⁺ , and increased concentrations of the potentially toxic cations Mn ²⁺ and Al ³⁺ . Results suggested an N deposition threshold of 28 kg N/ha/yr.	Lieb et al. (2011)
Sulfate leaching [SO ₄ ²⁻]	Northeastern forest	HBEF, NH, U.S.	Not specified	None	Monitoring: Over four decades of data were used to evaluate S budgets. Current declining inputs of atmospheric S and the higher outputs of SO ₄ ²⁻ in drainage waters relative to precipitation inputs are driven by the S stored in the soil. Climatic change will potentially increase SO ₄ ²⁻ mobilization and hence could slow the resultant recovery from acidification.	Mitchell and Likens (2011)
N accumulation C:N soil [N]	Northern hardwood forest	HBEF, NH, U.S.	~7 (since 1992)	None	Monitoring: Since 1992, the ecosystem shifted to a net N sink, either storing or denitrifying ~8 kg N/ha/yr.	Yanai et al. (2013)

Table 4-14 (Continued): Biogeochemistry monitoring and databases.

Process/ Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effects	Reference HERO ID
NO ₃ ⁻ leaching C:N (lake) C:N (mineral soil layer) TOC:TN	Boreal soils and lakes	Sweden	<3 to 17	None	Gradient: Significant relation found between C:N ratios of the organic soil layer and the ones of lake waters. Evidence found of N deposition having depressed the C:N ratios of lake waters more than the ones of organic soil layers. Clear sudden increase seen in NO ₃ ⁻ leaching in regions where N deposition exceeded 7.5 kg/ha/yr.	Khalili et al. (2010)
Oxidation of organic S in humic soils due to S dep Ratio of reduced to oxidized organic S	Grassland	Rothamsted Park Grass Experiment, Hertfordshire, England	Not specified	None	Monitoring: Analysis of the effects of atmospheric SO ₂ emissions since the late 1800s found acidification led to a depletion of exchangeable Ca and Mg and an 8× increase in exchangeable Al.	Lehmann et al. (2008)
Bc, N, and SO ₄ ²⁻ flux soil solution [Al] soil solution Bc soil solution [Inorganic N] soil solution [SO ₄ ²⁻] molar Bc:Al in soil solution	Forest, including beech and Norway spruce	Switzerland, Jura Mountains in southern Alps. The forests were not managed during the whole observation period	Between 2000 and 2007, mean (-0.02 to 1.99 kmol/ha/yr)	None	Monitoring: A decade (1995–2007) of monitoring data indicates acidifying deposition significantly decreased at three out of the nine study sites due to a decrease in total N deposition. In the soil solution, no trend in concentrations and fluxes of Bc, SO ₄ ²⁻ , and inorganic N were found at most soil depths at five out of the seven sites, suggesting that the soil solution reacted very little to the changes in atmospheric deposition.	Pannatier et al. (2011)

Table 4-14 (Continued): Biogeochemistry monitoring and databases.

Process/ Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effects	Reference HERO ID
pH, ANC, base cations, Al _i , Al _o	Forest and streams	Hubbard Brook Experimental Forest, NH	Variable	None	Field Observation: Soil solution monitoring 1984–2011 at HBEF showed that: pH and ANC did not change significantly in the Oa-horizon but ANC increased in Bs-horizon. Total base cations decreased in Bs-horizon. Al _o decreased and. Al _i decreased in the 2 high elevation subwatersheds.	Fuss et al. (2015)

Al = aluminum; Al_i = inorganic aluminum; Al_o = organic aluminum; Bc = base cation; C = carbon; Ca = calcium; ha = hectare; HBEF = Hubbard Brook Experimental Forest; kg = kilogram; kmol = kilomole; Mg = magnesium; Mn = manganese; N = nitrogen; NH₄NO₃ = ammonium nitrate; NO₃⁻ = nitrate; S = sulfur; SO₂ = sulfur dioxide; SO₄²⁻ = sulfate; TN = total nitrogen; TOC = total organic carbon; yr = year.

1 There are new studies evaluating long-term monitoring in Europe, including those
2 looking at S dynamics in England ([Lehmann et al., 2008](#)) and N and S dynamics in
3 Switzerland ([Pannatier et al., 2011](#)). In Sweden, [Khalili et al. \(2010\)](#) examined N and C
4 interactions between boreal soils and lakes. [Lehmann et al. \(2008\)](#) found that soil
5 acidification from the input of oxidized organic S proceeded much more rapidly than did
6 recovery the reversal after reductions of atmospheric emissions and deposition. [Pannatier](#)
7 [et al. \(2011\)](#) examined monitoring data at Swiss Long-Term Forest Ecosystem Research
8 sites. The results suggested that the fluxes of Bc , SO_4^{2-} , and inorganic N in soil solution
9 reacted very little to the changes in atmospheric deposition. A stronger reduction in base
10 cations compared to Al^{3+} was detected at two sites, possibly indicating that acidification
11 of the soil solution was proceeding faster at these sites than the other sites. In Sweden,
12 [Khalili et al. \(2010\)](#) examined samples collected in selected years between 1993 and
13 2005. Although they found a significant relation between C:N ratios of the organic soil
14 layer and lake waters, the large-scale variations in soil C content were not directly linked
15 to C concentrations in lake waters. Soil N seems to have leached in small amounts from
16 the soils directly into the lakes in the form of NO_3^- . NO_3^- leaching showed a clear and
17 sudden increase in regions where N deposition exceeded 7.5 kg/ha/yr.

4.5. Models

18 The 2008 ISA described the most commonly used soil biogeochemistry models in the
19 U.S. used to track N and/or S deposition (Section A.3 of the 2008 ISA). The focus of
20 [Appendix 4.5](#) is to update available information on several key models currently being
21 used in the U.S. to assess the effects of S and N deposition on terrestrial ecosystem soil
22 biogeochemistry. Steady-state models include steady-state simple mass-balance (SMB).
23 Dynamic models include the Very Simple Dynamic (VSD) soil acidification model,
24 MAGIC, PnET/BGC, and DayCent-Chem. One important input to these models is
25 estimating base cation weathering (BCw), and there are new updates on two methods to
26 estimate this parameter: Soil Texture Approximations (STA) and PROFILE.

4.5.1. Updates to Key Previously Identified Models

4.5.1.1. Soil Texture Approximation (STA) and PROFILE: Estimating Base Cation Weathering

27 Base cation weathering (BCw) rate is one of the most influential yet difficult to estimate
28 parameters in the calculation of critical acid loads of N and S deposition for terrestrial

1 systems. As discussed in [Appendix 4.3](#), acidifying deposition causes base cation leaching
2 from soil. The supply of base cations is largely replenished by base cation weathering of
3 minerals from rock within the ecosystems. Obtaining accurate estimates of weathering
4 rates is difficult because weathering is a process that occurs over very long periods of
5 time. There are some new studies on estimating BCw, including a study on the clay
6 correlation-substrate method and PROFILE ([Koseva et al., 2010](#)), a new application of
7 PROFILE in the U.S. ([Phelan et al., 2014](#)), and an evaluation of uncertainty in estimating
8 BCw ([Futter et al., 2012](#)).

9 The clay correlation-substrate method, also called clay-based Soil Texture
10 Approximation (STA), is an empirical steady-state model that has been used to estimate
11 BCw rates for forest ecosystems in the U.S. because it is simple and has low data
12 requirements. The STA method has an empirical function that was first developed for
13 European soils and later adapted to soils in Canada and the U.S. The method estimates
14 total base cation weathering rates (BCw, sum of Ca^{2+} , Mg^{2+} , Na^+ , and K^+), based on the
15 relationship between established weathering classes and clay content of soils for different
16 acidity classes—acidic, intermediate, and basic. An alternate steady-state model,
17 PROFILE ([Sverdrup and Warfvinge, 1993](#)), may offer an improved method to estimate
18 BCw rates. It is a transferable, process-based model that simulates the weathering rates of
19 groups of minerals. PROFILE was developed in Sweden and is a mechanistic,
20 steady-state kinetics model that calculates the weathering of Ca^{2+} , Mg^{2+} , K^+ , and Na^+ in
21 each horizon within a soil profile based on mineral specific chemical dissolution rates
22 and site and soil conditions. Because PROFILE is a steady-state model, weathering rates
23 calculated by PROFILE can be used with the SMB critical acid load model. One of the
24 main limitations that has discouraged the wider adoption of PROFILE for BCw rate
25 determinations in the U.S. is the large data requirements of the model ([Koseva et al.,](#)
26 [2010](#)).

27 [Koseva et al. \(2010\)](#) reported on their evaluation and revision of the STA model for use
28 in Canadian forests. The authors compared the performance of the STA model to
29 PROFILE weathering estimates for soils at 75 sites in Canada. The relative ability of the
30 STA and PROFILE models to provide reasonable weathering rates was evaluated using
31 base cation mass balances at a subset of sites in Ontario ($n = 19$). Mineral weathering
32 rates calculated with the STA method at 75 sites in Canada (6–367 eq/ha/yr) were up to
33 38 times lower (7 times on average) than rates estimated with PROFILE
34 (143–2,119 eq/ha/yr, $p < 0.0001$). Despite deviations from the 1:1 line, weathering
35 estimates obtained using the STA method were significantly correlated using PROFILE
36 weathering estimates ($p < 0.05$). The authors concluded that the “revised” STA model
37 they used may be more widely applicable in Canada, but not necessarily suited to all
38 regions in the U.S. The uncertainty of the model is largely unknown, and the three

1 equations of the clay correlation-substrate method require recalibration or revision when
2 transferred to new locations. In addition, the STA equations were derived for young soils
3 that developed following the Late Wisconsin glaciation ([Koseva et al., 2010](#)); the clay
4 correlation-substrate model, which is based on clay content and parent material acidity,
5 may not be suitable for older, more weathered soils that were not affected by the most
6 recent glaciation and which cover the majority of the U.S. ([U.S. EPA, 2009c](#)).

7 PROFILE requires over 26 time series or site parameters as model inputs. The U.S.
8 Geological Survey (USGS) recently completed a soil geochemical and mineralogical
9 survey of the U.S. as part of the North American Soil Geochemical Landscapes Project.
10 This project, hereafter referred to as the USGS Landscapes Project, included mineralogy
11 analyses conducted on soil samples collected from 4,871 evenly spaced sites across the
12 U.S. ([Smith et al., 2013](#)). These new data allow the PROFILE model to be applied at a
13 larger scale. [Phelan et al. \(2014\)](#) evaluated PROFILE using national data sets as a method
14 to estimate BCw rates for forests in the U.S., focusing on Pennsylvania as the first test
15 state. The model was successfully applied at 51 forested sites across Pennsylvania.
16 Weathering rates ranged from 11.9 to 924.5 meq/m²/yr and were consistent with soil
17 properties and regional geology. The authors suggest that the method be applied to other
18 locations to further evaluate the performance of the model.

19 A data set of published BCw rates was evaluated by [Futter et al. \(2012\)](#). The data set
20 included 394 individual silicate mineral weathering rate estimates from 82 poorly
21 buffered, silicate-mineral-dominated locations across the world where at least 3 published
22 estimates of BCw were available. The researchers found uncertainty for the input data
23 high relative to the estimated contribution of model parameter uncertainty of BCw
24 weathering rate (meq/m²/yr) to overall variability related to PROFILE and MAGIC,
25 ranging from 1.7 to 2.1 for the two models, respectively. The two models have been most
26 widely used to make assessments of weathering rates for environmental decision making,
27 and each represents the landscape differently. PROFILE provides estimates for shallow
28 one-dimensional soil, whereas MAGIC integrates weathering processes for the whole
29 catchment, including deep soil weathering. Therefore, lower weathering rate estimates
30 are shown from PROFILE in comparison to MAGIC, which considers deep soil
31 weathering to constitute a potentially important source of Bc in catchment weathering
32 ([Futter et al., 2012](#)).

33 [Whitfield \(2018\)](#) evaluated major sources of uncertainty associated with using PROFILE
34 for upland forests in the continental U.S. Mineral stoichiometry was not an important
35 influence on BCw estimates (uncertainty < 1%). Characterizing B-horizon mineralogy by
36 averaging A- and C-horizons was found to be a minor (< 5%) contributor to uncertainty
37 in some areas, but where mineralogy is known to vary with depth the uncertainty can be

1 large. Estimating mineral-specific surface areas had a strong influence on estimated
2 BCw, however the greatest uncertainty in BCw estimates, was due to the particle size
3 class-based method used to estimate the total specific surface area upon which
4 weathering reactions can take place.

4.5.1.2. Steady-State Mass Balance

5 The 2008 ISA documented a model to assess CLs for acidification in forest soils based on
6 simple mass-balance equations [SMBE; [\(McNulty et al., 2007\)](#)]. This study estimated
7 critical acid load and exceedance in soils at a 1-km² spatial resolution across the U.S. A
8 second publication discussed the uncertainties associated with this model and
9 national-scale assessment ([Li and McNulty, 2007](#)). The authors quantified uncertainty
10 under natural variability in 17 model parameters and determined the relative
11 contributions of each in predicting critical loads. The results indicated that uncertainty in
12 the CLs came primarily from components of base cation weathering (BCw; 49%) and
13 acid neutralizing capacity (46%), whereas the most critical parameters were BCw base
14 rate (62%), soil depth (20%), and soil temperature (11%). The authors concluded that
15 improvements in estimates of these factors are crucial to reducing uncertainty and
16 successfully scaling up SMBE for national assessments. This work remains the best
17 national-scale estimate of terrestrial soil acidification in the U.S. (see [Appendix 4.6](#)). A
18 new study by [Posch et al. \(2011\)](#) is a regional application of SMB models, while several
19 other studies using SMB have been published to determine acidification critical loads
20 based on critical limits of Bc:Al and ANC ([Phelan et al., 2014](#); [Duarte et al., 2013](#); [Jung](#)
21 [et al., 2013](#); [Whitfield and Watmough, 2012](#); [Forsius et al., 2010](#); [McNulty and Boggs,](#)
22 [2010](#); [Nasr et al., 2010](#)). The biological implications of these critical loads are discussed
23 in [Appendix 5](#) and a summary of SMB CLs in the U.S. is presented in [Appendix 4.6](#).

24 [Posch et al. \(2011\)](#) published an article outlining SMB models for use in N deposition on
25 ecosystem biodiversity. This approach has the well-established benefit of easy regional
26 applicability, while incorporating specified critical chemical criteria to protect specified
27 receptors. Rather than indicating an upper limit for deposition (i.e., critical load), linked
28 nutrient nitrogen and acidity chemical criteria for plant occurrence produce an “optimal”
29 nitrogen and sulphur deposition envelope. This method is similar to the methods
30 developed in the 2012 Policy Assessment for the Review of the secondary NAAQS for
31 Oxides of N and S.

4.5.1.3. ForSAFE and ForSAFE-VEG

1 The ForSAFE model ([Wallman et al., 2005](#)) is the biogeochemical simulator platform
2 that simulates the cycles of carbon, nitrogen, base cations (Bc), and water in a forest
3 ecosystem, including simulation of soil chemistry, tree growth, and soil organic matter
4 accumulation or depletion. ForSAFE requires site-specific inputs of the physical
5 properties of the soil (including mineralogy, hydrological parameters, density, depth, and
6 stratification), tree type, and time series of atmospheric deposition and climatic data
7 (temperature, light, and precipitation). The model gives monthly estimates of weathering
8 rates, soil moisture, soil solution concentrations, uptake fluxes of N and Bc, litterfall,
9 decomposition and mineralization, as well as photosynthesis and growth rates.
10 ForSAFE-VEG is a composite model, in which the VEG module ([Sverdrup et al., 2007](#))
11 reads a set of five drivers (soil solution pH, Bc concentration, N concentration, ground
12 level light, soil moisture) from ForSAFE, including air temperature, and uses them to
13 estimate the relative abundance of a set of indicator plants at the site. The result is a
14 model chain that can link changes in atmospheric deposition, climatic conditions, and
15 land use to responses in the biogeochemistry and plant community composition at the site
16 level, both historically and in the future. A new study by [Belyazid et al. \(2011a\)](#) revealed
17 limitations in the model simulation of N concentrations in soil solution. The authors
18 concluded that the biogeochemical model platform must be improved to simulate N
19 processes more accurately before it is used to calculate CL for N deposition. The model
20 overestimated the actual N concentrations in the soil solution. Several new applications
21 of ForSAFE-VEG have been published ([Sverdrup et al., 2012](#); [Belyazid et al., 2011a](#)),
22 and the results are discussed in [Appendix 5](#) and [Appendix 6](#).

4.5.1.4. Model of Acidification of Groundwater in Catchment (MAGIC)

23 The MAGIC (Model of Acidification of Groundwater in Catchment) ([Cosby et al.,](#)
24 [1985a](#); [Cosby et al., 1985c](#); [Cosby et al., 1985b](#)) is one of the most well-known dynamic
25 models of aquatic and terrestrial acidification. It is a lumped-parameter model of soil and
26 surface water acidification in response to atmospheric deposition based on process-level
27 information about acidification. “Lumped-parameter” refers to the extent that spatially
28 distributed physical and chemical processes in the catchment are averaged or lumped
29 together without affecting the model’s reproduction of catchment response. Process-level
30 information refers to how the model characterizes acidification into (1) a section in which
31 the concentrations of major ions are assumed to be governed by simultaneous reactions
32 involving SO_4^{2-} adsorption, cation exchange, dissolution-precipitation-speciation of
33 aluminum, and dissolution-speciation of inorganic carbon and (2) a mass balance section
34 in which the flux of major ions to and from the soil is assumed to be controlled by

1 atmospheric inputs, chemical weathering, net uptake and loss in biomass, and losses to
2 runoff. One strength of MAGIC is the size of the pool of exchangeable base cations in the
3 soil. As the fluxes to and from this pool change over time due to changes in atmospheric
4 deposition, the chemical equilibria between soil and soil solution shift to give changes in
5 surface water chemistry. The degree and rate of change of surface water acidity thus
6 depend both on flux factors and the inherent characteristics of the affected soils. The data
7 requirements to run dynamic models like MAGIC are considerable. The equations that
8 characterize the chemical composition of soil water in MAGIC contain 33 variables and
9 21 parameters. Data required to conduct dynamic modeling are not as available in as
10 many places as the data required to conduct steady-state modeling.

11 [Oulehle et al. \(2012\)](#) presented a new formulation of the acidification model MAGIC that
12 uses decomposer dynamics to link N cycling to C turnover in soils. In comparisons with
13 earlier versions, the new formulation more accurately simulates observed short-term
14 changes in NO_3^- leaching, as well as long-term retention of N in soils. The authors state
15 that the new formulation gives a more realistic simulation of observed changes in N
16 leaching. The new formulation also provides a reasonable simulation of the long-term
17 changes in C and N pools (and C:N ratio) with SOM.

18 MAGIC has recently been used to calibrate BCw at 140 locations throughout the
19 southern Appalachian Mountains, where input data were sufficient for running the
20 dynamic model ([Povak et al., 2014](#)). Results were then extrapolated to the region.
21 [McDonnell et al. \(2014b\)](#) used these calibrated regionalized BCw values as inputs for
22 regional steady-state CL modeling.

4.5.1.5. Photosynthesis and Evapo Transpiration-Biogeochemical (PnET-BGC)

23 The PnET-BGC (Photosynthesis and Evapo Transpiration-Biogeochemical) model is an
24 integrated forest-soil-water model that has been used to assess the effects of air pollution
25 and land disturbances on forest and aquatic ecosystems ([Gbondo-Tugbawa et al., 2001](#)).
26 The model was developed by linking two submodels: PnET-CN [PnET-carbon and
27 nitrogen; ([Aber et al., 1997](#))] and BGC ([Gbondo-Tugbawa et al., 2001](#)). The main
28 processes in the model include tree photosynthesis, growth and productivity, litter
29 production and decay, mineralization of organic matter, immobilization of nitrogen,
30 nitrification ([Aber et al., 1997](#)), vegetation and organic matter interactions of major
31 elements, abiotic soil processes, solution speciation, and surface water processes
32 ([Gbondo-Tugbawa et al., 2001](#)). The hydrologic algorithms used in PnET-BGC are
33 summarized by [Aber and Federer \(1992\)](#) and [Chen and Driscoll \(2005\)](#). PnET-BGC has
34 the capability of using multiple soil layers ([Chen and Driscoll, 2005](#)) to model seasonal

1 variations in soil parameters and chemistry. Applications and conceptual advancements
2 to the model published since 2008 are summarized in [Table 4-15](#).

4.5.1.6. DayCent-Chem

3 DayCent-Chem links two widely accepted and tested models, one of daily
4 biogeochemistry for forest, grassland, cropland, and savanna systems, DayCent ([Parton et](#)
5 [al., 1998](#)), and the other of soil and water geochemical equilibrium, PHREEQC
6 ([Parkhurst and Appelo, 1999](#)). The linked DayCent/PHREEQC model was created to
7 capture the biogeochemical responses to atmospheric deposition and to explicitly
8 consider those biogeochemical influences on soil and surface water chemistry. The linked
9 model expands on DayCent's ability to simulate N, P, S, and C ecosystem dynamics by
10 incorporating the reactions of many other chemical species in surface water.

Table 4-15 Photosynthesis and Evapo Transpiration-Biogeochemical (PnET-BGC) and DayCent.

Region	Deposition	Model (Dynamic or Steady State)	Approach/Observation	Reference HERO ID
Hubbard Brook Experimental Forest (HBEF), NH	526 eq S/ha/yr; 327 eq NO ₃ ⁻ /ha/yr; ~522 eq NO ₃ ⁻ + NH ₃ /ha/yr	PnET-BGC	Application: Combination of multiple deposition scenarios of S, NO ₃ ⁻ , and base cation deposition (0 to 100% decrease in 20% increments after 2008), as well as current climate and climate change scenarios to Year 2100.	Wu and Driscoll (2010)
Hubbard Brook Experimental Forest, NH	Not specified but see Wu and Driscoll (2010)	PnET-BGC	Conceptual Advancement: PnET-BGC modified to include CO ₂	Pourmokhtarian et al. (2012)
San Bernadino Mtns., CA	Two sites: (1) 8.8 kg N/ha/yr; (2) 70 kg N/ha/yr	DayCent	Conceptual Advancement: DayCent modified to include O ₃ effects	Bytnerowicz et al. (2013)
Adirondack Long-term Monitoring Program (ALTM; 128 lakes)	Mean wet + dry dep. 2009–2011: S = 20–34 meq/m ² /yr; N = 24–33 meq/m ² /yr	PnET-BGC	Application: Controlling S deposition is more effective in promoting acidic lake recovery than controlling S + N deposition. Reducing S dep. 60% beyond 2011 level is predicted to restore 28% of impaired lakes to ANC 20 µeq/L ≥ by 2050 and 60% of lakes by 2200. An ANC of 11 µeq/L can be achieved to 53% of lakes by 2050.	Fakhraei et al. (2014)
Adirondack Mtns. Region, NY	SO ₄ ²⁻ = 290.3–365.7 eq/ha/yr; NO ₃ ⁻ = 172.5–233.5 eq/ha/yr		Application: PnET-BGC was used to evaluate biophysical factors that affect CLs and TLs of acidity for the Constable Pond watershed, as an example of a chronically acidic drainage lake in the Adirondack region of New York, U.S. These factors included a range of future scenarios of decreases in atmospheric nitrate, ammonium and sulfate deposition from present to 2200.	Zhou et al. (2015c)
Great Smoky Mtns. National Park	6.8–27.8 kg S/ha/yr 6.1–16.6 kg N/ha/yr (2004–2008)	PnET-BGC	Application: Simultaneous reduction in SO ₄ ²⁻ and NO ₃ ⁻ deposition is more effective at increasing stream ANC than SO ₄ ²⁻ alone. NO ₃ ⁻ leaching continues as N deposition decreases. Stream recovery is delayed as NO ₃ ⁻ facilitates desorption of legacy SO ₄ ²⁻ that is adsorbed to acid soils.	Zhou et al. (2015a)

Table 4-15 (Continued): Photosynthesis and Evapo Transpiration-Biogeochemical (PnET-BGC) and DayCent.

Region	Deposition	Model (Dynamic or Steady State)	Approach/Observation	Reference HERO ID
Great Smoky Mtns. National Park	3.1 kg S/ha/yr 5.1 kg N/ha/yr	PnET-BGC	Application: Due to soil SO ₄ ²⁻ adsorption capacity, reducing NH ₄ ⁺ deposition would be more effective in stream recovery than reducing NO _x and SO ₂ .	Fakhraei et al. (2016)

4.5.2. New Models (Published since 2008)

4.5.2.1. SMARTml

1 SMARTml is an assemblage of surface complexation models (SCMs), which are used in
2 in predicting dynamics in soil chemistry without any site-specific calibration. In the first
3 published application of SMARTml to a spruce forest site in Germany, model results
4 matched observations well overall ([Bonten et al., 2011](#)). Simulations deviated from
5 observations only for soil layers or parameters for which insufficient information was
6 available. These positive results demonstrate the potential to further apply SCMs in
7 dynamic modeling. Current results only refer to a single site, and the testing of SCMs for
8 more cases with differences in soil types, depositions, and environmental conditions are
9 needed to better understand the strengths of this model.

4.5.2.2. Very Simple Dynamic (VSD) and VSD⁺

10 The VSD model (Very Simple Dynamic Soil Acidification Model) is the simplest
11 extension of the steady-state SMB model into a dynamic model. It does this by including
12 cation exchange and time-dependent N immobilization (accumulation). The VSD model
13 is designed for sites with little available data and for applications on a large regional or
14 continental scale. The model has a short execution time that allows rapid scenario
15 analyses and the calculation of target loads (i.e., deposition targets), which result in a
16 desired chemical condition in the soil (solution) in a specified year. [Posch and Reinds
17 \(2009\)](#) developed a version of the VSD for steady-state critical load applications at the
18 regional scale. Although simpler than other widely used dynamic models (such as
19 MAGIC and SAFE), VSD contains the basic physical and chemical relationships
20 common to all these models. However, the model's simplicity also means that some
21 processes have either been left out altogether (e.g., SO_4^{2-} -sorption) and others strongly
22 simplified (e.g., N cycling processes). As a consequence, VSD is not best suited for sites
23 where SO_4^{2-} adsorption is important. Furthermore, the simple description of N processes
24 does not allow simulating decreasing soil N pools (and increasing C:N ratios) under
25 reduced N inputs.

26 [Bonten et al. \(2015\)](#) describe an extension of the VSD model, called VSD⁺, which
27 includes an explicit description of C and N turnover. The VSD⁺ model includes an
28 explicit description of organic C and N turnover, whereas in the VSD model, N
29 immobilization depends on the N availability and C sequestration mostly depends on the

1 N immobilization rate, which is controlled by user-prescribed C:N ratios. The VSD⁺
2 model also includes S adsorption on soils. The authors apply VSD⁺ to three forest stands,
3 which differ in N deposition and soil C:N ratios. Results suggest that at some locations
4 VSD⁺ can accurately predict trends and absolute values of NO₃⁻ and NH₄⁺ concentrations
5 in soil and stream waters, soil C:N ratios and pH.

4.5.2.3. Soil Organic Matter

6 The Soil Organic Matter (SOM) model was developed as an alternative to the
7 decomposition module of the PnET model for application in northeastern forests. It relies
8 on empirical representations of litter decomposition and soil C turnover rates, and
9 explicitly represents multiple soil horizons. [Tonitto et al. \(2014\)](#) examined the effect of N
10 addition on SOM dynamics. Their model simulations suggested that ambient atmospheric
11 N deposition at the forest has led to an increase in cumulative O-, A-, and B-horizons C
12 stocks of 211 g C/m² (3.9 kg C/kg N) and 114 g C/m² (2.1 kg C/kg N) for hardwood and
13 pine standards, respectively. They concluded that the model proved largely able to
14 simulate soil C and N dynamics at their study site under control conditions and that field
15 observations, mechanistic experiments, and model simulations suggest that the addition
16 of N to forest ecosystems could have a substantial effect on forest soil C accumulation
17 via suppression of organic matter decomposition.

4.5.2.4. ORCHIDEE-Carbon-Nitrogen

18 ORCHIDEE Carbon Nitrogen (O-CN) is a terrestrial biosphere model which has been
19 developed from the land surface model ORCHIDEE and describes the N and C fluxes
20 and stocks of vegetation and SOM for 10 natural plant functional types, as well as C₃ and
21 C₄ croplands at a half-hourly timescale. [Zaehle \(2013\)](#) determined that the estimate C
22 sequestration from the process-based O-CN model is lower than was found in earlier
23 studies based on simple biogeochemical models and upscaling of field-based
24 measurement, which have estimated C sequestration based on N deposition estimates as
25 0.4–0.7 Pg C/yr in 1990. The O-CN results were within the range of previous model
26 simulations with the current generation of C-N cycle models (0.2–0.6 Tg N/yr). The
27 authors believe the study provides an advance over previous assessments because it relies
28 on a “process-based ecosystem model that integrates the key C-N cycle interactions and
29 their coupling to biogeophysical processes, while considering the impacts of atmospheric
30 (climate, CO₂) and land cover changes.” Key uncertainties in the modeling include (1) the
31 response of canopy-level photosynthesis to N additions, (2) changes in the allocation

1 patterns (root:shoot ratio), and (3) the competition of plants and soil microbes for the
2 added (or reduced) amount of N.

4.5.2.5. Dynamic Model N14C

3 Dynamic model N14C is a plant-soil N and C cycling model that simulates terrestrial
4 ecosystem responses to atmospheric N deposition ([Tipping et al., 2012](#)). The model
5 includes four plant functional types: broadleaved and coniferous trees, herbs, and dwarf
6 shrubs. It simulates net primary production (NPP); C and N pools; leaching of DOC,
7 DON, and inorganic N; denitrification; and the radiocarbon contents of organic matter on
8 an annual time step. The model simulates annual plant growth and turnover and soil C
9 and N cycling and is reasonably successful at reproducing average results. However, for
10 individual sites, there are no significant correlations for C pools or C:N ratios and only
11 weak relationships for N pools and inorganic N leaching. Inorganic leaching has
12 traditionally been considered one of the main indicators of N saturation (however, see
13 new studies in [Appendix 4.3.2](#)) and therefore an important goal of N¹⁴C is to simulate its
14 response to N enrichment.

4.5.2.6. Dynamic Simulation Model of Ecosystem Nitrogen

15 [Perakis and Sinkhorn \(2011\)](#) reported $\delta^{15}\text{N}$ constraints on long-term N balances in
16 temperate forests using a dynamic simulation model of ecosystem N and $\delta^{15}\text{N}$. Their
17 model evaluated which combination of N input and loss pathways could produce a range
18 of high ecosystem N contents characteristic of forests in the Oregon Coast Range, U.S.
19 Ecosystem $\delta^{15}\text{N}$ displayed a curvilinear relationship with ecosystem N content and
20 largely reflected mineral soil, which accounted for 96–98% of total ecosystem N. Model
21 simulations of ecosystem N balances parameterized with field rates of N leaching
22 required long-term average N inputs that exceed atmospheric deposition and asymbiotic
23 and epiphytic N_2 -fixation, and that were consistent with cycles of post-fire N_2 -fixation by
24 early successional red alder. Soil water $\delta^{15}\text{NO}_3^-$ patterns suggested a shift in relative N
25 losses from denitrification to NO_3^- leaching as N accumulated, and simulations identified
26 NO_3^- leaching as the primary N loss pathway that constrains maximum N accumulation.

4.5.3. Comparative Analyses

27 [Tominaga et al. \(2009\)](#) used HBEF, NH, U.S., as the setting to evaluate the performance
28 of three uncalibrated process-oriented models. They performed a Monte Carlo

1 multiple-model evaluation framework of the dynamic models MAGIC, SAFE, and VSD.
2 The greatest differences in model outputs were attributed to the cation exchange
3 submodel, with Gapon-exchange based models retaining more base cations on the
4 exchange complex and releasing less into solution, resulting in lower soil solution ANC
5 values. Given the same deposition scenario, the three models (without calibration)
6 simulate changes in soil and soil solution chemistry differently, but the basic patterns
7 were similar.

8 [Bonten et al. \(2015\)](#) compared common dynamic models used to evaluate soils
9 ([Table 4-16](#)). Comparisons are is summarized in [Table 4-17](#).

Table 4-16 Overview of properties of four dynamic soil chemistry models as characterized in [Bonten et al. \(2015\)](#).

Features	VSD	MAGIC	ForSAFE	SMARTml
Number of soil layers	1	1–3	1–20	1–15 soil horizons
Temporal resolution	Annual	Annual/monthly	Monthly	Variable (day–yr)
Bc weathering	External input	Calibrated, or external-input	Submodel	External input
Forest nutrient uptake	External input	External input	Submodel	Submodel
Runoff-to-precipitation ratio	External input	External input	Fixed ratio	External input
Sulfate adsorption	Not included	Langmuir isotherm	Yes	At Fe/Al hydroxides using a 2pK-DDL model
N immobilization	Fractional, fixed, or external input	Fractional, fixed, or external input	Submodel	Submodel
Nitrification	100%	Fractional	Submodel	Submodel
Denitrification	Fractional, fixed	Fractional	None or submodel	Submodel
Soil N build-up controlled by C:N ratio	Yes	Yes	No	Submodel
CO ₂ degassing in surface water	Yes	Yes	Yes	No surface water
Al(OH) ₃ precipitation in stream	Yes	Yes	Yes	No surface water
Lumped base cations (Ca ²⁺ , Mg ²⁺ , and K ⁺)	Yes	No	Yes	No
DOC dissociation model	Oliver or simple monoprotic	Triprotic	Oliver	NICA-Donnan

Table 4-16 (Continued): Overview of properties of four dynamic soil chemistry models as characterized in {Bonten, 2016, 3287736@@author year}.

Features	VSD	MAGIC	ForSAFE	SMARTml
Cation exchange	Gaines-Thomas or Gapon	Gaines-Thomas	Gapon	OM: NICA-Donnan clay: Donnan gel hydroxides: 2pk DDL
Number of cation exchange equations	2	4	1	Not relevant
Ions in soil solution charge balance	12	28	16	Full speciation of ions in the soil solution

Table 4-17 Model comparison.

Soil Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Modeled Observation	Reference HERO ID
Soil S	Forest	Three Swiss forest monitoring sites	Not specified	In a comparison of four models VSD, MAGIC, For-SAFE, and SMARTml, ForSAFE-modeled S concentrations tended to be underestimated by the model.	Bonten et al. (2015)
Soil pH	Forest	Three Swiss forest monitoring sites	Not specified	In a comparison of four models VSD, MAGIC, For-SAFE, and SMARTml, ForSAFE results indicated upper soil layers can have higher modeled pH than observed.	Bonten et al. (2015)
Soil ANC and pH	Scots pine plantation	Long-term forest monitoring site in U.K. (Peak District of northern England)	Not specified	In a comparison of four models VSD, MAGIC, For-SAFE, and SMARTml, MAGIC successfully reproduced the trend in acidity (ANC and pH) in soil solution over the majority of the (ca. 1990s) monitoring period.	Bonten et al. (2015)
Soil SO ₄ ²⁻	Spruce forest	Gårdsjön, Sweden	Not specified	In a comparison of four models VSD, MAGIC, For-SAFE, and SMARTml, ForSAFE modeling results showed SO ₄ ²⁻ was slightly underestimated compared to measured SO ₄ ²⁻ concentrations in soil solutions at 5-, 10-, and 20-cm depth (1990–2000).	Bonten et al. (2015)
Soil SO ₄ ²⁻	Spruce forest	Bechtel, Switzerland	Not specified	In a comparison of four models VSD, MAGIC, For-SAFE, and SMARTml, ForSAFE-modeled soil SO ₄ ²⁻ was reasonably well modeled at 20-cm depth but clearly below measured values at 100-cm depth (1990–2005).	Bonten et al. (2015)

Table 4-17 (Continued): Model comparison.

Soil Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Modeled Observation	Reference HERO ID
Ion concentrations, Al	Forest	Three Swiss forest monitoring sites	Not specified	Comparison of four models VSD, MAGIC, For-SAFE, and SMARTml. VSD reproduced the ion concentrations similar to measured values, however the modeled Al concentrations were substantially lower than measured ones. VSD only calculates free Al ³⁺ , whereas measurements also include other Al-species as Al-hydroxides and Al complexed by dissolved organic matter and fluoride.	Bonten et al. (2015)
Base cations (nutrients Ca + Mg + K; Na; and Ca)	Spruce forest	Gårdsjön, Sweden; Bechtel, Switzerland; and long-term monitoring site in Germany	Not specified	ForSAFE results compared to observations. In Sweden, nutrient base cations were slightly underestimated compared to measured values in soil solution at 5-, 10-, and 20-cm depth (1990–2000), while Na ⁺ in soil solution was relatively well modeled at 5-, 10-, and 20-cm depth but less well in deeper soil. In Switzerland, base cations modeling results were “within the range of the measured values with a slight underestimation at 20-cm depth” (1990–2005). In Germany, Ca ²⁺ agreed with measured values in soil solution (1990–2005).	Bonten et al. (2015)
Al	Spruce forest	Bechtel, Switzerland	Not specified	ForSAFE-modeled Al ³⁺ was “in the range of the measured soil solution values at 20-cm depth” (1990–2005).	Bonten et al. (2015)
Al, Ca, and protons	Norway spruce forest	Long-term monitoring site in Germany	Not specified	SMARTml results showed that modeled Al ³⁺ , Ca ²⁺ , and protons agree with measured values observations in soil solution (1990–2005).	Bonten et al. (2015)

Table 4-17 (Continued): Model comparison.

Soil Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Modeled Observation	Reference HERO ID
Base saturation	Forest	Great Smoky Mountains National Park	5.1 kg N/ha/yr (36.5 mmolc/m ² /yr)	PnET-BGC used to model 30 stream watersheds during 1981–2014 when SO ₄ ²⁻ and NO ₃ ⁻ deposition decreased (81 and 53%, resp.). Hindcast modeling (beginning ca. 1850) showed decreased soil base saturation from 17.8% (preindustrial median) to 12.6% (current median).	Fakhraei et al. (2016)

4.6. National-Scale Sensitivity

1 The 2008 ISA documented that by the end of the 1980s, after nearly a decade of intensive
2 research performed under the original National Acid Precipitation Assessment Program
3 (NAPAP) research program, the regions of the U.S. with acid-sensitive waters and
4 ecosystems were well recognized. These acid-sensitive ecosystems are generally located
5 in upland mountainous terrain in the eastern U.S. and are underlain by weathering-
6 resistant bedrock, such as granite or quartzite sandstone. The 2008 ISA documented maps
7 of the U.S. that showed areas sensitive to acidification. However, similar maps for areas
8 sensitive to the eutrophication effects of nitrogen were not available. Strong evidence was
9 documented demonstrating that biogeochemical sensitivity to deposition-driven
10 eutrophication and acidification is the result of historical loading, geologic/soil conditions
11 (e.g., mineral weathering and S adsorption), and nonanthropogenic sources of N and S
12 loading to the system. The 2008 ISA documented that there is no single deposition
13 level applicable to all ecosystems in the U.S. that will describe the onset of eutrophication
14 or acidification. Since the 2008 ISA, there are new publications commenting on recovery
15 of terrestrial ecosystems at either the national scale ([NAPAP, 2011](#)) or in specific regions
16 ([Lawrence et al., 2015a](#); [McDonnell et al., 2013](#); [Elliott et al., 2008](#)). One new paper
17 evaluates national-scale terrestrial critical loads for nitrate leaching ([Pardo et al., 2011b](#)),
18 but work on national-scale soil acidification published in 2007 remains the most recent
19 national assessment of this effect ([McNulty et al., 2007](#)).

4.6.1. Acidification Recovery

20 It is important to note that different chemical pools within the soil may recover from
21 declining N and S atmospheric deposition at different rates. For example, soil solution
22 Ca:Al ratio or SO_4^{2-} or NO_3^- concentration are faster responding indicators than total N.
23 Indicators that are linked to slow pools (such as soil percentage base saturations or soil
24 C-to-N ratios) will have slow response times with regard to changes in atmospheric
25 deposition. An indicator such as ANC which is influenced by both fast (solution) and
26 slow (soil) pools has an intermediate response time. In addition to how indicators convey
27 rates of recovery in different biogeochemical pools, recovery can be documented by
28 empirical evidence and projected by models of recovery trajectories.

29 The most recent national-scale assessment of recovery from acidifying deposition was the
30 National Acid Precipitation Assessment Program (NAPAP) report to Congress ([NAPAP,](#)
31 [2011](#)). NAPAP is a cooperative federal program first authorized in 1980 to coordinate
32 acid rain research and report the findings to Congress. The NAPAP member agencies are

1 the U.S. EPA, the U.S. Department of Energy, the U.S. Department of Agriculture, the
2 U.S. Department of Interior, the National Aeronautics and Space Administration, and the
3 National Oceanic and Atmospheric Administration. The report concluded that few studies
4 have evaluated terrestrial ecosystem health relative to acidification effects over time, and
5 soils in the most acid-sensitive regions for which there is more data continue to acidify.

6 New evidence since the publication of the [NAPAP \(2011\)](#) is summarized in [Table 4-18](#).
7 A new study supports the beginning of recovery from soil acidification in the
8 northeastern U.S. ([Fuss et al., 2015](#); [Lawrence et al., 2015a](#)). [Fuss et al. \(2015\)](#) studied
9 Hubbard Brook forest in NH and found indicators of recovery of acidification in soil
10 solution measurements taken from 1984–2011. At the same site, [Phelan et al. \(2016\)](#)
11 conducted a modeling study that showed current reductions in deposition generally halted
12 further damage to soils and plants and resulted in no or only partial recovery.

13 In the southern Appalachian Mountains, modeling studies suggest current stress and
14 recovery likely to take decades even under scenarios of large reductions in S deposition
15 ([McDonnell et al., 2013](#); [Elliott et al., 2008](#)). [Rice et al. \(2014\)](#) calculated for many
16 forested, unglaciated watersheds from Pennsylvania to Georgia will begin releasing SO_4^{2-}
17 over the next two decades ([Appendix 4.3.3](#)). Unglaciated soils, like those that occur in the
18 southeastern U.S., accumulate S that is slowly released from soil pools into drainage
19 water, a process that temporarily delays ecosystem recovery in response to decreases in S
20 deposition ([Appendix 4.3.3](#)).

21 The acid-base characteristics of DOC are an important part of understanding the recovery
22 potential for soils, lakes, and streams impaired by acid deposition; these effects are
23 discussed in [Appendix 4.3.9](#).

Table 4-18 Recovery.

Region	Type of Ecosystem	Empirical or Model	Approach/Observation	Reference HERO ID
Southern Appalachian Mountains, NC	Forest soil	NuCM	Model: Modeled three S deposition simulations: current, 50% decrease, and 100% increase, at Joyce Kilmer (JK), Shining Rock (SR), and Linville Gorge (LG) wilderness areas. Low Ca:Al ratios results suggest that forests at SR and LG are significantly stressed under current conditions. The soil SO ₄ ²⁻ retention is low, perhaps contributing to the high degree of acidification. The soils are very acidic and low in weatherable minerals. Even with large reductions in SO ₄ ²⁻ and associated acid deposition, it may take decades before these systems recover from depletion of exchangeable Ca, Mg, and K.	Elliott et al. (2008)
Southern Appalachian Mountains, U.S.	65 streams and their watersheds	MAGIC model	Model: A study used the MAGIC model to evaluate soil Bc status. Future S deposition reduction scenarios (6, 58, 65, and 78% reduction), and various changes in timber harvest, temperature, and precipitation were modeled. Each of the scenario projections indicated that median Year 2100 soil exchangeable Ca will be at least 20% lower than preindustrial values. The simulations suggested that substantial mass loss of soil Bc has already occurred since preindustrial times. Soil Bc pools in the study region are expected to remain significantly below preindustrial conditions for more than 100 yr, regardless of changes in climate, S deposition, or timber harvest.	McDonnell et al. (2013)
Great Smoky Mountains National Park, U.S.	Forest soils and streams	PnET-BGC	Application: Simultaneous reduction in SO ₄ ²⁻ and NO ₃ ⁻ deposition is more effective at increasing stream ANC than SO ₄ ²⁻ alone. NO ₃ ⁻ leaching continues as N deposition decreases (this is due to unmanaged forests). Stream recovery is delayed as NO ₃ ⁻ facilitates desorption of legacy SO ₄ ²⁻ that is adsorbed to acid soils.	Zhou et al. (2015b)
Great Smoky Mountains National Park, U.S.	Forest soils and streams	PnET-BGC	Model: Modeling of 30 stream watersheds characterized by decreased SO ₄ ²⁻ and NO ₃ ⁻ deposition during 1981–2014 (81 and 53%) showed that stream recovery has been limited and delayed due to the high sulfate adsorption capacity of soils in the park resulting in a long lag time for recovery of soil chemistry.	Fakhraei et al. (2016)

Table 4-18 (Continued): Recovery.

Region	Type of Ecosystem	Empirical or Model	Approach/Observation	Reference HERO ID
Eastern Canada and the northeastern U.S.	Forest and streams	Recovery	Field Observation: 27 sites exposed to reductions in wet SO ₄ ²⁻ deposition of 5.7–76%, over intervals of 8–24 yr. Results are decreased exchangeable Al in the O-horizon and increases in pH in the O and B-horizons at most sites. Among all sites, reductions in SO ₄ ²⁻ deposition were positively correlated with ratios of base saturation and negatively correlated with exchangeable Al ratios in the O-horizon. However, base saturation in the B-horizon decreased at one-third of the sites, with no increases.	Lawrence et al. (2015a)
Hubbard Brook Experimental Forest, NH	Forest and streams	Al _i Recovery	Field Observation: slowed losses of base cations from soil and decreased mobilization of dissolved inorganic aluminum were observed. Streamwater pH at the watershed outlet increased at a rate of 0.01 units/yr and the acid neutralizing capacity (ANC) gained 0.88 µeq/L/yr. Dissolved organic carbon generally decreased in stream water and soil solutions. Both baseline and chronic acidification (measured during snowmelt) are recovering at this site.	Fuss et al. (2015)
Hubbard Brook Experimental Forest, NH, and Bear Brook Watershed, ME	Forests soils and plants	Model For-SAFE-Veg	Model: Only when future deposition to 2100 was returned to preindustrial levels was recovery of soil and plant community to 1900 conditions projected. Policy-based reductions in deposition generally halted further damage to soils and plants and resulted in no or only partial recovery.	Phelan et al. (2016)
Adirondack Long-term Monitoring Program (ALTM; 128 lakes)	Forests soils and lakes	PnET-BGC	Model: Controlling S deposition is more effective at acidic lake recovery than controlling S + N deposition. Reducing N deposition is less effective because the resulting increase in soil pH leads to soil desorption of SO ₄ ²⁻ and other anions. Reducing S dep. 60% beyond 2011 level is predicted to restore 28% of impaired lakes to ANC 20 µeq/L ≥ by 2050 and 60% of lakes by 2200. An ANC of 1 µeq/L can be achieved to 53% of lakes by 2050.	Fakhraei et al. (2014)

Table 4-18 (Continued): Recovery.

Region	Type of Ecosystem	Empirical or Model	Approach/Observation	Reference HERO ID
Adirondack Mtns. Region, NY	Forests soils and lakes	PnET-BGC	<p>Model: Decreasing SO_4^{2-} deposition is 4.6× more effective than NO_3^- decrease for Years 2040–2050.</p> <p>Decreases in NO_3^- deposition is more effective at increasing lake ANC than an equal decrease in NH_4^+ deposition.</p> <p>Due to the higher mass transfer coefficient for in-lake retention of NO_3^-, decreasing NO_3^- deposition decreases NO_3^- leaching but lowers ANC production.</p> <p>As SO_4^{2-} and NO_3^- deposition decrease, a significant lake DOC concentration increase has been observed. However, PnET-BGC does not consider the decrease in soil organic matter partitioning as acid deposition decreases and soil pH increases.</p>	Zhou et al. (2015c)

MAGIC = ; NuCM = Nutrient Cycling Model; SO_4^{2-} = sulfate; Ca = calcium; Mg = magnesium; K = Potassium; S = sulfur; Bc = base cation.

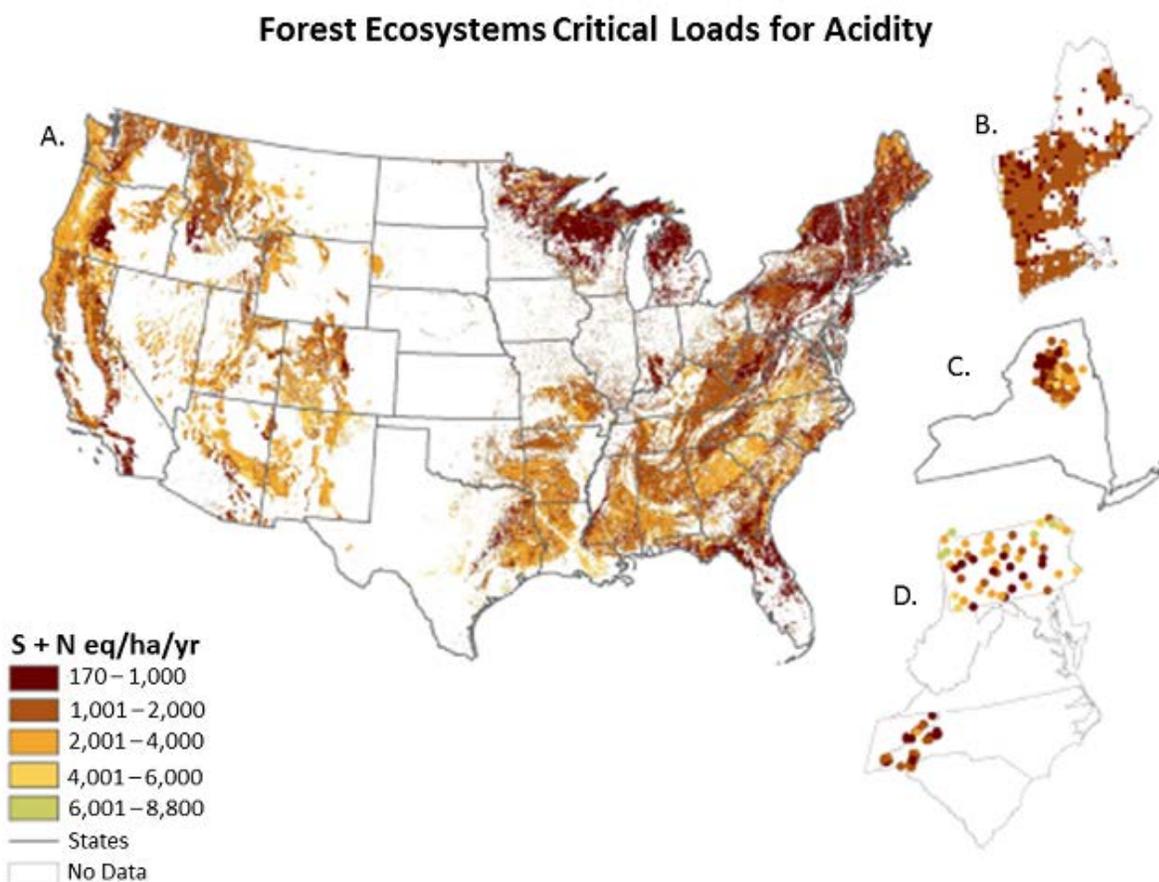

4.6.2. Critical Loads

4.6.2.1. Soil Acidification

1 The 2008 ISA included ([McNulty et al., 2007](#)) a national assessment of soil critical loads
2 for acidification calculated by a SMBE technique (see Section 4.5.1.8 of the 2008 ISA).
3 The uncertainty associated with the SMBE technique was discussed in a second
4 publication ([Li and McNulty, 2007](#)). In general, the SMBE predicted that 26% of U.S.
5 forest soils have critical loads less than 1,000 eq/ha/yr. Low critical loads outside of New
6 England, New York, and the Appalachian Mountain region are not necessarily
7 problematic to forest health because acid deposition is much lower across most of the
8 U.S. compared to these areas. Unfortunately, mountainous terrain comprises much of the
9 area with very low forest soil critical loads. Mountain forests receive some of the highest
10 local rates of acidic deposition.

11 No new publications are identified in this review on the subject of national-scale
12 sensitivity; however, there are new reports on regional sensitivity. [Figure 4-10](#) is a map of
13 soil CLs presented by [McNulty et al. \(2007\)](#) and updated with newer SMB modeling,
14 where available ([McDonnell et al., 2014b](#); [Phelan et al., 2014](#); [Duarte et al., 2013](#);
15 [Sullivan et al., 2011b](#); [Sullivan et al., 2011a](#)). [Duarte et al. \(2013\)](#) is a new evaluation of
16 critical loads for terrestrial acidification in New England, U.S. The steady-state mass
17 balance method is applied at over 4,000 plots. The acceptable ANC leaching rate was
18 calculated based on the critical chemical criteria of no change in base saturation. Over
19 80% of the critical loads were between 850 and 2,015 eq/ha/yr. [Phelan et al. \(2014\)](#)
20 evaluated PROFILE using national data sets as a method to estimate BCw rates for
21 forests in the U.S., focusing on Pennsylvania as the first test state. The model paired with
22 national data sets was successfully applied at 51 forested sites across Pennsylvania. The
23 soil critical loads were evaluated using a Bc:Al value of 10.0. The CL values ranged from
24 4 to 10,503 eq/ha/yr. [Sullivan et al. \(2011a\)](#) used the dynamic model MAGIC to model
25 terrestrial soil acidification in the Adirondacks, NY. Simulations were based on one
26 driver of acidic deposition (S) and included evaluation of CLs for soil solution molar
27 Bc:Al and Ca:Al ratio, two critical threshold levels (1 and 10), and two endpoint years of
28 model simulation (2050 and 2100). Statistically selected lakes (n = 44) were modeled to
29 represent a population of 1,320 sites. Nearly all (>93%) had a very low TL (<25 eq/ha/yr
30 for the Year 2100) when the protection threshold was set to Bc:Al = 10, and the majority
31 (>60%) had a high TL of (>100 eq/ha/yr for the Year 2100) to achieve Bc:AL = 1.
32 [Sullivan et al. \(2011b\)](#) calculated surface water CLs for 66 sites in the Blue Ridge
33 mountains (North Carolina, Tennessee, and South Carolina). CL were reported for

1 surface waters; however, the MAGIC model was parameterized for all 66 sites including
2 terrestrial geochemistry. [McDonnell et al. \(2014b\)](#) studied acidification in the southern
3 Appalachians from northern Georgia to southern Pennsylvania and from eastern
4 Kentucky and Tennessee to central Virginia and western North Carolina. Although soil
5 critical loads were not reported in the publication, soil solution data are reported in
6 [Figure 4-10](#).

eq = equivalent; ha = hectare; yr = year.

(A.) [McNulty et al. \(2007\)](#) critical loads are mapped at 1-km² grids (center map). For uncertainty, see [Li and McNulty \(2007\)](#).

(B.) [Duarte et al. \(2013\)](#) critical loads are mapped at 4-km² grids; (C. and D.) [Phelan et al. \(2014\)](#) critical loads are mapped for each sampling site (Pennsylvania). [McDonnell et al. \(2014b\)](#); [Sullivan et al. \(2011b\)](#); [Sullivan et al. \(2011a\)](#) critical loads are mapped as a single point at the center point of the watershed (New York and North Carolina).

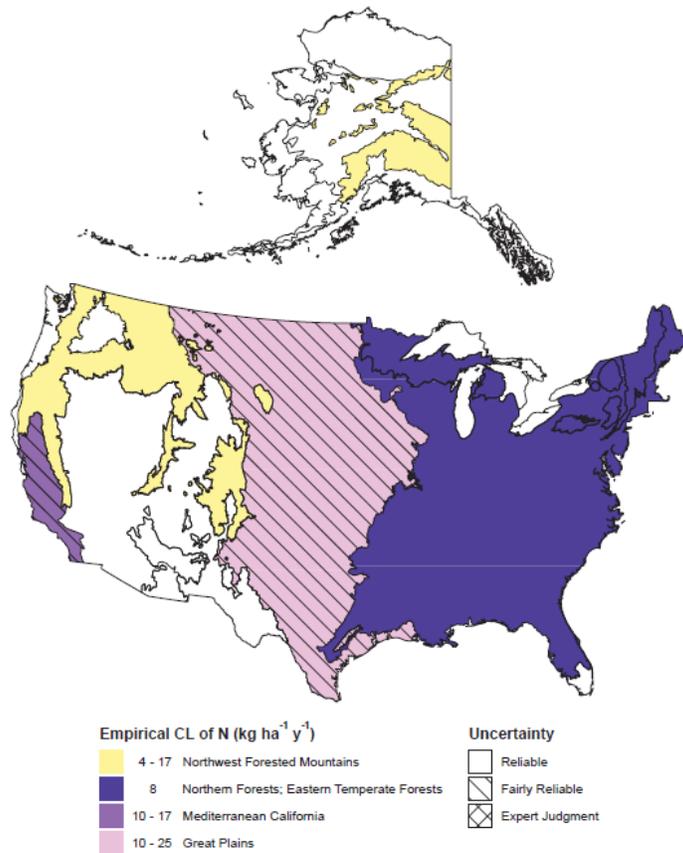

Source: http://nadp.sws.uiuc.edu/committees/clad/db/NCLDMapSummary_2015.pdf.

Figure 4-10 Forest ecosystem critical loads for soil acidity related to base cation soil indicators.

1 In the case of semiarid ecosystems of southern California, which are not highly sensitive
2 to acidification, soils in high N deposition areas of chaparral and forested areas in the Los
3 Angeles basin have acidified significantly ([Pardo et al., 2011b](#)).

4.6.2.2. Nitrate Leaching

4 [Pardo et al. \(2011b\)](#) documented the threshold N deposition value which caused
5 increased NO_3^- leaching from forest ecosystems into surface water was 8 to
6 25 kg N/ha/yr. This information is summarized by ecoregion (Omernick Level 1) in
7 [Figure 4-11](#). At 4 kg N/ha/yr, increasing NO_3^- was reported in the organic horizon in the
8 Colorado Front Range, which suggests incipient N saturation. In the northeastern U.S., N
9 budgets from 83 forested watersheds show that N retention averages 76% of incoming
10 atmospheric-N deposition and decreases from 90% retention for sites receiving
11 7 kg N/ha/yr to 60% retention for sites receiving 11 kg N/ha/yr ([Aber et al., 2003](#)). The
12 highest critical loads were reported for Mediterranean California mixed-conifer forests.
13 Since the publication of [Pardo et al. \(2011b\)](#), new studies have been published on nitrate
14 leaching in the U.S. (see [Appendix 4.3.2](#)); one critical load is from [Bowman et al. \(2014\)](#),
15 who identify 10 kg N/ha/yr as the deposition level associated with nitrate leaching in
16 RMNP. New evidence from Europe by [Dise et al. \(2009\)](#) shows approximately 95% of
17 forests receiving less than 8 kg N/ha/yr have leaching of less than 1 kg N/ha/yr. In
18 Sweden, [Khalili et al. \(2010\)](#) showed a clear sudden increase in NO_3^- leaching in regions
19 where N deposition exceeded 7.5 kg/ha/yr.

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

The range of critical loads based on increased nitrate leaching for each ecoregion. The hatch marks indicate increasing levels of uncertainty: no hatch marks for the most certain “reliable” category and single hatching for the “fairly reliable” category. White areas lack data for critical loads determination for nitrate leaching.

Source: [Pardo et al. \(2011b\)](#).

Figure 4-11 Map of critical loads for nitrate leaching by ecoregion in the U.S.

4.7. Modification of Terrestrial Soil Response to Nitrogen (N)

1 Biogeochemical responses to N deposition can be modified by many environmental
 2 factors including phosphorus, disturbance, stand age and climatic shifts in temperature
 3 and precipitation. Here we provide a very brief overview of these topics. [Appendix 13](#)
 4 provides an overview of modification of ecosystem response to N driven by climate,
 5 whereas this section describes a brief summary of how climate modifies terrestrial soil
 6 response to N.

4.7.1. Disturbance and Stand Age Effects on Nitrogen Retention

1 The 2008 ISA reported that varying degrees of N assimilation, leaching, and microbial
2 transformation often reflect differences in N status among treatment sites. These
3 variations have most often been attributed to disturbance history, dating back a century or
4 more ([Goodale and Aber, 2001](#)). Sites that have undergone disturbances that cause loss of
5 soil N, such as logging, fire, and agriculture, tend to be most effective at retaining
6 atmospheric and experimental inputs of N. Fire causes substantial N losses from
7 ecosystems. Timber harvest contributes to nutrient removal from the ecosystem via
8 biomass export and acceleration of leaching losses ([Mann et al., 1988](#); [Bormann et al.,
9 1968](#)). In particular, logging contributes to loss of N and Ca²⁺ from the soil ([Latty et al.,
10 2004](#); [Tritton et al., 1987](#)). N retention capability often decreases with stand age,
11 suggesting that older forests are more susceptible than younger forests to becoming N
12 saturated ([Hedin et al., 1995](#)).

13 One new study has been published since 2008 on how disturbance affects N retention
14 ([Vourlitis and Pasquini, 2008](#)). Fire did little to alter patterns of soil N enrichment from
15 atmospheric N deposition; however, periodic fires have important implications for the
16 structure and function of chaparral shrublands and their propensity to become N saturated
17 under current and future N deposition and fire regimes.

4.7.2. N and P Interactions

18 Mechanisms driving terrestrial N vs. P (phosphorus) limitations differ greatly since their
19 sources and biogeochemical dynamics differ; therefore, there is variability across
20 ecosystems ([Vitousek et al., 2010](#)). Organic N can be decomposed by a variety of
21 enzymes to mineralize N from substrate; however, organic P relies on phosphatase
22 enzymes to mineralize it, independent of C respiration and N mineralization ([Marklein et
23 al., 2016](#)).

24 Literature on N deposition's effect on N and P dynamics focuses on N and P cycling and
25 the influence of N on phosphatase enzyme activity. Phosphatase is an enzyme released
26 into the soil by organisms. It cleaves or hydrolyzes phosphorous (phosphoric acid) from
27 substrate (soil, roots) to yield available phosphate for uptake ([Marklein et al., 2016](#)). The
28 chemical structure of phosphatase includes N, therefore

29 [Vitousek et al. \(2010\)](#) explain that N fertilization increases P cycling because it enables
30 organisms to increase their extracellular phosphatase and, in turn, release more phosphate
31 from soil organic matter.

1 There are some conflicting ideas of how N addition effects P in soils. N addition can
2 acidify soil, therefore phosphatase activity may be suppressed by this mechanism,
3 decreasing P release to soil ([Wang et al., 2016b](#)). In contrast, N addition can decrease the
4 adsorption capacity of P ions in the soil, thus increasing P availability and uptake by
5 plants for productivity. It is also well known that N addition can increase increased litter
6 decomposition, which may also increase P release/cycling rates. An increased supply of P
7 can delay the onset of P limitation. It is important though to acknowledge that the type of
8 N applied, application rate, and ecosystem type may influence the phosphatase activity
9 ([Song et al., 2017](#)).

4.7.3. Climate Modification of Acidification Effects on Soil

10 For soil acidification, potential future changes in the quantity and temporal distribution of
11 precipitation and temperature (and their interactions) is expected to alter the wet-dry
12 cycles that govern the timing and amount of acidic inputs in precipitation, microbial
13 transformation in the soil, and the flush of acid anions from soils to surface waters.

14 There are two recent papers on the relationship between precipitation and sulfur in U.S.
15 watersheds. [Rice et al. \(2014\)](#) indicate that hydrology, and specifically runoff, is an
16 important controller of sulfate recovery in watersheds because drainage flushes the
17 accumulated sulfur from the soil. If precipitation and runoff patterns change under a
18 future climate, this important process will be affected. Similarly, [Mitchell et al. \(2011\)](#)
19 observed that following decades of changes in stream sulfate concentrations and fluxes
20 that have been driven by atmospheric deposition, variation in stream sulfate is now being
21 controlled by variations in precipitation inputs. Increased variation in precipitation will
22 increase wetting and drying cycles that promote mineralization of sulfate from soil and
23 subsequent methylation.

24 In general, if acid anions build up in soil during periods of drought, the eventual flushing
25 likely causes a more potent acidification event ([Mosley, 2015](#); [Whitehead et al., 2009](#)). If
26 the acidification event occurs during a time when sensitive biota or lifestyles of biota are
27 present, acidification may cause more adversity to these populations ([Kowalik et al.,](#)
28 [2007](#)). Increases in storm frequency associated with global climate change ([Collins et al.,](#)
29 [2014](#)) could increase the frequency and severity of acidification driven by high levels of
30 sea salt deposition in coastal regions ([Wright and Schindler, 1995](#)). Although the
31 mechanisms of interaction are unclear, increases in DOC concentrations in aquatic
32 ecosystems across Europe and the U.S. have been linked to acidification, N cycling, and
33 climate change, with important implications for water quality and ecosystem function
34 ([Evans et al., 2008](#)) (see [Appendix 4.3.9](#)).

1 Warmer temperatures increase decomposition and nitrification. Nitrification will also
2 increase with increased N supply caused by increased weathering or decomposition
3 ([Booth et al., 2005](#)). The process of nitrification generates protons that increase the rate
4 of nitrate and base cation leaching to drainage waters ([Murdoch et al., 1998](#)). The
5 combined increase of NO₃⁻ leaching and loss of base cations has the potential to magnify
6 acidification in forest soils ([Fernandez et al., 2003](#)). Soil weathering is typically the key
7 buffer to acidic deposition ([Li and McNulty, 2007](#)), and while weathering is increased by
8 both soil temperature and soil moisture ([Gwiazda and Broecker, 1994](#)), it is unclear
9 whether any future change in the magnitude of temperature and precipitation will be
10 enough to alter base cation supply or influence the acid-base balance of sensitive
11 ecosystems. Furthermore, it is unclear whether increased supply of N in soils from either
12 deposition, increased decomposition, or increased nitrogen fixation will negate the
13 ameliorative effect of enhanced weathering. Some studies show that climate change will
14 mitigate acidification through increased weathering ([Belyazid et al., 2011a](#)), while others
15 show that climate change will aggravate acidification although increased nitrification
16 outpacing enhanced weathering ([Wu and Driscoll, 2010](#)). In general, increased
17 temperature and precipitation will likely enhance inputs of buffering agents from
18 weathering and deposition, but also increase inputs of acidifying agents from deposition
19 and enhanced N cycling. The relative sensitivity of these opposing processes to a given
20 change in climate remains unresolved.

21 Ecological effects of atmospheric nitrogen (N) and sulfur (S) deposition on two
22 hardwood forest sites in the eastern United States were simulated in the context of a
23 changing climate using the dynamic coupled biogeochemical/ecological model chain
24 ForSAFE-Veg. The main driver of ecological effects was soil solution N concentration
25 ([Mcdonnell et al., 2018a](#)).

4.7.4. Climate Modification of Nitrogen-Driven Eutrophication in Soil

26 The following is brief summary of how temperature, snow, and precipitation affect soil
27 response to N. In addition, information is summarized on N effects on the flux of three
28 GHGs (CO₂, CH₄ and N₂O) from terrestrial ecosystems.

29 Snow interacts with soil biogeochemistry in a number of ways, mostly by temperature
30 shifts associated with snowpack and soil moisture flux during snowmelt. The highest
31 flow and lowest ANC periods of the year tend to coincide with times of high snowmelt.
32 This is when acidification is likely to occur. Snow pack insulates soils from frigid winter
33 air temperatures. With a warming climate, soils are expected to become colder and
34 experience more winter soil freeze-thaw cycles as snow cover continues to decline.

1 A number of experiments have evaluated snow effects on soil N; these include studies on
2 the timing, frequency, and severity (snow depth). [Groffman et al. \(2001\)](#) conducted a
3 snow manipulation experiment at HBEF and found mild late-season freezing increases
4 soil NO₃⁻ levels by physical disruption (increased fine root mortality) causing reduced
5 plant N uptake and reduced competition for inorganic N, allowing soil NO₃⁻ levels to
6 increase even with no increase in net mineralization or nitrification. Later studies at the
7 same site have shown that soil N mineralization rates were more strongly related to soil
8 volumetric water content than to root biomass, snow or soil frost, or winter soil
9 temperature ([Sorensen et al., 2016](#)), and the more freeze/thaw cycles anticipated with
10 climate warming supported lower rates of N mineralization at HBEF ([Duran et al., 2016](#)).
11 The effects of snow depth on soil N have been synthesized in a meta-analysis by [Li et al.](#)
12 [\(2016c\)](#), who evaluated the central tendencies from 41 publications on 12 variables
13 related to soil N. Results are that snow depth significantly increased foliar N (+4.5%) and
14 microbial N (MBN, +35.9%), but significantly decreased soil N₂O efflux (-34.1%) and
15 nitrification (-24.8%). However, altered snow depth did not significantly affect soil
16 dissolved organic N (DON), total inorganic N, nitrate, and N leaching. Because
17 increasing snowpack depth promoted MBN, the unchanged, net N mineralization and soil
18 ammonium content were probably due to limitation of the soil N availability and other
19 soil abiotic factors rather than soil microbes.

20 [Greaver et al. \(2016\)](#) created a synthesis of meta-analyses to study the effects of the
21 individual effects of either N, temperature, or precipitation on different pools and
22 processes related to ecosystem C pools and fluxes ([Figure 13 2](#)). Nineteen different pools
23 and processes were included in this analysis.

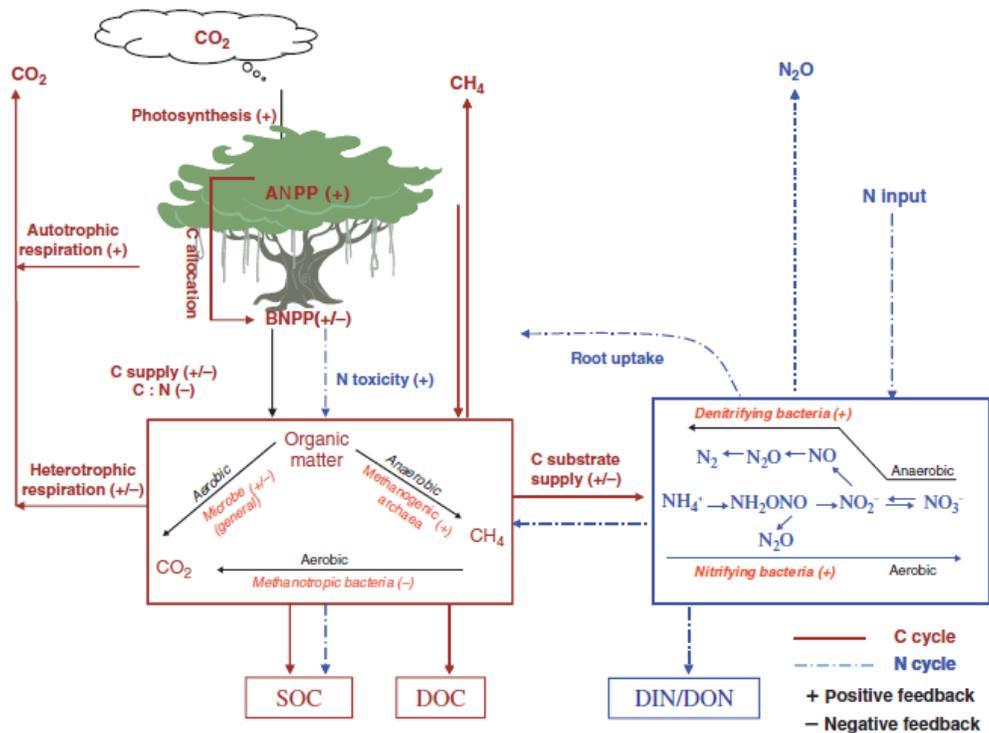

24 Initial findings are consistent with the biokinetic effects of warming; long-term data and
25 meta-analyses show that soil respiration, including decomposition and microbial
26 respiration, is stimulated by increasing temperature ([Lu et al., 2013](#); [Bond-Lamberty and](#)
27 [Thomson, 2010](#); [Rustad et al., 2001](#)). Most empirical studies show rising temperature
28 stimulates N release by mineralization ([Churkina et al., 2010](#)), which may be driven more
29 by temperature effects on moisture ([Emmett et al., 2004](#)). In some dynamic land models,
30 the additional N from mineralization will stimulate C uptake by plants even more than
31 current N deposition ([Burd et al., 2016](#)). At the same time, increased N from
32 mineralization may cause N induced inhibition of decomposition, a feedback mechanism
33 that might decrease the amount of N released and which is currently considered by a few
34 models ([Gerber et al., 2010](#)). The mechanisms causing N driven reduction in
35 decomposition are not well understood but are thought to result from changes in
36 microbial community composition and the production of decomposition enzymes, as well
37 as possible changes in the character and degradability of soil organic matter ([Conant et](#)
38 [al., 2011](#); [Janssens et al., 2010](#)). Climate change could also affect decomposition rates by

1 altering both available soil moisture and microscale connectivity among microorganisms,
2 water, and nutrients within the soil matrix, which, in turn, may alter microbial processes
3 ([Xiang et al., 2008](#)). Although there is no consensus about how dissolved organic carbon
4 (DOC) in surface water is regulated overall, increasing N and temperature increase DOC
5 concentrations ([Laudon et al., 2012](#)). While few meta-analyses have examined
6 precipitation effects on the soil C cycle, precipitation tends to increase the root C pool
7 ([Figure 13-2](#)).

8 [Ni et al. \(2017\)](#) created a meta-analysis to evaluate the interactions between warming and
9 N deposition and found the interaction greatly increased the soil C input (+49%)
10 compared with the single factor of either warming (+5%) or N deposition (+20%). Soil C
11 loss was not significantly affected by the interaction of N and warming likely because
12 increases in decomposition due to warming are offset by the decreases by N addition.

13 The N addition alters fluxes of GHGs by regulating plant and microbial activities that are
14 directly associated with GHG production and consumption processes ([Figure 4-12](#)). It is
15 extremely important to consider total ecosystem flux because consumption may be offset
16 by production, even within the same ecosystem. For example, N addition stimulates plant
17 growth in most ecosystems ([LeBauer and Treseder, 2008](#)), and may in turn increase C
18 sequestration in plant biomass. On the other hand, maintenance respiration is positively
19 correlated with tissue N content ([Reich et al., 2008](#)), and litter with higher N content also
20 decomposes faster. Therefore, increased leaf N content under elevated N may result in
21 higher C loss by increasing both autotrophic and heterotrophic respiration. Like CO₂,
22 ecosystems may consume and produce CH₄ and N₂O, and the balance determines their
23 net release.

24 [Liu and Greaver \(2009\)](#) conducted a meta-analysis of 313 observations across 109 studies
25 to evaluate the effect of N addition on the flux of three GHGs: CO₂, CH₄ and N₂O. The
26 results indicated that N addition increased ecosystem carbon content of forests by 6%,
27 marginally increased soil organic carbon of agricultural systems by 2%, but had no
28 significant effect on net ecosystem CO₂ exchange for nonforest natural ecosystems.
29 Across all ecosystems, N addition increased CH₄ emission by 97%, reduced CH₄ uptake
30 by 38%, and increased N₂O emission by 216%. Most often, N addition is considered to
31 increase forest C sequestration without consideration of N stimulation of GHG
32 production in other ecosystems. However, this study indicated that although N addition
33 increased the global terrestrial C sink, the CO₂ reduction could be largely offset
34 (53–76%) by N stimulation of global CH₄ and N₂O emission from multiple ecosystems.

ANPP = aboveground net primary productivity; BNPP = belowground net primary productivity; SOC = soil organic carbon; DOC = dissolved organic carbon; DIN = dissolved inorganic nitrogen; DON = dissolved organic nitrogen.

Figure 4-12 The potential mechanisms that regulate the responses of carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O) production and consumption to elevated nitrogen (N).

4.8. Summary

4.8.1. Sources

- 1 The effects of N and S deposition on soil biogeochemistry cause cascading effects on
- 2 biological species. The biological effects are discussed in [Appendix 5](#) and [Appendix 6](#).
- 3 Since 2008, there have been and number of estimates of sulfate, oxidized nitrogen, and
- 4 reduced nitrogen from atmospheric deposition. The most recent estimates are
- 5 summarized in [Appendix 2](#), and maps showing the geographic distribution of deposition
- 6 are presented for total acidifying deposition ([Figure 2-12](#)), total N deposition
- 7 ([Figure 2-13](#)), and total S deposition ([Figure 2-31](#)). Maps depicting how the relative

1 contribution of oxidized and reduced N species varies across the U.S. are presented in in
2 [Figure 2-14](#).

3 In the 2008 ISA, atmospheric deposition was identified as the main source of
4 anthropogenic N, relative to other N sources, to nonmanaged terrestrial ecosystems. This
5 has been confirmed by new studies on N sources to U.S. lands and waterways, which find
6 human-mediated N inputs are spatially heterogeneous across the country, ranging from
7 <1.0 to 34.6-fold the rate of background N input across the conterminous U.S. Synthetic
8 N fertilizer and atmospheric N deposition are the largest and second-largest overall
9 human-mediated N sources (the single largest sources in 41 and 33% of HUC-8s,
10 respectively). There is no new information published on non- deposition sources of S in
11 terrestrial ecosystems. S inputs from emissions to the atmosphere are discussed in
12 [Appendix 2](#).

4.8.2. Soil Processes and Indicators

13 Soil N enrichment and soil acidification are occurring in sensitive ecosystems across the
14 U.S. at recent levels of deposition. Soil acidification is a natural process that can be
15 accelerated by N and/or S deposition. A number of soil geochemical processes are
16 associated with acidification ([Appendix 4.3](#) and [Table 4-19](#)). Base cations counterbalance
17 acid anions. Base cations are added to a watershed by weathering and atmospheric
18 deposition and are removed by leaching and (perhaps temporarily) by uptake into
19 growing vegetation. Acidifying deposition can deplete exchangeable base cation pools in
20 soils where acid deposition is high relative to base cation input. The limited mobility of
21 anions associated with naturally derived acidity (organic acids and carbonic acid)
22 controls the rate of base cation leaching from soil where rates of atmospheric deposition
23 of S and N are low. In addition to increasing ion concentration in soil, inputs of S and N
24 in acidifying deposition provide anions that are highly mobile, further accelerating the
25 rates of base cation leaching. In addition, the deposition of reduced forms of N
26 (e.g., NH_x) can stimulate nitrification, which is the microbial oxidation of NH_4^+ to NO_3^- .
27 This oxidation process acidifies soils because 2 moles of hydrogen ion (H^+) are released
28 per mole of NH_4^+ converted to NO_3^- . Therefore, both chemically reduced and oxidized
29 forms of N and S deposition contribute to terrestrial acidification. Several useful
30 indicators of soil acidification ([Table 4-19](#)) include indicator thresholds related to
31 biological responses, the biological basis of which are discussed in [Appendix 5](#).

32 It is clear from [Table 4-19](#) that some of the same processes and indicators associated with
33 acidification are also associated with N enrichment. The N enrichment of terrestrial soils
34 occurs in response to the input of exogenous N. The new studies on N deposition

1 contribution to total N loading in terrestrial U.S. ecosystems are discussed in
2 [Appendix 4.2](#).

3 The 2008 ISA documented that most N, often more than 85% of the total ecosystem N, is
4 stored in the soil in temperate forest ecosystems. There is new evidence that soil litter is
5 the largest N pool in grasslands, shrublands, and wetlands ([Appendix 4.3.1](#)). The ability
6 of atmospheric deposition to increase soil N is indicated by a positive correlation between
7 atmospheric deposition levels and total N concentration in the upper soil horizon. Soil N
8 accumulation is linked to increased N leaching and decreased N retention
9 ([Appendix 4.3.2](#)). Thresholds of N deposition that are associated with the onset of
10 elevated NO_3^- leaching are discussed in [Appendix 4.6.2.2](#).

11 Recent work suggests that N leaching from soil can precede the complete saturation of
12 the biotic and abiotic processes that retain N ([Appendix 4.3.2](#)). [Lovett and Goodale](#)
13 ([2011](#)) proposed a model of N saturation in which NO_3^- leaching can occur even if the
14 ecosystem N retention capacity has not yet been saturated, as is observed at many sites
15 and supported by several new studies. Although N leaching may occur prior to saturation,
16 N budgets from 83 forested watersheds in the northeastern U.S. show that N retention
17 averages 76% of incoming N deposition. Nitrogen retention decreases from 90%
18 retention for sites receiving 7 kg N/ha/yr to 60% retention for sites receiving
19 11 kg N/ha/yr, suggesting a range of response in which leaching is exacerbated in this
20 region ([Aber et al., 2003](#)).

21 The 2008 ISA documented that N enrichment alters rates of microbial transformation of
22 chemicals in the soil, such as increased rates of nitrification and denitrification, and
23 altered rates of decomposition. The addition of N to terrestrial ecosystems can increase
24 nitrification, an important process for soil acidification and the production of NO_3^- .
25 Nitrification is often stimulated in soils with a C:N ratio below approximately 20 to 25,
26 and N deposition often causes the ratio to fall below this threshold. The NO_3^- created by
27 nitrification may be leached or denitrified. In terrestrial ecosystems, denitrification of
28 NO_3^- mainly occurs in saturated zones. Several syntheses have been published since 2008
29 evaluating N addition effects on denitrification and nitrification in terrestrial ecosystems
30 ([Appendix 4.3.6](#)). A new meta-analysis shows N addition significantly increases
31 denitrification from many types of ecosystems (coniferous forest, deciduous forest,
32 tropical forest, wetland, grassland), except heathlands.

Table 4-19 Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N-Driven Nutrient Enrichment	Acidification	The Effect of Deposition
PROCESS			
N saturation	X	X	New empirical evidence suggests revising the N saturation concept, because observed NO ₃ ⁻ leaching can occur even if the ecosystem N retention capacity has not yet been saturated.
Soil N accumulation	X	X	New meta-analysis across ecosystem types confirms inorganic soil NO ₃ ⁻ concentration increases with N addition. New gradient study confirms that N concentration increases with N deposition. New addition study confirms increased soil accumulation.
NO ₃ ⁻ leaching	X	X	New meta-analysis confirms leaching increases with N addition. New regional-scale gradient analyses: <8 kg N/ha/yr onset of leaching <1 kg N/ha/yr in European forests. Second study suggests <7.5 kg N/ha/yr increases leaching in Swedish forests. New addition study: 9 to 14 kg N/ha/yr increase in inorganic N concentrations. New USFS critical loads for the onset of leaching: 8 to 10 kg N/ha/yr in eastern and western U.S., 17 kg N/ha/yr in the Sierra Nevada and San Bernardino Mountains.
S accumulation and adsorption		X	Some soils (notably in many watersheds in the SE U.S.) have the capacity to adsorb substantial quantities of S, with essentially no acidification of drainage water. Nevertheless, S adsorption capacity is finite and under continual high S deposition loading, the adsorptive capacity of soil will eventually be depleted. New studies of 27 watersheds in the SE indicates most will begin releasing SO ₄ ²⁻ in the next two decades, and northeastern watersheds show a net loss of S from soils now in response to decreased levels of atmospheric S deposition.
SO ₄ ²⁻ leaching		X	Atmospheric S deposition generally increases leaching of SO ₄ ²⁻ to surface waters. The amount of deposition that causes the onset of leaching varies across the landscape.

Table 4-19 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N-Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Base cation release/depletion		X	<p>Base cation (Ca, Mg, K, Na) release occurs in response to the input of acid anions (SO_4^{2-} and NO_3^-) from deposition. This proportional change in base cations relative to acid anions from N and S deposition is called the F-factor.</p> <p>New studies confirm base cation depletion continues to occur in the Rocky Mountains (threshold 28 kg N/ha/yr) and in U.K. grasslands, while in a northeastern forest, 17 yr of N addition did not cause further depletion. A meta-analysis indicates cation depletion occurs early after increased deposition of acid anions, which tapers off with time.</p>
Al mobilization		X	<p><15 to 20% soil base saturation is the threshold for inorganic Al mobilization from soil. This is an extremely important effect of acidifying deposition because inorganic monomeric Al, including Al^{3+} and various hydroxide species, is toxic to biota (Appendix 5). Inorganic Al is minimally soluble at pH about 6.0, but solubility increases steeply at pH values below about 5.5.</p> <p>There have been no new studies on Al mobilization.</p>
Nitrification	X	X	<p>Nitrification releases 2 mol hydrogen ion (H^+) per mol NH_4^+ converted to NO_3^-, acidifying soils. As soil inorganic N accumulates, net nitrification rates often increase, and NO_3^- can leach from the ecosystem.</p> <p>New N gradient and meta-analysis studies confirm N addition increases nitrification.</p>
Denitrification	X		<p>Denitrification is the microbial reduction of NO_3^- to nitrite (NO_2^-), nitric oxide (NO), the greenhouse gas nitrous oxide (N_2O), and N_2. It occurs under anaerobic conditions. In Europe, soil switched from a source to a sink after two decades of N deposition exclusion.</p> <p>New meta-analysis confirms N addition increases denitrification rates.</p>
DOC leaching	X	X	<p>Acidity of some surface waters is partly regulated by DOC concentrations. Soil acidification can suppress the natural production of DOC. In recent years, the DOC concentration of some lakes and streams has risen, with adjacent terrestrial ecosystems as the DOC source. However, the mechanism for this increase is unclear. It may be due to soil recovery from acidification or N deposition effects on decomposition.</p> <p>New studies include a meta-analysis and field addition studies.</p>

Table 4-19 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.

Endpoint	N-Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Decomposition/mineralization	X	X	Decomposition rates correlate with ratios of C:N, lignin:N, or lignin:cellulose in litter. The addition of N can stimulate the decomposition of labile compounds that degrade during the initial stages of decomposition, but added N can suppress the decomposition of more recalcitrant material. Evidence for this is widespread in forests but has not yet been well documented in grasslands and other ecosystems. There are new addition studies and meta-analysis to better understand the mechanisms and response trends.
INDICATOR			
Soil [N]	X	X	Increasing N deposition increases concentration of N in soil and reflects soil N accumulation that may be assimilated by organisms or mobilized via leaching.
Soil C:N ratio	X	X	Increasing N deposition decreases the C:N in plant tissue, causing cascading effects during decomposition on microbial transformation, especially nitrification, leading to increased NO ₃ ⁻ leaching. THRESHOLD: <20 to 25 associated with elevated rates of nitrification and elevated risk of nitrate leaching in the U.S. and <25 to 30 for increased NO ₃ ⁻ leaching in Europe.
Soil base saturation		X	Increasing N + S deposition decreases the soil pool of exchangeable base cations. THRESHOLD: <15 to 20% is the value at which exchange ion chemistry is dominated by inorganic Al and may cause injury to vegetation (see Appendix 5).
Soil Bc:Al ratio		X	Increasing N + S deposition decreases the soil pool of exchangeable base cations, often decreasing the Ca:Al ratio. THRESHOLD: Ca:Al <1.0 to 10 causes physiological stress and decreased growth and survival of sensitive plant species (see Appendix 5).
Fungi:bacteria ratio	X		New indicator since 2008 ISA: Increasing N deposition decreases the fungi-to-bacteria ratio and causes a transition from N to C limitation among soil food webs.

Al = aluminum; Bc = base cation; C = carbon; Ca = calcium; DOC = dissolved organic carbon; H⁺ = hydrogen ion; ha = hectare; K = potassium; kg = kilogram; Mg = magnesium; N = nitrogen; N₂ = molecular nitrogen; N₂O = nitrous oxide; NE = northeast; NH₄⁺ = ammonium; NO = nitric oxide; NO₂⁻ = nitrite; NO₃⁻ = nitrate; S = sulfur; SE = southeast; yr = year.

1 The effects of N on decomposition, which is the breakdown of organic matter, is an
2 active area of research ([Appendix 4.3.7](#)). Within the soil microbial community, bacteria
3 and fungi are the primary decomposers of organic matter. Both microbial community
4 composition (see [Appendix 6](#)) and microbial enzyme activity can respond dynamically to
5 shifts in inorganic nutrient and substrate availability, reflecting the nutrient and energy
6 limitation of the microbial community. Litter decay rates are also well established to
7 correlate with ratios of C:N, lignin:N, or lignin:cellulose in litter. These chemical traits
8 have been shown to account for over 73% of the variation in litter decomposition rates
9 worldwide. Based on these observations, it could be assumed that added N would
10 stimulate decomposition and the loss of C from soil pools. There is now widespread
11 evidence, however, that the stimulatory effects of N on decomposition are limited to the
12 early stages of mass loss, when more labile compounds are degraded. During the later
13 stages of decomposition when the rates of mass loss are slow and controlled by the
14 degradation of recalcitrant compounds, the addition of N slows decomposition. This
15 slowing of decomposition appears to be a consequence of decreases in the production of
16 some extracellular enzymes by fungi. It is clear that N additions generally decrease
17 respiration from soil heterotrophs, but this may not decrease total soil respiration because
18 heterotrophic respiration accounts for only a portion of soil CO₂ efflux.

19 Several new meta-analyses have been published since 2008 on N addition effects on
20 belowground carbon cycling ([Appendix 4.3.10](#)). About half of C fixed annually by
21 terrestrial vegetation is allocated to belowground C pools; therefore, it is important to
22 understand how N affects belowground C to better understand changes in plant
23 physiology, plant growth, and ecosystem C cycling ([Appendix 6](#)). Many studies have
24 shown that the belowground C cycle does not always match the aboveground C cycle.
25 Therefore, it is inappropriate to extrapolate from aboveground responses to belowground
26 processes.

4.8.3. Monitoring

27 Several new studies use long-term monitoring data sets. ([Yanai et al., 2013](#)) evaluated
28 45 years of biogeochemical monitoring data at the Hubbard Brook Experimental Forest
29 LTER, New Hampshire, U.S. Since 1992, the ecosystem shifted to a net N sink of
30 ~8 kg N/ha/yr. [Mitchell and Likens \(2011\)](#) examines sulfur accumulation observed in
31 over four decades of continuous long-term record for four watersheds (reported in
32 [Appendix 4.3.3](#)). At the Niwot Ridge LTER, CO, U.S., [Lieb et al. \(2011\)](#) found that a
33 decade of simulated N deposition to alpine ecosystems caused ongoing changes in
34 diversity and soil biogeochemistry, including lower soil acid buffering capacity,
35 decreased concentrations of Mg²⁺, and increased concentrations of the potentially toxic

1 cations Mn^{2+} and Al^{3+} . Their results suggested an N deposition threshold of
2 28 kg N/ha/yr.

3 There are new studies on long-term monitoring in Europe, including investigations of S
4 dynamics in England ([Lehmann et al., 2008](#)) and N and S dynamics in Switzerland
5 ([Pannatier et al., 2011](#)) and N and C interactions between boreal soils and lakes in
6 Sweden, ([Khalili et al., 2010](#)). Notably, [Khalili et al. \(2010\)](#) found a significant relation
7 between C:N ratios of the organic soil layer and C in lake waters, and a clear sudden
8 increase in NO_3^- leaching regions where N deposition exceeded 7.5 kg N/ha/yr.

4.8.4. Models

9 The most commonly used ecosystem models in the U.S. were described in the 2008 ISA.
10 Here we focus on the several primary models that are currently being used in the U.S. to
11 assess the effects of S and N deposition on terrestrial ecosystems. One important input to
12 these models are estimates of base cation weathering (BCw). There are new updates on
13 two methods to estimate this parameter: Soil Texture Approximations (STA) and
14 PROFILE. Steady-state models include steady-state mass balance equations (SMBE),
15 while dynamic models include the VSD and VSD⁺, MAGIC, NuCM, PnET/BGC, and
16 DayCent-Chem.

17 Base cation weathering rate is one of the most influential yet difficult to estimate
18 parameters in the calculation of critical acid loads of nitrogen (N) and sulfur (S)
19 deposition for terrestrial systems. Commonly used models include STA, a simple
20 empirical steady-state model with low data requirements, and PROFILE, a mechanistic,
21 steady-state kinetics model that requires 26 input parameters. There is a new study on
22 estimating BCw. [Koseva et al. \(2010\)](#) confirm that the STA equations were derived for
23 young soils that developed following the Late Wisconsin glaciation and may not be
24 suitable for older, more weathered soils that were not affected by the most recent
25 glaciation and which cover the majority of the U.S. ([U.S. EPA, 2009c](#)). The larger data
26 set required to run PROFILE prohibits applying the model to many parts of the U.S.
27 However, a recent soil geochemical data set compiled by the USGS has made it possible
28 to apply PROFILE in the U.S. The initial application in 51 forested sites across
29 Pennsylvania indicates this technique may be appropriate for applications nationwide
30 ([Phelan et al., 2014](#)). The uncertainty associated with the calculation of BCw has recently
31 been evaluated by [Futter et al. \(2012\)](#), who estimated that the contribution of model
32 parameter uncertainty to overall variability related to PROFILE and MAGIC (a dynamic
33 model that typically uses PROFILE for initial estimates of BCw) was relatively small.

1 Estimates of BCw are input parameters in soil acidification models. The simplest
2 acidification models are the steady-state mass balance models. The 2008 ISA
3 documented a model based on simple mass-balance equations (SMBE) to assess critical
4 loads for acidification in U.S. forest soils ([McNulty et al., 2007](#)). A second publication
5 discussed the uncertainties associated with this model and national-scale assessment ([Li
6 and McNulty, 2007](#)). The results indicated that uncertainty in the critical load came
7 primarily from components of BCw (49%) and acid neutralizing capacity (46%), whereas
8 the most critical parameters were BCw base rate (62%), soil depth (20%), and soil
9 temperature (11%). The authors concluded that improvements in estimates of these
10 factors are crucial to reducing uncertainty and successfully scaling up SMBE for national
11 assessments. [Posch et al. \(2011\)](#) discusses a regional application of SMB models.

12 Dynamic models are typically applied to much smaller spatial areas than steady-state
13 models because they require more data and parameterization. The VSD model is the
14 simplest extension of the steady-state SMB model into a dynamic model that is designed
15 for sites with few data available and applications on a large regional or continental scale.
16 [Posch and Reinds \(2009\)](#) have developed a version of the VSD for steady-state critical
17 load applications at the regional scale. The ForSAFE model [Wallman et al. \(2005\)](#)
18 simulates the cycles of carbon, nitrogen, base cations (Bc), and water in a forest
19 ecosystem, while simultaneously simulating soil chemistry, tree growth, and soil organic
20 matter accumulation or depletion. ForSAFE-VEG is a composite model ([Sverdrup et al.,
21 2007](#)) that can link changes in atmospheric deposition, climatic conditions, and land use
22 to responses in the biogeochemistry and plant community composition at the site level,
23 both historically and into the future. [Belyazid et al. \(2011a\)](#) stated that the
24 biogeochemical model platform must be improved to simulate N processes more
25 accurately before being applied to calculate critical loads. The model overestimated the
26 actual N concentrations in the soil solution. Several new applications of ForSAFE-VEG
27 were published [([McDonnell et al., 2013](#); [Sverdrup et al., 2012](#); [Belyazid et al., 2011a](#)),
28 and the results are discussed in [Appendix 5](#) and [Appendix 6](#)].

29 MAGIC ([Cosby et al., 1985a](#); [Cosby et al., 1985c](#); [Cosby et al., 1985b](#)) is one of the most
30 well-known dynamic models of aquatic acidification. An update to MAGIC by [Oulehle et
31 al. \(2012\)](#) gives a more realistic simulation of observed changes in N leaching. The new
32 formulation also provides a reasonable simulation of the long-term changes in C and N
33 pools (and C:N ratio) with SOM. PnET-BGC is an integrated forest-soil-water model that
34 has been used to assess the effects of air pollution and land disturbances on forest and
35 aquatic ecosystems; it uses a new conceptual advancement that incorporates CO₂
36 dynamics into the model. DayCent-Chem links two widely accepted and tested models,
37 one of daily biogeochemistry for forest, grassland, cropland, and savanna systems,
38 DayCent ([Parton et al., 1998](#)), and the other of soil and water geochemical equilibrium,

1 PHREEQC ([Parkhurst and Appelo, 1999](#)). There is a new conceptual advancement for
2 DayCent which now includes O₃ ([Bytnerowicz et al., 2013](#)). The Nutrient Cycling Model
3 (NuCM) was developed to synthesize current understanding of nutrient cycling in forests
4 and to predict how forests respond to changing S and N atmospheric deposition rates. No
5 revisions to these models have been identified.

4.8.5. National-Scale Sensitivity

6 The 2008 ISA documented that by the end of the 1980s, after nearly a decade of intensive
7 research performed under the original NAPAP, the regions of the U.S. with many
8 acid-sensitive waters and ecosystems were well recognized. These acid-sensitive
9 ecosystems are generally located in upland mountainous terrain in the eastern U.S. and
10 are underlain by weathering-resistant bedrock like granite or quartzite sandstone.
11 However, similar work characterizing areas sensitive to the eutrophication effects of
12 nitrogen is not available. Typically, all terrestrial ecosystems are sensitive to N
13 deposition.

14 There is strong evidence to show that biogeochemical sensitivity to N-driven
15 eutrophication and acidification from atmospheric deposition is the result of historical
16 loading, geologic/soil conditions (e.g., mineral weathering and S adsorption), and
17 nonanthropogenic sources of N and S loading to the system. No single deposition level is
18 applicable to all ecosystems in the U.S. that will describe the onset of eutrophication or
19 acidification. Ecosystem sensitivity is heterogeneous.

20 New publications have commented on recovery of terrestrial ecosystems from
21 acidification at the national scale ([NAPAP, 2011](#)), specifically in the Northeast ([Phelan et
22 al., 2016](#); [Fuss et al., 2015](#); [Lawrence et al., 2015a](#)), and the lack of recovery in the
23 southern Appalachian Mountains ([Fakhraei et al., 2016](#); [Zhou et al., 2015b](#); [McDonnell et
24 al., 2013](#); [Elliott et al., 2008](#)). Work on national-scale soil acidification published in 2007
25 remains the most recent national assessment of this effect ([McNulty et al., 2007](#));
26 however, [Figure 4-10](#) is a map of soil CLs that updates ([McNulty et al., 2007](#)) with newly
27 available modeling ([McDonnell et al., 2014b](#); [Phelan et al., 2014](#); [Duarte et al., 2013](#);
28 [Sullivan et al., 2011b](#); [Sullivan et al., 2011a](#)).

29 New critical loads for nitrate leaching in forest ecosystems by [Pardo et al. \(2011b\)](#) ranges
30 from 8 to 25 kg N/ha/yr across ecoregions (Omernick Level 1) in the U.S. ([Figure 4-11](#)).
31 At 4 kg N/ha/yr, increasing NO₃⁻ was reported in the organic horizon in the Colorado
32 Front Range, which suggests incipient N saturation. In the northeastern U.S., N budgets
33 from 83 forested watersheds show that N retention averages 76% of incoming
34 atmospheric-N deposition and decreases from 90% retention for sites receiving

1 7 kg N/ha/yr to 60% retention for sites receiving 11 kg N/ha/yr ([Aber et al., 2003](#)). The
2 highest critical loads were reported for Mediterranean California mixed-conifer forests.
3 Since the publication of [Pardo et al. \(2011b\)](#), new studies have been published on nitrate
4 leaching (see [Appendix 4.3.2](#)). Evidence from Europe by [Dise et al. \(2009\)](#) shows
5 approximately 95% of forests receiving less than 8 kg N/ha/yr have leaching of less than
6 1 kg N/ha/yr. In Sweden, [Khalili et al. \(2010\)](#) showed a clear sudden increase in NO₃⁻
7 leaching in regions where N deposition exceeded 7.5 kg/ha/yr.

4.8.6. Climate Modification of Soil Response to N Addition

8 Soil biogeochemistry response to N deposition can be modified by climatic shifts in
9 temperature and precipitation. For soil acidification, potential future changes in the
10 quantity and temporal distribution of precipitation and temperature (and their
11 interactions) is expected to alter the wet-dry cycles that govern the timing and amount of
12 acidic inputs in precipitation, microbial transformation in the soil, and the flush of acid
13 anions from soils to surface waters. In general, increased temperature and precipitation
14 will likely enhance inputs of buffering agents from weathering and deposition, but also
15 increase inputs of acidifying agents from deposition and enhanced N cycling. The relative
16 sensitivity of these opposing processes to a given change in climate remains unresolved.

17 Snow interacts with soil biogeochemistry in a number of ways, mostly by temperature
18 shifts associated with snowpack and soil moisture flux during snowmelt ([Duran et al.,
19 2016](#); [Sorensen et al., 2016](#); [Groffman et al., 2001](#)). The highest flow and lowest ANC
20 periods of the year tend to coincide with times of high snowmelt. This is when
21 acidification is likely to occur. Snow pack insulates soils from frigid winter air
22 temperatures. With a warming climate soils are expected to become colder and
23 experience more winter soil freeze-thaw cycles as snow cover continues to decline. There
24 have been a number of experiments evaluating snow effects soil N, these include studies
25 on the timing, frequency, and severity (snow depth) ([Li et al., 2016c](#)).

26 [Greaver et al. \(2016\)](#) created a synthesis of meta-analyses to study the effects of either N,
27 temperature, or precipitation on different pools and processes related to ecosystem C
28 responses to these variables and to gain some insight as to the direction and magnitude of
29 the change observed ([Figure 13-2](#)). Nineteen different pools and processes were included
30 in this analysis. [Liu and Greaver \(2009\)](#) conducted a meta-analysis of 313 observations
31 across 109 studies of terrestrial and wetland ecosystems to evaluate the effect of N
32 addition on the flux of three GHGs (CO₂, CH₄ and N₂O). This study indicated that
33 although N addition increased the global terrestrial C sink, the CO₂ reduction could be
34 largely offset (53–76%) by N stimulation of global CH₄ and N₂O emission from multiple

1 ecosystems. The authors noted that N addition alters fluxes of GHGs by regulating plant
2 and microbial activities that are directly associated with GHG production and
3 consumption processes. It is therefore extremely important to consider total ecosystem
4 flux of GHGs because consumption may be offset by production, even within the same
5 ecosystem.

APPENDIX 5. BIOLOGICAL EFFECTS OF TERRESTRIAL ACIDIFICATION

1 This appendix characterizes the biological effects of acidifying deposition of nitrogen (N)
2 and sulfur (S) to terrestrial ecosystems. [Appendix 5.2](#) discusses effects on trees and
3 forests ([Appendix 5.2.1](#)), understory plants and grasslands ([Appendix 5.2.2](#)), lichens
4 ([Appendix 5.2.3](#)), soil biota ([Appendix 5.2.4](#)), and fauna ([Appendix 5.2.5](#)). The
5 characteristics, distribution and extent of sensitive ecosystems is presented in
6 [Appendix 5.3](#). Next, [Appendix 5.4](#) presents the application of terrestrial acidification
7 models. Finally, levels of deposition at which effects are manifested is discussed in
8 [Appendix 5.5](#), including a discussion of critical loads ([Appendix 5.5.3](#)). Climate
9 modification of acidifying deposition effects is discussed in [Appendix 5.6](#). A summary
10 section with causal determinations based on a synthesis of new information and previous
11 evidence of biological effects of terrestrial acidification is presented in [Appendix 5.7](#).

5.1. Introduction

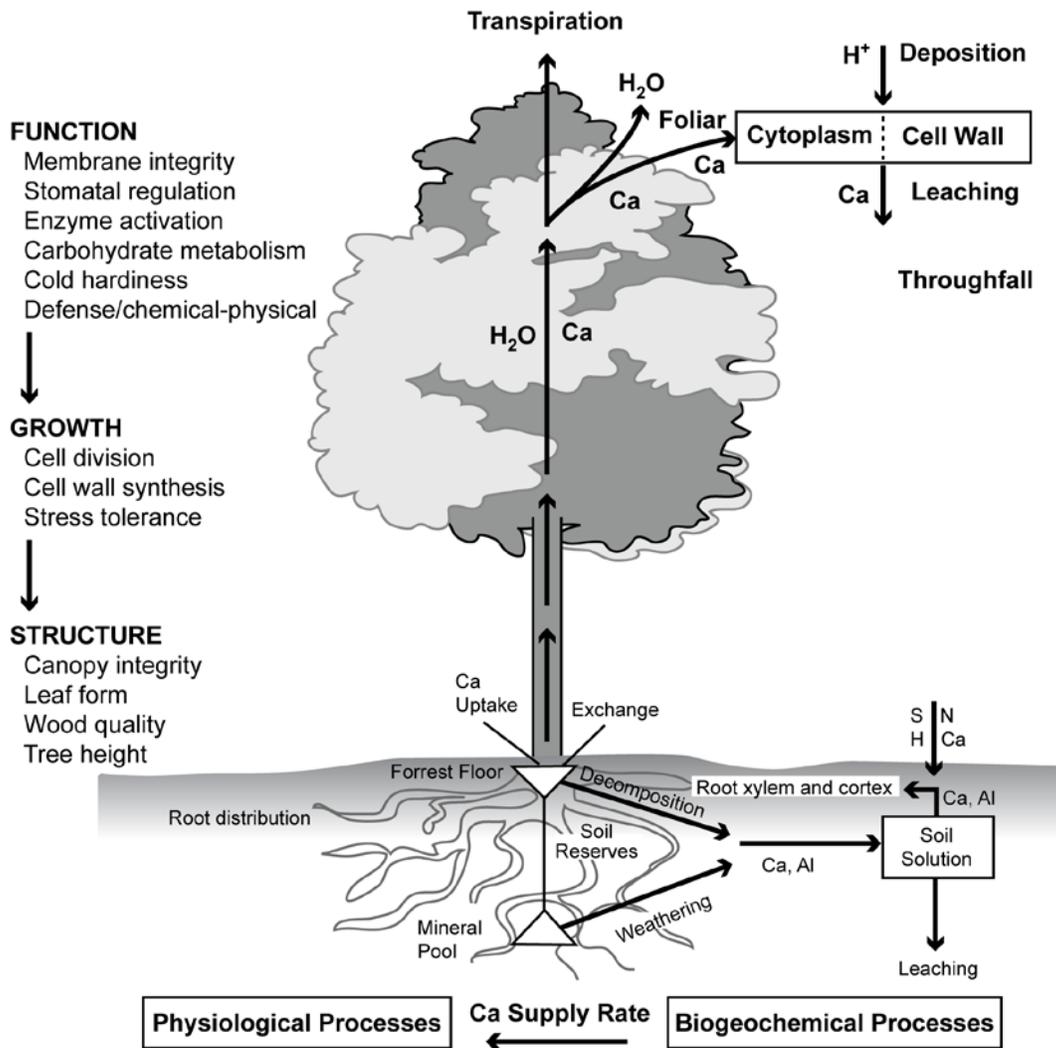

12 Changes in biogeochemical processes caused by acidifying deposition of N and S to
13 terrestrial systems ([Appendix 4](#)) are linked to changes in terrestrial biota and have
14 significant ramifications for biological functioning of these ecosystems. In the *2008 ISA*
15 *for Oxides of Nitrogen and Oxides of Sulfur—Ecological Criteria* (hereafter referred to as
16 the 2008 ISA), the evidence was sufficient to infer a causal relationship between
17 acidifying N and S deposition and changes in terrestrial biota. The strongest evidence for
18 a causal relationship comes from studies of terrestrial systems exposed to elevated levels
19 of acidifying deposition that show decreased plant health, reduced plant vigor, and/or loss
20 of terrestrial biodiversity. In multiple studies, consistent and coherent evidence has
21 shown that acidifying deposition can affect terrestrial ecosystems by causing direct
22 effects on plant foliage and indirect effects associated with changes in soil chemistry
23 (Section 3.2.2.3 of 2008 ISA). Biological indicators with reported responses to acidifying
24 deposition and conditions created by acidifying deposition include forest trees, shrubs,
25 lichens, grasslands, and Arctic and alpine tundra.

26 Acidifying deposition can affect terrestrial ecosystems via direct effects on plant foliage
27 and indirect effects associated with changes in soil chemistry ([Figure 5-1](#)). Biological
28 effects of acidification on terrestrial ecosystems are generally attributable to aluminum
29 (Al) toxicity and decreased ability of plant roots to take up base cations (especially
30 calcium [Ca]) and water from the soil ([Cronan and Grigal, 1995](#)). Acidifying deposition
31 to acid-sensitive soils can cause soil acidification, increased mobilization of Al from soil

1 to drainage water, and depletion of the pool of exchangeable base cations in the soil (see
2 [Appendix 4.3.4](#) and [Appendix 4.3.5](#) for descriptions of these processes). Effects on the
3 soil and direct effects of acidifying deposition on foliage can influence the response of
4 plants to climatic stresses such as drought and cold temperature. The effects of acidifying
5 deposition can also influence the sensitivity of plants to other stresses, including insect
6 pests and disease ([Joslin et al., 1992](#)).

7 Since publication of the 2008 ISA, the overarching understanding of terrestrial
8 acidification has not appreciably changed. More recent research has confirmed and
9 strengthened this understanding and provided more quantitative information, especially
10 across the regional landscape. This appendix highlights findings from the literature after
11 the completion of the 2008 ISA. A number of studies have evaluated the relationships
12 between soil chemistry indicators of acidification and ecosystem biological endpoints
13 ([Table 5-6](#)). Much of the new literature reviewed in [Table 5-6](#) concerns natural variability
14 in soil pH, Ca concentrations and studies that have used elevated N and S have been
15 noted in that table under the “N and S Deposition/Additions” column. Soil chemistry
16 indicators examined in recent literature include exchangeable base cations, soil pH,
17 exchangeable acidity (hydrogen ions [H⁺] and Al), exchangeable Ca:Al ratio, base
18 saturation, and Al concentrations. Biological endpoints evaluated included physiological
19 responses of trees and other vegetation, lichens, soil biota, and fauna. Trees and other
20 vegetation included sugar maple (*Acer saccharum*), red spruce (*Picea rubens*), yellow
21 birch (*Betula alleghaniensis*), American beech (*Fagus grandifolia*), American basswood
22 (*Tilia americana*), black cherry (*Prunus serotina*), eastern hophornbeam (*Ostrya*
23 *virginiana*), white ash (*Fraxinus americana*), hickories (*Carya* spp.), northern red oak
24 (*Quercus rubra*), and forest understory, grassland, and alpine plant species. [Table 5-1](#)
25 provides a summary of the soil chemistry indicator-biological endpoint relationships that
26 have been evaluated in the literature since the 2008 ISA. The 2008 ISA only considered
27 changes in vegetation in the analysis of how acid deposition affected terrestrial
28 ecosystems. More recent research has quantified effects on fauna (e.g., birds, snails) and
29 soil biota ([Appendix 5.2.4](#); [Appendix 5.2.5](#)).

30 Together with the information available in the 2008 ISA, **this body of evidence is**
31 **sufficient to infer a causal relationship between acidifying N and S deposition and**
32 **the alteration of the physiology and growth of terrestrial organisms and the**
33 **productivity of terrestrial ecosystems. Further, the body of evidence is sufficient to**
34 **infer a causal relationship between acidifying N and S deposition and the alteration**
35 **of species richness, community composition, and biodiversity in terrestrial**
36 **ecosystems.**

Al = aluminum; Ca = calcium; H = hydrogen; H₂O = water; S = sulfur.

Source: [Fenn et al. \(2006\)](#).

Figure 5-1 Diagram based on [Fenn et al. \(2006\)](#) showing indicators of forest physiological function, growth, and structure that are linked to biogeochemical cycles through processes that control rates of calcium supply. Calcium affects plant physiological processes that influence growth rates and the capacity of plants to resist environmental stresses, such as extremes of temperature, drought, insects, and diseases. Therefore, acidifying deposition, which can deplete soil calcium or interfere with calcium uptake through mobilization of soil aluminum, can affect forest health.

Table 5-1 Relationships between soil chemistry indicators and biological endpoints that have been evaluated in the literature since the 2008 Integrated Science Assessment.

Taxa	Exchangeable Base Cations	pH	Exchangeable Acidity	Exchangeable Ca:Al Ratio	Base Saturation	Exchangeable Al or Al Concentrations

Al = aluminum; Ca = calcium.

Note: only soil chemistry indicators with a reported significant relationship (positive or negative) with a biological endpoint are indicated in this table. See [Table 5-6](#) for a listing of soil chemical indicators included in each study.

5.2. Effects on Terrestrial Organisms and Ecosystems

5.2.1. Trees and Forests

1 Both coniferous and deciduous forests throughout the eastern U.S. have been
2 experiencing gradual losses of base cation nutrients from the soil due to accelerated
3 leaching from acidifying deposition. This change in base cation nutrient availability can
4 reduce the quality of forest nutrition over the long term in sensitive areas of low base
5 cation soils. Evidence suggests that red spruce and sugar maple in some areas in the
6 eastern U.S. have experienced declining health as a consequence of acidifying deposition.

7 The 2008 ISA reported several indicators of stress to forest trees (Table 3-3 in the 2008
8 ISA), including the percentage of dieback of canopy trees, dead tree basal area (as a
9 percentage), crown vigor index, and fine twig dieback. Biological effects of acidification
10 on terrestrial ecosystems were generally attributed to Al toxicity, decreased ability of
11 plant roots to take up nutrient cations (due to leaching of base cations from soil and
12 interference with uptake), and elevated leaching of Ca^{2+} from conifer needles. The Ca:Al
13 ratio in soil solution is a chemical indicator of the negative impacts of soil acidification
14 on terrestrial vegetation ([Cronan and Grigal, 1995](#)). As tree species have shown similar
15 sensitivities to Ca:Al and the molar ratio of base cation (Bc):Al in soil solution (with Bc
16 representing Ca^{2+} , Mg^{2+} , and K^{+}), the Bc:Al ratio was used to represent the Ca:Al ratio,
17 and it is the most commonly used indicator in the simple mass balance (SMB) model to
18 estimate critical acid loads in the European Union, Canada, and the U.S. ([McNulty et al.,
19 2007](#); [Ouimet et al., 2006](#); [Spranger et al., 2004](#)).

20 [Sverdrup and Warfvinge \(1993\)](#), in a meta-analysis of laboratory, greenhouse, and field
21 studies, reported that the critical soil solution Bc:Al ratios for a large variety of tree
22 species ranged from 0.09 to 20.0, although the Bc:Al ratio range reported for tree species
23 native to North America was more restricted at 0.09 to 2.0. This range is similar to that
24 described by [Cronan and Grigal \(1995\)](#) for Ca:Al. In their meta-analysis of studies
25 examining sensitivities to the soil solution Ca:Al ratio, plant toxicity or nutrient
26 antagonism was reported to occur at Ca:Al ratios ranging from 0.2 to 2.5. The
27 meta-analyses conducted by [Sverdrup and Warfvinge \(1993\)](#) explored the relationships
28 between Bc:Al ratios in soil solution and the growth of different tree species. They
29 reported the Bc:Al ratios at which growth was reduced by 20% relative to controls. A
30 Bc:Al ratio of 1.0 is often applied to protect forested systems of Europe, particularly
31 conifers ([Spranger et al., 2004](#)), and a Bc:Al ratio of 10.0 has been identified for forests
32 in North America, to protect deciduous forests ([McNulty et al., 2007](#); [Ouimet et al.,](#)

1 [2006](#)). The higher ratio (i.e., 10.0 vs. 1.0) provides a greater level of protection for a
2 wider range of species and various biotic and abiotic conditions.

3 However, when using soil solution Bc:Al or Ca:Al ratios as the chemical indicators or
4 criterion in the estimation of terrestrial acidification critical loads, several uncertainties
5 must be considered. Many of these considerations have been addressed in the reviews
6 conducted by [Cronan and Grigal \(1995\)](#) and [Vanguelova et al. \(2007\)](#). Although
7 recognized as one of the best indicators of soil acidity risk in forest ecosystems, soil
8 Ca:Al and Bc:Al ratios are variable and can change with soil conditions temporarily and
9 spatially. Estimates of soil base cations and Al concentrations are also influenced by
10 sampling and laboratory analysis methods, and there is still uncertainty regarding which
11 forms of Al are phytotoxic. Soil solution Al occurs in many different ionic and
12 complexed forms, depending on the soil pH and concentrations of soil ligands. In
13 addition, uncertainties regarding the sensitivity of the biological receptor should also be
14 considered. Critical Bc:Al and Ca:Al ratios are often based on seedling studies in
15 controlled environments, and the relationships are less consistent for trees growing in the
16 forest. Environmental and biological conditions, such as differences in tree age, soil
17 horizon chemistry experienced by the roots, and root mycorrhizae are important to
18 consider when comparing laboratory and field-based research studies. Recognizing these
19 different sources of variability, [Cronan and Grigal \(1995\)](#) recommended applying a $\pm 50\%$
20 uncertainty to their critical soil Ca:Al ratio of 1.0. Critical fine root Ca:Al ratios have also
21 been suggested as indicators of stress in acidic forest soils ([Vanguelova et al., 2007](#);
22 [Cronan and Grigal, 1995](#)). Fine root Ca and Al indicate what is absorbed by the tree, and
23 there are often strong correlations between fine root and soil solution Ca:Al ratios.
24 Similarly, studies have shown relationships between fine root Ca:Al ratio and metrics of
25 root and above-ground tree health and productivity. However, similar to critical soil
26 solution Ca:Al and Bc:Al ratios, fine root Ca:Al ratios also have sources of uncertainty
27 that can be attributed to factors including soil water and chemistry variability, analysis
28 methods and timing, fine root age, and differences in tree physiology. In addition, EPA is
29 unaware of a method that uses fine root Ca:Al ratio as the chemical indicator within SMB
30 calculations of critical loads.

31 The tree species most commonly studied in North America and used in the 2008 ISA to
32 assess the impacts of acidification due to total nitrogen and sulfur deposition include red
33 spruce and sugar maple, although other tree species like flowering dogwood (*Cornus*
34 *florida*) can also be sensitive to conditions created by acidifying deposition. New
35 information regarding the effects of acidifying deposition on the commonly studied sugar
36 maple and red spruce, as well as other tree, understory, and grassland species is
37 summarized below.

5.2.1.1. Sugar Maple

1 Among broadleaf tree species in the northeastern U.S., sugar maple is the species most
2 commonly associated with adverse acidification-related effects resulting from S and N
3 deposition, although other base cation accumulating hardwoods may also be at risk
4 ([Driscoll et al., 2001b](#)). Sugar maple is distributed from Missouri and Minnesota in the
5 northcentral U.S. eastward to Maine and the central Appalachian Mountain region, and
6 the species is a dominant component of the northern hardwood forest type ([Braun, 2001](#)).
7 Within this range, soil acidification is widespread throughout the northeastern U.S. and
8 within many portions of the Appalachian Mountains ([Warby et al., 2009](#)).

9 The 2008 ISA reported that acidifying deposition, in combination with other stressors, is
10 a likely contributor to the decline of sugar maple trees (Section 3.2.2.3 of 2008 ISA).
11 Sugar maple decline has been noted to occur in some portions of the eastern U.S., on base
12 cation-poor soils developed from parent material dominated by sandstone or other base
13 cation-poor substrates. Sugar maple appears to be particularly sensitive to reduced Ca and
14 magnesium (Mg) availability caused by acidifying deposition. Based on the results from
15 a compilation of laboratory studies, sugar maple growth can be reduced by approximately
16 20% at a Bc:Al soil solution ratio of 0.6 ([Sverdrup and Warfvinge, 1993](#)).

17 The more recent literature on sugar maple is consistent with the 2008 ISA. In these
18 studies, sugar maple was sensitive to soil conditions and chemistries associated with
19 acidifying deposition ([Appendix 5.2.1.1.1](#)). Soil chemical indicators that were evaluated
20 included exchangeable base cations, soil pH, exchangeable acidity (H⁺ and Al),
21 exchangeable Ca:Al ratios, base saturation, and Al concentrations (Al form unspecified).
22 Measured sugar maple responses included changes in basal area, growth, regeneration
23 success, and foliar nutrient concentrations and chemistry ([Table 5-6](#)). In addition, several
24 studies evaluated physiological mechanisms that could explain the response of sugar
25 maple to changes in soil chemistry induced by acidifying deposition ([Table 5-2](#)).

Table 5-2 Summary of calcium addition studies in North America.

Reference	Region	Species	Additions (Ca and/or Al)	Description
Battles et al. (2014)	New Hampshire	Sugar maple, American beech, yellow birch, red spruce, and balsam fir	Approximately 1,000 kg Ca/ha (applied in 1999)	Ca additions resulted in the recovery of tree biomass increments, higher aboveground NPP, and increased photosynthetic surface area. Sugar maple exhibited the largest cumulative change in biomass, while American beech showed a negative cumulative change in biomass.
Boyce et al. (2013)	New Hampshire, Vermont	Red spruce and balsam fir	Total of 38 g Ca/m ² and/or 10.8 g Al/m ²	Trends toward greater foliar Ca and Ca:Al ratios and lower Al concentrations across the treatment gradient. Ca availability appeared to enhance the ability of red spruce and balsam fir to repair oxidative stress damage.
Cleavitt et al. (2011b)	New Hampshire	Sugar maple	Approximately 1,000 kg Ca/ha (applied in 1999)	Masting events were not influenced by the Ca treatment. Seeds from the Ca treated sites had lower concentrations of Al, K, and Mg and significantly higher concentrations of Si (but no differences in Ca concentrations). Seeds from the Ca treated sites had higher percentage of seedling emergence and higher seedling survival for the first 3 yr.
Halman et al. (2008)	New Hampshire	Red spruce	Approximately 1,000 kg Ca/ha (applied in 1999)	Foliar Ca and total sugar concentrations were significantly higher in trees in the Ca addition watershed. Cold tolerance of foliage was significantly greater in trees in the Ca addition watershed.
Halman et al. (2013)	New Hampshire	Sugar maple	Total of 38 g Ca/m ² and/or 10.8 g Al/m ²	Ca additions were found to increase C allocation to sugar maple growth. Al additions increased root Al concentrations, root cell membrane disturbance, and ascorbate peroxidase and glutathione reductase activity, and reduced foliar reflush following frost injury and the number of viable seeds.
Halman et al. (2015)	New Hampshire	Sugar maple and American beech	Annual application of CaCl ₂ (2.5 g/m ²) and AlCl ₃ (0.9 g/m ²) from 1995–1999; Wollastonite (38 g/m ²) was applied in 1999 a single dose	The Al and Ca treatments did not affect beech foliar chemistry. Ca additions resulted in significantly higher Ca concentrations in both dominant and nondominant sugar maple trees. By 2008, the growth of American beech was higher than that of sugar maple on the control plots and Al treated plots, and nondominant sugar maple growth was greater than that of American beech and dominant sugar maple on the Ca treated plots. Increases in tree mortality on the Al treated plots may have released surviving American beech and increased their growth.

Table 5-2 (Continued): Summary of calcium addition studies in North America.

Reference	Region	Species	Additions (Ca and/or Al)	Description
Minocha et al. (2010)	New Hampshire	Sugar maple, yellow birch, and American beech	Approximately 1,000 kg Ca/ha (applied in 1999)	Foliar soluble Ca increased significantly in all species at mid and high elevations at Ca supplemented watershed. Sensitivity to Ca limitation increased with elevation.
Moore et al. (2012)	Quebec, Canada	Sugar maple	8 dolomite lime addition rates—0, 0.5, 1, 2, 5, 10, 20, and 50 megatonnes/ha (applied in 1994)	Foliar Ca and Mg concentrations were found to be higher for treated trees relative to the control trees. Mean crown dieback of trees decreased and seedling density increased with the lime rate. The stem basal area increment for maple trees and proportion of the sugar maple seedlings was increased with lime treatment.
Schaberg et al. (2011)	New Hampshire	Red spruce	Approximately 1,000 kg Ca/ha (applied in 1999)	Trees from the Ca addition watershed had higher estimated levels of foliar biomass. Ca addition increased the stress tolerance of red spruce foliage during the cold season, resulting in greater crown mass.
Smith et al. (2009)	New York, Vermont	Red spruce	Total of 160 kg Ca/yr (1992–1995)	Greater amounts of Ca were found in the wood from the high-Ca location than from the low-Ca location. Ca concentration was greater in wood formed in the 1970s than for wood formed in the 1980s, and Ca treatments resulted in increased concentration of Ca in both the 1970s and 1980s decadal bands of wood. Foliar concentrations of Ca oxalate were also higher on the high-Ca site.
Sridevi et al. (2012)	New Hampshire	Soil microbes (bacteria)	Approximately 1,000 kg Ca/ha (applied in 1999)	Bacterial community structure in the Ca treated and nontreated reference soils was found to be significantly different, with differences among communities being more pronounced in the mineral soils.

Al = aluminum; AlCl₃ = aluminum chloride; C = carbon; Ca = calcium; CaCl₂ = calcium chloride; g = gram; ha = hectare; K = potassium; kg = kilograms; m = meter; Mg = magnesium; NPP = net primary production; Si = silicon; yr = year.

5.2.1.1.1. Soil Chemical Indicators for Sugar Maple

Soil Exchangeable Base Cations

1 Sugar maple basal area and growth were responsive to soil exchangeable base cation
2 concentrations in several studies in the northeastern U.S. In the Adirondack Mountains of
3 New York, [Beier et al. \(2012\)](#) reported sugar maple basal area was positively correlated
4 to forest floor and mineral soil (B-horizon) exchangeable soil Ca on sites that ranged in
5 soil Ca from 1.83 to 53.89 cmol_c/kg (in Oa-horizon) and 0.28 to 7.73 cmol_c/kg in the
6 B-horizon (see Figure 3-2 in the 2008 ISA for a description of soil horizons). Similar
7 results were reported in Quebec, Canada by [Bilodeau-Gauthier et al. \(2011\)](#) who found
8 that sugar maple basal area growth was positively correlated to concentrations of base
9 cations (Ca, potassium [K], and Mg) in wood and mineral soil (B-horizon), and [Long et](#)
10 [al. \(2009\)](#) who reported that sugar maple basal area increment (BAI) was positively
11 correlated with exchangeable Ca and Mg in the upper B-horizon in the northeastern U.S.
12 [Page and Mitchell \(2008\)](#) also found that the relative basal area of sugar maple was
13 positively correlated with mineral soil (0–10 cm) exchangeable Ca in the Adirondack
14 Mountains. In the same region, [Sullivan et al. \(2013\)](#) determined that sugar maple canopy
15 vigor was positively correlated with soil exchangeable Ca and Mg, and mean growth
16 rates (measured as BAI) were positively correlated with exchangeable Ca at the
17 watershed level.

18 Relationships between soil exchangeable base cations and sugar maple regeneration (the
19 growth and abundance of seedlings and saplings) have also been demonstrated. [Cleavitt](#)
20 [et al. \(2014\)](#) evaluated sugar maple seedling survival and cause of death across 22 sites in
21 New Hampshire that varied in soil Ca and topographic position. Soil Ca concentration
22 exhibited a nine times change across the study sites and was positively correlated to
23 increases in sugar maple abundance and initial seedling densities. However, soil Ca
24 concentration was not a significant predictor of first-year mortality, nor was it a factor
25 that distinguished among the three main site types. In a study in Quebec, Canada,
26 [Duchesne and Ouimet \(2009\)](#) explored relationships between soil chemistry and sugar
27 maple in the sapling stratum and found that the basal area of sugar maple was positively
28 correlated with soil exchangeable Ca and Mg.

29 [Pitel and Yanai \(2014\)](#) evaluated the abiotic and biotic factors influencing the mortality
30 of dominant and codominant sugar maple trees in 47 stands in Massachusetts, Vermont,
31 and New York that had experienced defoliation by native forest tent caterpillars
32 (*Malacosoma disstria*) between 2002 and 2007. A total of 54 predictive variables
33 (defoliation year, stand and site characteristics, and soil chemistry variables) were

1 evaluated through multiple linear regression followed by stepwise regression to produce
2 the best predictive models of sugar maple mortality from 2006 to 2008. Mortality was
3 highest in stands with the greatest amount of crown dieback the previous year, and
4 drought, cold winter temperatures, concave micro-relief, and soil base cation availability
5 were significant predictors of mortality. Concentrations of exchangeable Ca, Mg, and K
6 in the upper B soil horizon were inversely correlated with sugar maple mortality, with
7 exchangeable K showing the strongest relationship. Sites with above average sugar maple
8 mortality (>3 or 4%) were found to occur on soils with low concentrations of
9 exchangeable Ca (0.31–0.46 cmol_e/kg), Mg (0.06–0.10 cmol_e/kg), and K
10 (0.03–0.05 cmol_e/kg). There was also an interaction between defoliation and soil base
11 cation availability: stands defoliated in 2005 that had low soil (A-horizon) Mg saturation
12 suffered higher rates of mortality.

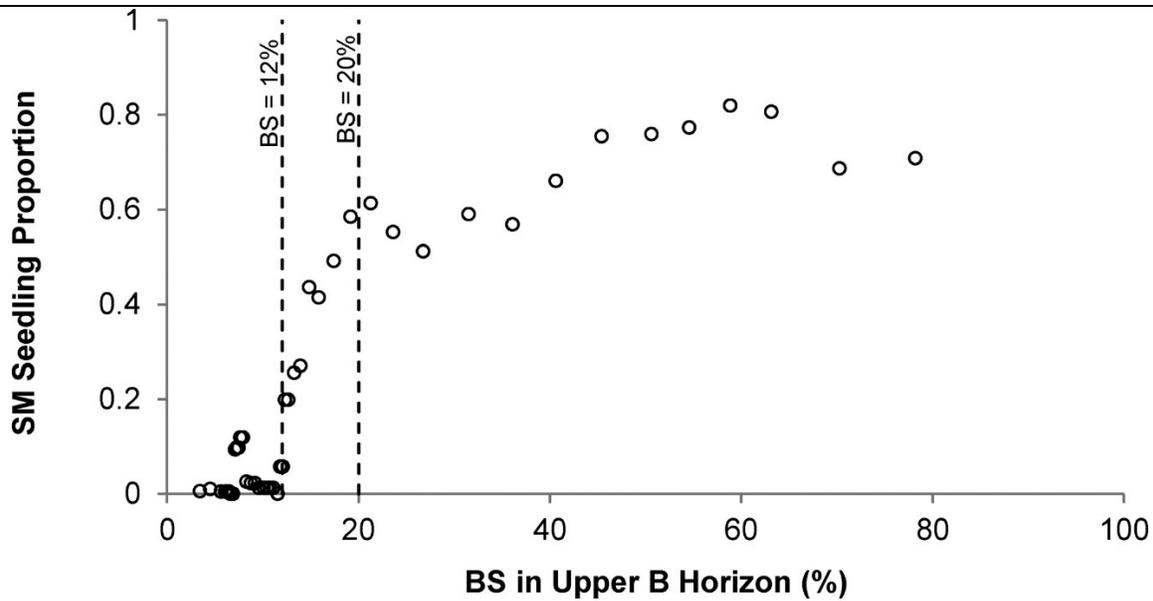

Soil Exchangeable Acidity and pH

13 [Bilodeau-Gauthier et al. \(2011\)](#) found that sugar maple tree growth was negatively
14 correlated to soil exchangeable acidity (H⁺ and exchangeable Al), and through a
15 multifactor analysis, showed that tree age and soil exchangeable Al accounted for 51% of
16 the variation in sugar maple BAI. Positive correlations between mineral soil pH and sugar
17 maple basal area growth have also been reported by [Long et al. \(2009\)](#) and [McEathron et
18 al. \(2013\)](#). [Sullivan et al. \(2013\)](#) found that sugar maple canopy vigor was positively
19 correlated with soil pH.

20 One study reported a relationship between sugar maple foliar chemistry and
21 exchangeable soil chemistry. [Miller and Watmough \(2009\)](#), in their evaluation of
22 hardwood plots along air-pollution (N, S, and ozone), soil-acidity, and climate gradients
23 in Ontario, Canada, showed that foliar Ca and Mg content was positively correlated and
24 foliar manganese (Mn) content was negatively correlated with soil A-horizon pH.

Soil Base Saturation

25 An investigation of every relationship between sugar maple BAI and soil variables
26 revealed that base saturation was the best predictor of BAI (nonlinear) and explained
27 43% of variance ([Bilodeau-Gauthier et al., 2011](#)). Similarly, [Sullivan et al. \(2013\)](#) found
28 that soil base saturation was related to sugar maple regeneration and growth. Plots with
29 lower soil base saturation did not have sugar maple regeneration; the proportion of sugar
30 maple seedlings dropped substantially at base saturation levels less than 20%
31 ([Figure 5-2](#)). Mean growth rates were positively correlated with soil base saturation at the
32 watershed level.

BS = base saturation; SM = sugar maple.

Note: plots were rank ordered based on soil base saturation, and a 5-plot rolling average was applied to both the soil base saturation and the seedling proportion data. Reference lines are added at base saturation values of 12 and 20%, indicating break points in the sugar maple seedling proportion-response function.

Source: [Sullivan et al. \(2013\)](#).

Figure 5-2 Relationship between the proportion of seedlings that were sugar maple and soil base saturation in the upper B-horizon.

Soil Exchangeable Calcium:Aluminum Ratio

1 The relationship between sugar maple BAI and a soil exchangeable Ca:Al threshold of
 2 <0.03 was evaluated by [Long et al. \(2009\)](#) through an analysis of a regional network of
 3 76 forest sites that spanned Pennsylvania, New Hampshire, New York, and Vermont.
 4 However, a repeated-measures analysis did not reveal statistically significant effects of
 5 the Ca:Al soil ratio threshold of <0.03 on BAI.

5.2.1.1.2. Physiological Mechanisms for Sugar Maple

6 A number of studies were also conducted to determine the potential mechanisms
 7 underlying the sensitivity of sugar maple to the soil conditions created by acidifying
 8 deposition. These studies evaluated the influence of Ca additions on sugar maple
 9 physiology, growth, seeds, and seedlings ([Table 5-2](#)). In Hubbard Brook Experimental
 10 Forest (HBEF), NH, one study involved the addition of a total of approximately 1,000 kg
 11 Ca/ha as pelletized wollastonite (CaSiO₃) in October 1999 to a watershed ([Battles et al.](#),

1 [2014](#)). This treatment resulted in increases in: soil pH (in Oie-horizon) from 4.29 to 5.45;
2 base saturation from 9.6 to 78.6% (in Oie layer), 56% (in Oa-horizon), and 14.3% (in
3 upper mineral soil); and soil solution Ca:Al (inorganic monomeric Al) from 1.6 to 6.4 (in
4 Oa-horizon) and from 0.97 to 3.8 (in the mineral soil). As part of this study, [Battles et al.](#)
5 [\(2014\)](#) evaluated the effects of the Ca additions on tree growth and found that sugar
6 maple in the treated watershed exhibited the largest increase in cumulative biomass
7 relative to other species. Another study at the same experiment reported that sugar maple
8 seedlings were 50% larger in the treated watershed and mycorrhizal colonization of
9 seedlings was much higher in the treated watershed (22.47% of root length) as compared
10 with the reference watershed [4.4%; [Juice et al., 2006](#)]. Mycorrhizal colonization also
11 increased in mature sugar maple in the treated watershed (56%) compared to the
12 reference watershed [35%; [Juice et al., 2006](#)]. In contrast to sugar maple, American
13 beech showed a negative cumulative change in biomass. [Minocha et al. \(2010\)](#) examined
14 the effects of the Ca addition treatment on foliar chemistry and found that sugar maple
15 had increased foliar concentrations of Ca, which were accompanied by increases in
16 soluble phosphorous (P), chlorophyll, and two amino acids (i.e., glutamate and glycine).
17 The authors also reported decreases in known metabolic indicators of physiological stress
18 (i.e., arginine and γ -aminobutyric acid, as well as putrescine, a diamine). Sugar maple
19 also exhibited a decrease in foliar putrescine at higher elevations in the watershed,
20 indicating possible remediation from Ca deficiency. [Cleavitt et al. \(2011b\)](#) evaluated
21 sugar maple seed production, seed chemistry, seedling growth (lifestage), and seedling
22 survival on the Ca treated watershed and found that seeds from the Ca treated sites had
23 lower concentrations of Al, K, and Mg and significantly higher concentrations of silicon
24 (Si) than seeds from the reference watershed. The percentage of seedling emergence was
25 also higher, average lifestage was more significantly advanced, and seedling survival was
26 greater on the Ca treated watershed.

27 In a second study (NuPert Study) conducted at HBEF, [Halman et al. \(2013\)](#) evaluated the
28 impacts of Ca (380 kg/ha) and Al (108 kg/ha) additions on sugar maple physiology. The
29 Ca additions increased the proportion of carbon allocated to sugar maple growth. In
30 contrast, Al additions increased root Al concentrations and root cell membrane
31 disturbance, increased ascorbate peroxidase (APX) and glutathione reductase (GR)
32 activity, reduced foliar reflush following frost injury, and reduced the number of viable
33 seeds. Ascorbate peroxidase and GR are antioxidant enzymes that target reactive oxygen
34 species generated by environmental stresses, such as photo-oxidative stress damage at
35 low temperatures. Elevated APX and GR activity are indicators of increased oxidative
36 stress. Several years later, [Halman et al. \(2015\)](#) re-evaluated the NuPert study to
37 determine the long-term and contrasting responses of sugar maple and American beech to
38 the Ca and Al treatments following a major ice storm in 1998. The Al and Ca treatments
39 did not affect beech foliar chemistry. However, Ca additions significantly increased Ca

1 concentrations in both dominant and nondominant sugar maple trees, relative to the trees
2 treated with Al. Interestingly, for all treatments, foliar Al concentrations were higher in
3 the nondominant than dominant sugar maple trees, and the opposite was found for foliar
4 Ca concentrations. By 2008 (11 years after the ice storm), the growth of American beech
5 was higher than that of sugar maple on the control plots and Al treated plots, and
6 nondominant sugar maple growth was greater than that of American beech and dominant
7 sugar maple on the Ca treated plots. These differential growth responses emerged within
8 2 to 11 years following the ice storm, depending on the treatment and species. Although
9 plots were mainly composed of sugar maple, American beech experienced the greatest
10 growth on Al treated plots. Increases in overstory tree mortality on the Al treated plots
11 may have increased light availability, released surviving American beech, and increased
12 beech growth.

13 [Moore et al. \(2012\)](#) evaluated soil chemistry and sugar maple status 15 years after
14 treatment with dolomite lime (0 to 50 megatonnes/ha) to a hardwood forest in Quebec,
15 Canada, and found results similar to those in HBEF. Foliar Ca and Mg concentrations
16 were higher for treated trees relative to the control trees, and mean crown dieback of trees
17 decreased quadratically with the lime addition rate, from 39% for the control trees to a
18 value of 1 to 3% for the lime rates of 5 megatonnes/ha and higher. In addition, sugar
19 maple BAI for the limed trees was nearly double that of the nonlimed trees. The lime
20 application was also beneficial to the sugar maple regeneration. The overall sugar maple
21 seedling density increased with the lime rate, doubling in the 50 megatonnes/ha
22 (32 seedlings/m²) compared with the controls (16 seedlings/m²). The proportion of the
23 sugar maple seedlings to all of the other species increased quadratically from 22% in
24 controls to more than 55% in the 5 to 50 megatonnes/ha treatments. In contrast, the
25 proportion of competitive species decreased quadratically with the lime rate, including
26 American beech, for which the proportion in the treated plots (24%) was nearly half the
27 proportion observed in the controls (46%).

5.2.1.2. Red Spruce

28 Red spruce is a conifer that occurs mainly in the northeastern U.S. and at scattered
29 high-elevation sites (e.g., mountain and ridge tops) in the Appalachian Mountains. Red
30 spruce dieback or decline has been observed across high elevation landscapes of the
31 northeastern, and to a lesser extent, southeastern U.S. At high elevations in the
32 Adirondack Mountains in New York and the Green Mountains in Vermont, more than
33 50% of the canopy red spruce trees died during the 1970s and 1980s. In the White
34 Mountains in New Hampshire, about 25% of the canopy spruce died during that same
35 period ([DeHayes et al., 1999](#)). Dieback of red spruce has also been observed in mixed

1 hardwood-conifer stands at relatively low elevations in the western Adirondack
2 Mountains, an area that receives high inputs of acidifying deposition ([Shortle et al.,
3 1997](#)); acidifying deposition has been implicated as a causal factor ([DeHayes et al.,
4 1999](#)).

5 The 2008 ISA reported that changes in soil chemistry (e.g., depletion of soil base cations,
6 Al toxicity to tree roots, leaching of base cations into drainage water; see [Appendix 4.3.4](#)
7 and [Appendix 4.3.5](#)) have contributed to high mortality rates and decreased growth of red
8 spruce trees in some areas of the eastern U.S. over the past three decades. Studies
9 evaluating the physiologic basis behind the responses of red spruce to acidifying
10 deposition have attributed the reduced vigor of the species to increased sensitivity to frost
11 injury and cold temperatures. The frequency of freezing injury to red spruce needles had
12 increased during a period in the latter half of the 20th century that coincided with
13 increased emissions of S and N oxides and increased acidifying deposition ([DeHayes et
14 al., 1999](#)).

15 Since the 2008 ISA, research evaluating the sensitivity of red spruce to soil indicators of
16 acidifying deposition have mainly focused on the potential mechanisms underlying the
17 sensitivity of the species to acidic soil conditions. These studies have examined the
18 physiological response of red spruce to Ca additions ([Table 5-2](#)).

19 In the HBEF study that involved the addition of approximately 1,000 kg Ca/ha, [Halman
20 et al. \(2008\)](#) and [Schaberg et al. \(2011\)](#) evaluated the response of red spruce foliar
21 chemistry. [Halman et al. \(2008\)](#) reported significantly higher foliar Ca and total sugar
22 (fructose and glucose) in the Ca addition watershed than in trees in the reference
23 watershed. Foliar APX activity was also higher in trees in the Ca addition watershed
24 during winter. Cold tolerance of foliage was significantly greater in trees in the Ca
25 addition watershed than in trees in the reference watershed. [Schaberg et al. \(2011\)](#)
26 measured concentrations of foliar polyamines and free amino acids, foliar chlorophyll,
27 and sapwood area (as a proxy for foliar biomass) in Ca treated and nontreated trees.
28 Foliar polyamines (putrescine and spermidine) and free amino acids (alanine,
29 aminobutyric acid [GABA]) are putative stress protection compounds that may directly
30 protect or provide other benefits to foliage that increase stress tolerance. The Ca additions
31 increased November concentrations of alanine, GABA, putrescine, and spermidine
32 relative to foliage from the reference watershed. Consistent with increased stress
33 protection indicated by the elevated polyamine and free amino acids, foliage from the Ca
34 addition watershed had higher total chlorophyll concentrations than foliage from the
35 reference watershed. In contrast, foliage from the reference watershed had significantly
36 higher alanine:glutamic acid ratios, which have been attributed to cold sensitivity or
37 damage in other species. In addition to concentration-based differences in foliar

1 compounds, trees from the Ca addition watershed had higher estimated levels of foliar
2 biomass than trees from the reference watershed. These findings suggested that Ca
3 addition increased the stress tolerance and productive capacity of red spruce foliage
4 during the cold season and resulted in greater crown mass compared to trees growing on
5 nontreated soils.

6 Similar findings were reported by [Boyce et al. \(2013\)](#), who examined the influence of Ca
7 and Al on the physiology of red spruce and balsam fir (*Abies balsamea*) in three different
8 locations that varied in soil nutritional status. Processes known to be Ca sensitive (root
9 and foliar cation concentrations, chlorophyll fluorescence, soluble sugar concentrations,
10 and the activities of APX and GR in current-year foliage) were measured, and the results
11 from the study suggest that Ca availability enhanced the ability of red spruce and balsam
12 fir to repair oxidative stress damage, including photo-oxidation.

13 Concentrations of Ca in sapwood and accumulations of Ca oxalate in foliage have been
14 used as markers of environmental change due to acidic deposition or forest management
15 practices. [Smith et al. \(2009\)](#) compared the effects of different Ca fertilization treatments
16 (approximately 178 kg Ca/ha/yr during 1992–1995) on Ca concentrations in wood and
17 Ca and oxalate (Ox) concentrations in red spruce foliage at two locations with different
18 initial concentrations of Ca in the soil (6.4 cmol/kg vs. 13.7 cmol/kg). Greater amounts
19 of Ca were found in the wood from the high-Ca location than from the low-Ca location.
20 Foliar concentrations of Ca oxalate were higher on the high-Ca site than on the low-Ca
21 site and increased in response to Ca additions.

5.2.1.3. Other Tree Species

22 In the 2008 ISA, there was some information regarding the effects of acidification on
23 dogwood (*Cornus*) species. Loss of base cations, specifically Ca²⁺, had been implicated
24 in increased susceptibility of flowering dogwood to dogwood anthracnose, its most
25 destructive disease. Susceptibility to the disease and disease severity in stands appeared
26 dependent on several factors, including acid deposition and various edaphic
27 characteristics and meteorological conditions. Studies pointed to greater vulnerability of
28 dogwoods to anthracnose under simulated acid rain treatments ([Britton et al., 1996](#)) and
29 under Ca²⁺ deficiency [([Holzmueller et al., 2007](#)); Section 3.2.2.3 of 2008 ISA].

30 Since the 2008 ISA, no further research on dogwood has been published. However, other
31 tree species have been evaluated in studies relating soil chemistry to tree physiology,
32 including red maple, white oak, yellow birch, white ash, American beech, black cherry,
33 northern red oak, hickories, American basswood, and eastern hophornbeam. These

1 species were reported to vary in their sensitivities to soil conditions associated with
2 acidifying deposition ([Table 5-6](#)).

3 In a recent study in West Virginia, [Thomas et al. \(2013\)](#) used dendroisotopic techniques
4 to show the recovery of eastern redcedar (*Juniperus virginiana*) trees from decades of S
5 pollution using an analysis of a tree ring chronology from 1909 to 2008. Growth,
6 measured as BAI, in eastern redcedar old-growth stands (118–480 years old) increased
7 significantly since 1970. A multivariate correlation analysis using historical climate
8 variables, atmospheric CO₂ concentrations, and U.S. SO₂ and NO_x emissions estimates
9 showed that the growth of cedar trees over the 100-year chronology is explained best by
10 increases in atmospheric CO₂ and NO_x emissions, and decreases in SO₂ emissions.
11 Through carbon isotope (¹³C) analyses, the researchers were able to show that the stomata
12 of cedar may be more sensitive to SO₂ emissions than to increasing atmospheric CO₂. A
13 breakpoint in the 100-year δ¹³C tree ring chronology occurred around 1980, as SO₂
14 emissions declined, indicating a gradual increase in stomatal conductance and a
15 concurrent increase in photosynthesis related to decreasing SO₂ emissions and increasing
16 atmospheric CO₂. After 1990, calculated stomatal conductance increased more than
17 photosynthesis. These patterns in physiology led to changing trends in intrinsic water use
18 efficiency (*i*WUE; the ratio of photosynthesis to water loss through stomatal
19 conductance). The calculated *i*WUE generally increased from the 1940s to 1990 mainly
20 because of SO₂ emission effects on stomatal conductance, and then *i*WUE began to
21 decrease after 1990 because SO₂ emissions no longer constrained stomatal function.
22 Through S isotope analysis (tree ring δ³⁴S), the study showed a synchronous change in
23 the sources of S used at the whole-tree level that indicated a reduced anthropogenic
24 influence. The increase in growth and the δ¹³C and δ³⁴S trends in the tree ring chronology
25 of these *Juniperus* trees provide evidence for a distinct physiological response to changes
26 in atmospheric SO₂ emissions since 1980. The authors attributed the changes since 1980
27 to an indirect effect of decreases in acid deposition. However, the exact mechanism is
28 unclear because the 100-year chronology could only be correlated to estimated SO₂
29 emissions because acidifying deposition measurements were not available. Other
30 researchers have pointed out that the trees in the ([Thomas et al., 2013](#)) study were
31 growing on a limestone outcrop that could be well buffered from soil acidification
32 ([Schaberg et al., 2014](#)). Further, the rapid recovery of tree growth could also point to a
33 direct effect of gaseous SO₂ rather than an indirect effect of soil acidification, which
34 would have a longer response time to decreases in emissions. See [Appendix 3.2](#) for
35 further discussion of direct gaseous SO₂ effects on vegetation.

5.2.1.3.1. Soil Chemical Indicators for Other Tree Species

Soil Exchangeable Base Cations

1 Several studies reported on the relationships between species-specific basal area and
2 growth and soil exchangeable base cations. In the Adirondack Mountains, [McEathron et](#)
3 [al. \(2013\)](#) evaluated the relationships between basal area and soil chemistry and reported
4 that yellow birch basal area was positively correlated with mineral soil exchangeable Ca.
5 Similarly, [Page and Mitchell \(2008\)](#) compared the basal areas of American basswood,
6 American beech, and white ash with mineral soil (0–10 cm in depth) exchangeable Ca
7 concentrations and found exchangeable Ca had a positive correlation with relative basal
8 area of American basswood, a negative correlation with the relative basal area of
9 American beech, and no correlation with relative basal area of white ash. The positive
10 relationship between American basswood and soil exchangeable Ca is consistent with
11 other studies. [Beier et al. \(2012\)](#), in their evaluation of vegetation communities across
12 northern hardwood sites that ranged in exchangeable Ca concentrations from 1.83 to
13 53.89 cmol/ha (in Oa-horizon) and 0.28 to 7.73 cmol/ha (in B-horizon), reported that
14 American basswood and eastern hophornbeam were only found on the sites with the
15 highest exchangeable Ca concentrations. Similarly, negative relationships between
16 American beech and soil exchangeable Ca have been reported elsewhere. [Duchesne and](#)
17 [Ouimet \(2009\)](#) found that basal area of American beech in the sapling stratum in sugar
18 maple-dominated forests was negatively correlated with exchangeable Ca and Mg. Soil
19 concentrations of Ca and Mg on sites colonized by American beech were, on average,
20 roughly half those on sites where American beech was absent, thereby suggesting that
21 beech effectively colonizes sites with low base status. These findings are also consistent
22 with the responses of American beech to the Ca addition studies described earlier ([Battles](#)
23 [et al., 2014](#); [Moore et al., 2012](#)).

Soil Base Saturation

24 One study of 30 forest plots within Monongahela National Forest, WV reported on the
25 relationship between soil base saturation and tree abundance. [Elias et al. \(2009\)](#) evaluated
26 relationships between tree growth parameters and soil indicators of acidifying deposition
27 and found that hickories were the only species (out of four within-species comparisons)
28 to have significantly lower numbers on sites with base saturation below 20% (A-horizon)
29 and 2.5% (B-horizon). They also found that the percentage of dead northern red oak was
30 highest on sites with Al concentrations (A-horizon) above 43 cmol/kg. The authors
31 reported that sites in the Year 2000 with subsurface base saturation above 10% had more
32 unique species.

Soil Exchangeable Calcium:Aluminum Ratio

1 A study of 76 hardwood stands across the northeastern U.S. noted the relationship
2 between exchangeable Ca:Al ratios and BAI. [Long et al. \(2009\)](#) found that, unlike sugar
3 maple, black cherry BAI was greater in stands with exchangeable Ca:Al ratios
4 (B-horizon) below the <0.03 threshold adopted by the study.

5.2.2. Forest Understory and Grassland Species

5 The 2008 ISA did not specifically assess the effect of acidification on forest understory
6 species due to the lack of studies. Also, the 2008 ISA reported that grasslands were
7 thought to be less sensitive to acidification than woodlands ([Köchy and Wilson, 2001](#);
8 [Blake et al., 1999](#)), and grasslands with calcareous soils will be less sensitive than those
9 with acidic soils ([Bobbink et al., 1998](#)).

10 Since the 2008 ISA, several studies have evaluated the relationships between soil
11 chemistry indicators of acidification and forest understory and grassland species
12 ([Table 5-6](#)).

5.2.2.1. Soil Chemical Indicators for Forest Understory and Grassland Species

Soil pH, Exchangeable Base Cations, and Exchangeable Acidity

13 One study examined the relationship between soil chemistry indicators of acidification
14 and forest understory species. [Horsley et al. \(2008\)](#) evaluated 35 soil chemistry, stand,
15 and climatic variables as predictors of understory plant species composition in northern
16 hardwood stands, and found that a base cation-acid cation nutrient gradient accounted for
17 71.9% (in New Hampshire and Vermont) and 63% (in Pennsylvania and New York) of
18 the variation in the nonmetric multidimensional scaling ordination analyses of plant
19 community composition. Soil Ca, Mg, and pH formed the base end and Al, Mn, K, soil
20 acidity, and organic matter represented the acid end of the gradient. Based on results from
21 McNemars' exact test, a total of 50 of the 234 understory species were associated with
22 the base end of the base cation-acid cation nutrient gradient. These species have value as
23 indicators of sites at the high end of the base cation nutrient gradient in northern
24 hardwoods, sites that would be suitable for acid-sensitive species such as sugar maple.

25 In the U.K., [Stevens et al. \(2010b\)](#) used data from a national survey to evaluate the
26 species richness of 68 grasslands along an N deposition gradient. Ellenberg R
27 (reaction-soil pH) and N (soil nutrient) scores and an index of soil acidity preference

1 were used as the metrics to characterize the plant diversity responses to the soil chemistry
2 conditions created by N deposition. Although the study did not find any significant
3 relationships between the Ellenberg and soil acidity index values and N deposition, there
4 was evidence that soil acidification was contributing to changes in species diversity and
5 community composition. Soil acidification may have led to decreased nutrient
6 availability and increased Al solubility, thus, masking the effects of increased soil N
7 availability (see also [Appendix 6.3.5](#) for N discussion).

8 A similar analysis along an N deposition gradient (2.4 to 43.5 kg N/ha/yr) was conducted
9 by [Pannek et al. \(2015\)](#) using a vegetation data set from 153 seminatural acidic
10 grasslands in northwestern Europe. Species frequency in response to N and other factors
11 including soil (0–10 cm) P, pH, NH_4^+ , and NO_3^- and geographical, climatic, and
12 management factors were evaluated. A second set of data from acidic grasslands in
13 Germany (392 plots) and the Netherlands (144 plots) containing plots from different time
14 periods were also included in the analyses to determine whether the results of the spatial
15 gradient approach coincided with temporal changes in the abundance of species. Out of
16 44 species included in the study, 16 were found to be affected by N deposition, with 12 of
17 them exhibiting a decreased abundance response. Increasing soil pH and P influenced 24
18 and 14 species, respectively, predominantly increasing abundance. Change of species
19 over time was unrelated to their responses to pH. However, species were found to
20 significantly decline over time in both Germany and the Netherlands in response to N
21 deposition, soil P, and NO_3^- . These results show the influence of N deposition in a
22 decline for many plant species in seminatural acidic grasslands, although impacts of N
23 deposition on pH did not appear to be the mechanism of plant responses (see also
24 [Appendix 6.2.5](#) for N discussion).

5.2.3. Lichens

25 In the 2008 ISA it appeared that lichen populations were affected in areas with acidifying
26 deposition ([Davies et al., 2007](#)). However, it was not clear whether effects were due to
27 direct effects of SO_2 , N effects, or acidifying deposition. See [Appendix 6.3.7](#) for a
28 discussion of N deposition on lichens.

29 We have not identified any new studies published since the 2008 ISA that evaluated the
30 relationships between conditions created by acidifying deposition and lichen physiology.
31 However, in Acadia National Park, [Cleavitt et al. \(2011a\)](#) evaluated the interactions
32 among N and S deposition, tree type, and epiphytic lichen and bryophyte diversity,
33 biomass, and abundance to (1) document any differences in the depositional
34 environments (throughfall and cloud water) of red spruce and red maple (*Acer rubrum*)

1 trees, (2) relate deposition differences to both chemistry of the bark and corresponding
2 epiphyte biomass and composition on the bark, and (3) describe any species-specific
3 relationships that emerged between the epiphytes and bark chemistry ([Table 5-6](#)).
4 Throughfall N and S deposition were higher under spruce trees than under maple trees,
5 and average S concentrations in cloud water were negatively correlated with bark Ca and
6 bark Mg. Epiphytic lichen richness was higher on maple trees than spruce trees, and tree
7 species differed in the number of rare epiphytic species. Several pollution-sensitive
8 epiphytes were restricted to the maples: the cyanolichens *Leptogium cyanescens*
9 (bipartite) and *Lobaria pulmonaria* (tripartite), the large ruffle lichen *Parmotrema*
10 *crinitum*, and the moss *Zygodon viridissimus* var. *rupestris*. Cyanolichens only occurred
11 on maple bark and did not occur on any bark with a pH below 5.02. Apparent overlap
12 between the bark chemistry of spruce and maple, particularly for samples from higher on
13 maple boles, suggest a reduction in the area of chemically suitable substratum for
14 epiphytes.

5.2.4. Soil Biota

15 Soil biota were not specifically addressed in the 2008 ISA. Since the 2008 ISA, several
16 studies have evaluated the relationships between soil chemistry indicators of acidification
17 and soil biota ([Table 5-6](#)). The effects of elevated N on soil biota is addressed throughout
18 [Appendix 6](#) (see [Appendix 6.2.3](#), [Appendix 6.2.4](#), [Appendix 6.2.5](#), and [Appendix 6.3.5](#)).

5.2.4.1. Soil Chemical Indicators for Soil Biota

Soil pH and Exchangeable Calcium:Aluminum Ratio

19 [Bardhan et al. \(2012\)](#) evaluated the relationships between soil chemistry and bacterial
20 diversity in 30 plots along a soil chemistry and deposition gradient in high-elevation
21 spruce-fir forests in the Great Smoky Mountain National Park (GSMNP). Modeled S
22 deposition ranged from 6 to 41 kg S/ha/yr, measured soil pH ranged from 3.0 to 4.6, and
23 measured CEC ranged from 1.3 to 23.1 cmol/kg (soil samples pooled from the O-, A-,
24 and B-horizons). However, bacterial diversity and community composition did not
25 change along the gradients of S deposition, soil pH, or exchangeable Ca:Al ratio.

Soil pH and Aluminum Concentrations

26 [Chen et al. \(2013\)](#) evaluated the impacts of S additions on soil microbial and nematode
27 communities in a grassland system of Inner Mongolia. Seven treatments of 28 to 166 mol

1 H⁺/ha were applied in three doses in the form of sulfuric acid (H₂SO₄) from 2009 to 2010.
2 The authors found that the proportions of soil bacteria, fungi, and nematodes were altered
3 by the treatments, and the responses were related to soil pH and Al concentrations.
4 Increases in fungal fatty acids (49% increase) and fungi:bacteria ratio (120% increase)
5 and decreases in total and bacterial fatty acids (40–47% decrease) relative to the controls
6 were attributed to soil pH and Al concentrations. High Al concentrations (51 to
7 83 mg/kg) were associated with decreases in total fatty acids and bacterial fatty acids and
8 increases in fungal fatty acids. These results are consistent with a study of an agricultural
9 soil gradient that showed that at soil pH below 4.5, microbes (bacteria and fungi) are
10 decreased due to increased Al solubility ([Rousk et al., 2009](#)), and that fungi are often
11 more dominant in acidic soils. [Chen et al. \(2013\)](#) also reported that acid additions also
12 impacted the soil nematode community by initially increasing the total number of soil
13 nematodes and then altering nematode community composition: bacterivorous and
14 fungivorous nematodes increased, but plant-feeding and omnivorous and carnivorous
15 nematodes decreased. The shifts in the nematode community were attributed to decreased
16 soil pH and changes in soil moisture.

Soil pH and Exchangeable Calcium

17 One study also investigated the influence of Ca addition (~1,000 kg Ca/ha/yr in 1999) on
18 the soil bacterial community in a northeastern hardwood forest ([Sridevi et al., 2012](#)). The
19 study detected 1,756 taxa spanning 42 phyla, 53 classes, 127 orders, and 154 families in
20 the Ca treated and reference watersheds. Bacterial community structure was significantly
21 different between the Ca treated and nontreated reference soils, with differences among
22 communities being more pronounced in the mineral soils. Calcium additions resulted in
23 significant changes in bacterial community composition in the organic and in the mineral
24 soil horizons. The numbers of detectable taxa in families such as Acidobacteriaceae,
25 Comamonadaceae, and Pseudomonadaceae were lower in the Ca amended soils, while
26 Flavobacteriaceae and Geobacteraceae were higher. Analyses of relationships between
27 soil chemistry and the bacterial communities indicated that only exchangeable Ca, pH,
28 and P were significantly correlated with bacterial community structure.

Soil pH

29 [Gilliam et al. \(2011b\)](#) evaluated the microbial community across a soil weathering
30 gradient in a northern hardwood forest in West Virginia. Microbial community
31 composition, characterized through phospholipid fatty acid (PLFA) analysis, varied
32 among sites. Fungi were dominant at the most weathered, low NO₃⁻-production site,
33 while Gram-negative bacteria were significantly higher at the less weathered, moderate

1 and high NO₃⁻-production sites. Accordingly, the fungi:bacteria ratio increased in the
2 direction of the low NO₃⁻-production plots in ordination space. Correlations between the
3 soil parameters and PLFA results suggest that low soil pH and NO₃⁻ concentrations
4 supported fungal dominance, although other important factors including differences in
5 plant community and clay and organic matter content may have also influenced the soil
6 microbial community.

Soil Exchangeable Calcium

7 A study in Japan evaluated the relationship between forest type and soil invertebrate
8 communities in evergreen broad-leaved forests versus Japanese cedar (*Cryptomeria*
9 *japonica*) plantation forests ([Ohta et al., 2014](#)). Exchangeable Ca was found to be
10 significantly higher in soil from the Japanese cedar plantations than the evergreen forest.
11 The invertebrate community composition also differed significantly between the two
12 forest types and was best explained by exchangeable Ca concentrations. Two major taxa
13 of soil crustaceans, Talitridae and *Ligidium japonicum*, were only found in the Japanese
14 cedar plantations. In contrast, millipedes (Paradoxosomatidae) and beetles were relatively
15 abundant in the evergreen plots.

5.2.5. Fauna

16 Fauna were not specifically assessed in the 2008 ISA. Since the 2008 ISA, two studies
17 were found that evaluated the relationships between soil chemistry indicators of
18 acidifying deposition and fauna ([Table 5-6](#)).

5.2.5.1. Soil Chemical Indicators for Fauna

Soil Exchangeable Calcium

19 [Beier et al. \(2012\)](#) characterized the variation in gastropod, salamander, and vegetation
20 communities among northern hardwood forests attributable to soil exchangeable Ca. The
21 sites represented the variability in soil Ca in the Adirondack Mountains, ranging from
22 1.83 to 53.89 cmol_c/kg (Oa-horizon) and 0.28 to 7.73 cmol_c/kg (B-horizon). Snail
23 community richness and the abundance and live biomass of red-backed salamanders
24 (*Plethodon cinereus*) were all positively correlated with soil Ca. Land snail species
25 richness and abundance were positively correlated with Oa-horizon Ca and negatively
26 correlated to SO₄²⁻ deposition and site elevation (and NO₃⁻ deposition for snail
27 abundance). Salamander communities were dominated by mountain dusky salamanders

1 (*Desmognathus ochrophaeus*) at Ca poor sites, with composition continuously shifting
2 toward dominance by red-backed salamanders as Ca availability increased. Several
3 known calciphilic species of snails (*Paravitrea multidentata*, *Gastrocopta pentodon*, and
4 *Euconulus polygyrus*) were found only at the highest Ca sites. Some of the observations
5 (e.g., decreasing snail abundance) were confounded by a strong positive correlation
6 between elevation and estimated acid deposition. However, although the underlying
7 mechanisms require further study, these findings indicate that Ca availability, which is
8 shaped by geology and acidic deposition inputs, influences northern hardwood forest
9 ecosystems at multiple trophic levels.

Soil Exchangeable Calcium and pH

10 [Pabian and Brittingham \(2012\)](#) determined the relationships between soil (Oa-horizon)
11 chemistry and forest bird community composition, abundance, and diversity, and
12 evaluated potential mechanisms responsible for the relationships in oak and red
13 maple-dominated forests in Pennsylvania. Mean soil (Oa-horizon) exchangeable Ca for
14 the 14 forest sites ranged from 5.28 to 23.5 meq/100 g and pH ranged from 3.6 to 5.1.
15 Bird community composition (species richness and species abundances) varied with soil
16 Ca and pH, with 10 bird species having the highest abundances in forests with high-Ca
17 soils, and 5 species having the highest abundances with low-Ca soils. Five species were
18 classified as “generalists” because they had high abundances and were present at all
19 forest sites. Bird species associated with low-Ca soils were associated with high densities
20 of mountain laurel (*Kalmia latifolia*) and five tree species whose basal areas were
21 explained by low soil pH and Ca. Bird species associated with high-Ca soils were
22 associated with high densities of saplings and high basal areas of acid-sensitive tree
23 species (17 species whose basal areas were, in part, explained by high Ca and soil pH).
24 All environmental and soil variables explained 37.8% of the variation in bird species
25 abundance data, with environmental variables explaining 36.0%, soils explaining 0.5%,
26 and 1.3% being explained by both. Most (67%) of the variation in the bird abundance
27 data explained by soils was also explained by the vegetation and invertebrate variables,
28 thereby supporting the hypothesis that the environmental variables were responsible for
29 the soil-bird relationships.

5.3. Characteristics, Distribution, and Extent of Sensitive Ecosystems

30 In the 2008 ISA, it was known that geology (particularly surficial geology) is the
31 principal factor governing the sensitivity of terrestrial and aquatic ecosystems to

1 acidification from S and N deposition. Geologic formations with low base cation supply
2 (e.g., sandstone, quartzite), due mainly to low weathering, generally underlie the
3 watersheds of acid-sensitive lakes and streams. Bedrock geology has been considered in
4 numerous acidification studies ([Sullivan et al., 2007b](#); [Vertucci and Eilers, 1993](#); [Stauffer
5 and Wittchen, 1991](#); [Stauffer, 1990](#); [Bricker and Rice, 1989](#)). Other factors contribute to
6 the sensitivity of soils and surface waters to acidifying deposition, including topography,
7 soil chemistry, land use, and hydrologic flowpath.

8 Forests of the Adirondack Mountains of New York, Green Mountains of Vermont, White
9 Mountains of New Hampshire, the Allegheny Plateau of Pennsylvania, and mountain top
10 and ridge forest ecosystems in the southern Appalachians are the region's most sensitive
11 to terrestrial acidification from atmospheric deposition (Section 3.2.4.2 of 2008 ISA).
12 Recent decreases in acid deposition had been linked to improvements in surface water
13 chemistry ([Appendix 7](#)). However, there remains widespread measurements of ongoing
14 depletion of exchangeable base cations in forest soils in the northeastern U.S.
15 ([Appendix 4.3.4](#)).

16 At the time of the 2008 ISA, there had been no systematic national survey to determine
17 the extent and distribution of terrestrial ecosystem sensitivity to the effects of acidifying
18 deposition. However, one preliminary national evaluation by [McNulty et al. \(2007\)](#) used
19 a simple mass balance model and available national databases to estimate forest soil
20 critical acidifying deposition loads (for wet and dry deposition of S and N) and
21 exceedances. They found that approximately 15% of forest soils in the U.S. receive
22 acidifying deposition that exceeds the estimated critical load of wet and dry deposition of
23 S and N by more than 250 eq/ha/yr ([McNulty et al., 2007](#)). The areas where exceedances
24 reach this level could be considered to represent those areas that are likely most sensitive
25 to continued high levels of acidifying deposition.

26 Since the 2008 ISA, a series of studies have evaluated the characteristics, distribution,
27 and/or sensitivity of ecosystems to acidifying N and S deposition. For descriptions of
28 studies that characterized ecosystem sensitivity through critical load and critical load
29 exceedance determinations, see [Appendix 5.5](#).

5.4. Application of Terrestrial Acidification Models

30 The models that were used in recent studies to evaluate terrestrial acidification and its
31 components included the simple mass balance [SMB; ([Phelan et al., 2014](#); [Duarte et al.,
32 2013](#); [Jung et al., 2013](#); [Whitfield and Watmough, 2012](#); [Forsius et al., 2010](#); [McNulty
33 and Boggs, 2010](#); [Nasr et al., 2010](#))], soil texture approximation [STA; ([Whitfield et al.,
34 2010b](#))], MAGIC ([Sullivan et al., 2011a](#); [Whitfield et al., 2010a](#); [Whitfield et al., 2009](#)),

1 ForSAFE-VEG ([McDonnell et al., 2014a](#); [Sverdrup et al., 2012](#)), and empirical models
2 outlined by [Spranger et al. \(2004\)](#) ([Krzyzanowski, 2011](#)). See [Appendix 4.5](#) for a review
3 of models.

4 [Phelan et al. \(2014\)](#) applied the PROFILE model (see [Appendix 4.5.1.1](#)) to estimate BCw
5 to support SMB critical load estimates for 51 hardwood forest sites in Pennsylvania. The
6 rates of BCw ranged from 119 to 9,245 eq/ha/yr, and were consistent with soil properties
7 and regional geology. Critical loads ranged from 4 to 10,503 eq/ha/yr. The PROFILE
8 model estimates by [Phelan et al. \(2014\)](#) were three times larger than those reported for the
9 same sites by [McNulty et al. \(2007\)](#) who used the clay correlation-substrate method and
10 SMB models to estimate BCw rates and critical loads, respectively. These PROFILE
11 model results suggest that the hardwood sites in Pennsylvania may not be as sensitive to
12 acidifying deposition as previously estimated by [McNulty et al. \(2007\)](#). It should be
13 noted that BCw rates were not measured for these areas and may be a result of the
14 different (empirical vs. mechanistic) approaches of each model. As the [Phelan et al.](#)
15 [\(2014\)](#) study only tested and compared the PROFILE model in Pennsylvania, the
16 researchers recommended applying PROFILE in different regions and ecosystems in the
17 U.S. to gain a better understanding of the model performance and the degree to which
18 BCw rates estimated by PROFILE differ from those estimated using the clay
19 correlation-substrate model.

5.5. Levels of Deposition at Which Effects Are Manifested

20 Since the 2008 ISA, several studies have evaluated the relationships between N and S
21 deposition and the growth and physiology of terrestrial organisms and ecosystem
22 function. In addition, numerous studies have used estimates of critical load exceedances
23 caused by historic, current, and future N and S deposition levels to characterize the
24 impacts of acidifying deposition. In this section, these relationships are described as
25 (1) impacts of elevated N and S deposition, (2) impacts of ambient levels of N and S
26 deposition, and (3) critical loads and exceedances.

5.5.1. Impacts of Elevated Nitrogen and Sulfur Deposition

27 A number of studies published since the 2008 ISA have evaluated the impacts of elevated
28 N and S deposition on trees, herbaceous species, and soil biota ([Table 5-3](#)). “Elevated” N
29 and S deposition in this section refers to additions of N and S above ambient atmospheric
30 deposition during the time of the specified study. As detailed in [Appendix 6](#), N deposition
31 may lead to enrichment effects as well as acidification.

1 In Bear Brook Watershed, ME, [Bethers et al. \(2009\)](#) investigated the effects of
2 chronically elevated N and S deposition (i.e., 25.2 kg N/ha/yr and 28.8 kg S/ha/yr
3 additions since 1989) on growth, foliar nutrients, and photosynthetic capacity of sugar
4 maple saplings. Sugar maple saplings in the treated watershed had higher foliar Al
5 (+56%), N (+15%), P (+10%), and K (+15%) and lower foliar Ca (-25%) compared to
6 the nontreated watershed, presumably through influences on soil chemistry. The treated
7 saplings also had lower photosynthetic capacity, higher N:P ratios, negative correlations
8 between leaf N and electron transport capacity, and reduced carboxylation capacity,
9 which suggest nutrient imbalances induced by the elevated N and S deposition. However,
10 sapling growth was unaffected by the treatments. In another study conducted in Quebec,
11 Canada, [Moore and Houle \(2013\)](#) observed similar results in their evaluation of the
12 effects of 8 years of NH₄NO₃ additions (26 and 85 kg N/ha/yr applied from 2001–2008)
13 on sugar maple physiology and soil chemistry. Foliar Ca in the high N treatment
14 decreased by 79% compared to the control and reached 0.24%, the lowest foliar Ca
15 concentration ever reported for sugar maple. The treatments did not significantly alter
16 dieback rate or basal area growth. These results corresponded to changes in soil
17 chemistry; the treatments significantly decreased exchangeable Ca, Mg, Mn, and K in at
18 least one of the top organic soil layers. The largest differences were observed for
19 exchangeable Ca between the control and the high N treatment, with the L and the H
20 layers of the soil organic horizon showing exchangeable Ca decreases of 29 and 72%,
21 respectively. These results suggest that increased N deposition can strongly affect Ca
22 nutrition of sugar maple at sites with low base cation saturation.

23 In West Virginia, [Jensen et al. \(2014\)](#) examined long-term impacts of relatively high N
24 and S additions (22 years of 169 kg/ha/yr (NH₄)₂SO₄) on black cherry and yellow poplar
25 (*Liriodendron tulipifera*) bole wood Ca, Mg, and Mn concentrations; tree growth; and
26 basal area. Bole wood Ca concentrations were lower and Mn concentrations higher in
27 both species on the treated versus nontreated watershed. Growth responses, measured
28 through relative growth rates of cored trees and changes in basal area, were not
29 conclusively affected by the treatment.

30 [Jung and Chang \(2012\)](#) evaluated the impacts of 4 years of elevated N and S deposition
31 (30 kg N/ha/yr, 30 kg S/ha/yr, and 30 kg N/yr + 30 kg S/ha/yr additions from 2006 to
32 2009) on a forest composed of trembling aspen (*Populus tremuloides*), white spruce
33 (*Picea glauca*), balsam fir, black spruce (*Picea mariana*), and paper birch (*Betula*
34 *papyrifera*) in the Athabasca oil sands region of Alberta, Canada. None of the treatments
35 influenced the growth of the understory plants or soil microbial biomass; understory and
36 microbial community composition were not measured. However, N increased tree growth
37 in the N and N + S treatments, indicating N limitation. Nitrogen and S additions
38 decreased soil exchangeable Ca²⁺ and Mg²⁺, and these decreases were attributed to a

1 combination of increased tree uptake to support greater growth and increased leaching
2 with SO_4^{2-} .

3 [Guy et al. \(2013\)](#) conducted a greenhouse experiment to assess the potential effects of
4 acidic deposition on the root system morphology of three endemic species that grow on
5 sand dunes in the Athabasca oil sands region of Alberta, Canada: *Armeria maritima*,
6 *Deschampsia mackenzieana*, and *Stellaria arenicola*. Plants were exposed to three pH
7 treatments (pH 5.6, 5.0, and 4.2) together with additions of 2.61 to 4.67 mg/L of SO_4^{2-}
8 and 1.95 to 3.51 mg/L NO_3^- for 55–60 days. There were no statistically significant
9 differences in plant survival, root length, root surface area, or root tip numbers between
10 acid treatments. Therefore, current rates of acidifying N and S deposition are not likely a
11 threat to these species.

12 Since the 2008 ISA, three studies were identified on the impacts of N and/or S deposition
13 on soil biota. [Payne et al. \(2010\)](#) examined the impacts of elevated SO_4^{2-} deposition on
14 the microbial community in a Scottish peatland and showed that additions of 95 kg
15 SO_4^{2-} /ha/yr applied over 18 months decreased the concentrations and percentages of live
16 amoebae. Abundances of *Trinema lineare*, *Corythion dubium*, and *Euglypha rotunda*
17 were also significantly reduced. These results suggest the potential importance of SO_4^{2-}
18 deposition in influencing testate amoebae communities in the peatland soils. In another
19 study, [Chen et al. \(2013\)](#) evaluated the impacts of S additions on soil microbial and
20 nematode community composition in an Inner Mongolian grassland in China. Seven
21 treatments of 28 to 166 mol H^+ /ha were applied in three doses in the form of sulfuric acid
22 (H_2SO_4) from 2009 to 2010. Fungal fatty acids were increased by 49% and fungi:bacteria
23 ratio increased by up to 120% by the acid additions. Total and bacterial fatty acids were
24 decreased by the S treatments by up to 47 and 40%, respectively. Acid additions also
25 impacted the soil nematode community by initially increasing the total number of soil
26 nematodes, then altering community composition; bacterivorous and fungivorous
27 nematodes increased, while plant-feeding and omnivorous and carnivorous nematodes
28 decreased. [Hu et al. \(2013\)](#) examined the impacts of N and S additions on soil microbial
29 biomass and function in a boreal mixed-wood forest in the Athabasca oil sands region of
30 Alberta, Canada. Five years of N and S additions (30 kg N/ha/yr and/or 30 kg S/ha/yr)
31 did not influence soil microbial biomass C and N. However, activities of some
32 extracellular enzymes in the soil were decreased by the treatments, with greater
33 β -glucosidase activity in the N + S treatment than in the S treatment and decreased soil
34 arylsulfatase activity in the S addition treatment. Thus, the additions of N and/or S
35 strongly affected soil microbial community functions and enzymatic activities without
36 changing soil microbial biomass in this boreal forest.

Table 5-3 Impacts of acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
Bardhan et al. (2012)	Forest Great Smoky Mountain National Park, TN, NC	Soil microbes (bacteria)	6 to 41 kg S/ha/yr (modeled)	Soil analyses indicated only minor differences in bacterial diversity among sites; the bacterial community did not change along the gradients of S deposition.
Bethers et al. (2009)	Forest Bear Brook watershed, ME	Sugar maple	Ambient: 8.4 kg N/ha/yr and 14.4 kg S/ha/yr; elevated: 25.2 kg N/ha/yr and 28.8 kg S/ha/yr	Treated watershed had a 56% increase in foliar Al, a 25% reduction in foliar Ca, N (+15%), P (+10%), and K (+15%). The treated saplings had lower photosynthetic capacity, high N:P ratios, and negative correlations between leaf N and electron transport capacity, which may indicate nutrient imbalance.
Boot et al. (2016)	Loch Vale watershed in Rocky Mountain National Park, CO	Soil microbes	17 yr of 25 kg N/ha/yr (as NH ₄ NO ₃) addition	Long-term fertilization resulted in increased soil acidity and reduced soil C. Soil microbial biomass in the fertilized soils was also lower (22%), the microbial community was altered through reductions in vesicular arbuscular mycorrhizae and saprotrophic fungi, and activity of N degrading microbial enzymes was decreased.

Table 5-3 (Continued): Impacts of acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
Chen et al. (2013)	Grassland Mongolia, China	Soil microbes, bacteria, fungi, and nematodes	Sulfuric acid (0, 2.76, 5.52, 8.28, 11.04, 13.8, and 16.56 mol H ⁺ /m ²)	Fungal fatty acids were increased by 49% and fungi:bacteria ratio increased by up to 120% by the acid additions relative to the controls. Total and bacterial fatty acids were decreased by the S treatments by up to 47 and 40%, respectively. In the treatments, bacterivorous and fungivorous nematodes increased, while herbivorous and omnivorous + carnivorous nematodes decreased.
Cleavitt et al. (2011a)	Forest Acadia National Park, ME	Epiphytic lichens	12 to 18 kg S/ha/yr	Throughfall chemistry influenced bark pH and the suitability of tree boles as habitat for lichen; epiphytic lichen species richness and presence of pollution-sensitive epiphytes were greater on red maple trees, which have a higher pH in the bark relative to red spruce trees.
Dietze and Moorcroft (2011)	Forest Eastern and central portions of the U.S.	267 tree species organized into 10 PFTs	6 to 16 kg/ha/yr as NO ₃ ⁻ ; 4 to 30 kg/ha/yr as SO ₄ ²⁻ (NADP wet)	Mean sensitivity by covariate and PFTs showed that overall tree mortality was most sensitive to atmospheric pollutants, with acid deposition (SO ₄ ²⁻) showing the highest sensitivity and N deposition the third highest sensitivity. Stand DBH showed the second highest sensitivity.

Table 5-3 (Continued): Impacts of acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
Duarte et al. (2013)	Forest Northeastern U.S.	21 tree species	256 to 920 eq/ha/yr of N; 242 to 1,154 eq/ha/yr of S (modeled)	Statistically significant negative correlations between critical load exceedance and growth (17 species), and crown density (4 species) were determined. Positive correlations between critical load exceedance and declining vigor (4 species), crown dieback (4 species), and crown transparency (7 species) were determined. Species that were most negatively affected by N and S deposition included balsam fir, red spruce, quaking aspen, and paper birch.
Jensen et al. (2014)	Forest Fernow Experimental Forest, WV	Yellow poplar and black cherry	35.5 kg N/ha/yr; 40.5 kg S/ha/yr as (NH ₄) ₂ SO ₄ (addition)	Bole wood Ca concentrations were lower and Mn concentrations were higher in both species on the treated watershed. Growth responses were not conclusive and appeared to differ by species.
Jung and Chang (2012)	Forest Alberta, Canada	Trembling aspen, white spruce, balsam fir, black spruce, and paper birch	30 kg N/ha/yr, 30 kg S/ha/yr, and 30 kg N/yr + 30 kg S/ha/yr (additions)	Nitrogen addition increased tree growth in the N and N + S treatments. None of the treatments affected understory growth or soil microbial biomass. Annual leaching losses of SO ₄ ²⁻ were increased by S and S + N additions. Leaching of base cations showed a similar trend to SO ₄ ²⁻ leaching.
Miller and Watmough (2009)	Forest Southern Ontario, Canada	Sugar maple	9 to 12.8 kg N/ha/yr; 7.6 to 14.8 kg S/ha/yr (ambient)	Sugar maple foliar S and N contents were positively correlated with modeled N and S deposition. Foliose lichen species richness was negatively correlated with modeled air pollution levels (S deposition, N deposition, and atmospheric ozone).

Table 5-3 (Continued): Impacts of acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
Pannek et al. (2015)	Acidic grassland Atlantic biogeographic region of Europe	44 grassland species within the <i>Violion caninae</i> alliance	2.4 to 43.5 kg N/ha/yr (ambient)	Out of 44 species studied, 16 were affected by N deposition, with 12 of them exhibiting a negative response. Increasing soil pH and P influenced 24 and 14 species, respectively, predominantly positively. Species that were negatively affected by high N deposition and/or high soil P also showed a negative temporal trend characterized by short stature and slow growth.
Payne et al. (2010)	Peatland Scotland	Soil microbes (testate amoebae)	Ambient: 5 kg SO ₄ ²⁻ /ha/yr; elevated: 95 kg SO ₄ ²⁻ /ha/yr	Analysis showed that the SO ₄ ²⁻ treatment reduced the concentrations and percentages of live amoebae, suggesting a less active community as a result of the treatment. In addition, abundances of <i>Trinema lineare</i> , <i>Corythion dubium</i> , and <i>Euglypha rotunda</i> were significantly reduced.
Quesnel and Cote (2009)	Forest Boreal region of Canada	White spruce	NA	Meta-analysis of foliar results (nutrient concentrations) from 23 white spruce forests (natural and nonfertilized plantation forests) revealed that N deficiencies occurred in less than 10% of the sites. Base cation deficiencies identified were attributed to removals with harvest, higher requirements of white spruces for K and Ca, and nutrient deficiencies/imbalance induced by N additions/deposition.

Table 5-3 (Continued): Impacts of acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
Rose et al. (2016)	Open uplands, open lowlands, and woodlands U.K.	Vascular plants	NA	Changes in vegetation from 1993–2012 at a network of plots (504) within 12 Environmental Change Network (ECN) sites. Significant increases in species richness were detected at the network level. Increases in acid-sensitive species and comparatively little change in acid-tolerant species were noted. Changes are consistent with increases in pH observed and attributed to the large reductions in acid deposition. Increases in species diversity were also attributed to wetter summers and a reduction in soil N availability at some of the upland locations.
Soulé (2011)	Forest Grandfather Mountain, NC	Red spruce	NA	Radial growth rates of red spruce increased through time, and growth rates were significantly correlated to temperature (positively), days with precipitation (negatively), atmospheric CO ₂ (positively), and emissions of SO _x and NO _x (negatively).
Sullivan et al. (2013)	Forest/Adirondack Mountains, NY	Sugar maple	750 to 1,120 eq/ha/yr as N + S (NADP wet, CASTNET dry)	Found that plots without sugar maple seedlings had higher rates of atmospheric N + S deposition.
Thomas et al. (2013)	Forest Appalachian Mountains, WV	Eastern redcedar	NA	Dendroisotopic techniques showed the recovery of eastern redcedar trees from decades of S pollution. Analysis provided evidence for a distinct physiological response to changes in atmospheric SO ₂ emissions since 1980.

Table 5-3 (Continued): Impacts of acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
Cleavitt et al. (2015)	Forest VT, NH, ME	Lichens	3 to 8 kg N/ha/yr and 4.5 to 5.2 kg S/ha/yr	Annual mean and cumulative N deposition was strongly correlated with decreases in lichen species richness, decreases in N sensitive species, and poorer thallus condition. Cumulative dry deposition of S had the best fit to decreases in thallus condition, poorer community-based S index values, and the absence of many S sensitive species.

Al = aluminum; C = carbon; Ca = calcium; CASTNET = Clean Air Status and Trends Network; CO₂ = carbon dioxide; DBH = diameter at breast height; eq = equivalents; H⁺ = hydrogen ion; ha = hectare; K = potassium; kg = kilogram; L = liter; m = meter; mg = milligram; MN = manganese; mol = mole; N = nitrogen; NA = not applicable; Na₂SO₄ = sodium sulfate; NADP = National Acid Deposition Program; NH₄NO₃ = ammonium nitrate; (NH₄)₂SO₄ = ammonium sulfate; NO₃⁻ = nitrate; NO_x = the sum of nitric oxide and nitrogen dioxide; P = phosphorus; PFT = plant functional types; S = sulfur; SO₂ = sulfur dioxide; SO₄²⁻ = sulfate; SO_x = sulfur oxides; yr = year.

5.5.2. Impacts of Ambient Deposition

1 Five studies that were published since the 2008 ISA have been identified that
2 documented the impacts of ambient N and S deposition on terrestrial biological
3 endpoints, including tree species, tree species grouped into plant functional types (PFTs),
4 lichens, and soil biota ([Table 5-3](#)). “Ambient” N and S deposition in this section refers to
5 the levels of atmospheric N and S deposition experienced during the time of the specified
6 study.

7 [Dietze and Moorcroft \(2011\)](#) conducted a large-scale analysis of central and eastern U.S.
8 that investigated 13 covariates (including climate, air pollutants [N deposition, acid
9 deposition, and ozone averaged 1994–2005], topography, and stand characteristics) as
10 predictors of individual tree mortality. Tree species (267 species) were grouped into
11 10 PFTs based on hardwoods/softwoods, latitude, successional phase (early, mid, and late
12 successional), and hydrological soil status (i.e., hydric). The researchers found that tree
13 mortality was most sensitive to stand characteristics and air pollutants. Nine PFTs had
14 decreased mortality with increased N deposition, and only the northern midsuccessional
15 hardwoods showing the opposite pattern (i.e., increased mortality with increased N
16 deposition). Seven PFTs showed large increases in mortality with acid deposition (as
17 SO_4^{2-}), with only late successional conifers showing the inverse (i.e., a weak decline in
18 mortality with increased acid deposition). Mean sensitivity by covariate and PFT showed
19 that overall tree mortality was most sensitive to atmospheric pollutants, with acid
20 deposition (SO_4^{2-}) showing the highest sensitivity and N deposition the third highest
21 sensitivity. Individual tree DBH showed the second highest sensitivity.

22 [Duarte et al. \(2013\)](#) evaluated the responses of tree species in 4,057 forest plots in the
23 northeastern U.S. to the exceedance of critical loads of N and S deposition. Modeled S
24 and N deposition ranged from 242 to 1,154 eq/ha/yr and 256 to 920 eq/ha/yr,
25 respectively. Critical loads were exceeded in 45% (calculated using midpoint weathering
26 rates) of the plots. See [Appendix 5.5.3](#) for a greater description of critical loads and
27 exceedances from this study. Results from Spearman’s rank correlation analyses showed
28 that the growth of 17 species and crown density of 4 species were negatively correlated
29 with critical load exceedance ([Table 5-4](#)). Positive correlations between critical load
30 exceedance and declining vigor (three species), crown dieback (four species), and crown
31 transparency (seven species) were also found ([Table 5-5](#)). Crown dieback was considered
32 the most reliable indicator of forest health. Based on this metric, balsam fir, red spruce,
33 quaking aspen, red maple, and paper birch were identified as the species most negatively
34 impacted by N and S deposition.

Table 5-4 Results of Spearman’s rank correlation analysis comparing growth versus critical load exceedance by species for the forested plots in the northeastern U.S. [from [Duarte et al. \(2013\)](#)]. Modeled sulfur and nitrogen deposition on the plots ranged from 242 to 1,154 eq/ha/yr and 256 to 920 eq/ha/yr, respectively. Correlations shown here are significant at $\alpha = 0.05$.

Species	Correlation Coefficient	Sample Size (n)
Black spruce (<i>Picea mariana</i>)	-0.44	41

eq = equivalents; ha = hectare; yr = year.

Source: [Duarte et al. \(2013\)](#)

1 [Sullivan et al. \(2013\)](#) evaluated relationships between deposition and sugar maple
2 regeneration in the Adirondack Mountains. Total N and S deposition ranged between 750
3 and 1,120 eq/ha/yr, and plots that received higher rates of N (median of approximately
4 560 eq/ha/yr), S (median of approximately 480 eq/ha/yr), and N + S (median of
5 approximately 1,040 eq/ha/yr) deposition had no sugar maple seedlings.

6 [Soulé \(2011\)](#) sampled red spruce trees within a high elevation red spruce-Fraser fir (*Abies*
7 *fraseri*) forest on Grandfather Mountain, NC between 2006 and 2008, and used
8 dendrochronology to evaluate the influences of climate (precipitation, temperature, and
9 CO₂ concentrations) and emissions of SO_x and NO_x on growth. Radial growth rates of
10 red spruce increased through time and were positively correlated to temperature and
11 atmospheric CO₂, but were negatively correlated to emissions of SO_x and NO_x and
12 number of days with precipitation in a year.

13 [Miller and Watmough \(2009\)](#) evaluated hardwood plots along air pollution (N, S, and
14 ozone), soil acidity, and climate gradients in Ontario, Canada, and found that foliose
15 lichen species richness was negatively correlated with modeled air pollution levels (S
16 deposition, N deposition, and atmospheric ozone). In the same study, however, no
17 relationship was seen in canopy condition and ground vegetation richness and diversity.

18 [Bardhan et al. \(2012\)](#) evaluated bacterial diversity along a soil and S deposition gradient
19 in high elevation spruce-fir forests in GSMNP. Modeled S deposition ranged from 6 to
20 41 kg S/ha/yr. However, neither bacterial diversity nor community composition changed
21 along the gradient of S deposition. The bacterial community on all sites was dominated
22 by members of the phyla Actinobacteria, Acidobacteria, Planctomycetes, Proteobacteria,
23 and Chloroflexi. Species from these phyla are often found in highly acidic environments
24 such as acid-mine drainage and sphagnum bogs. Therefore, these analyses suggested that
25 despite reductions in acid deposition, the soil conditions in these GSMNP sites were still
26 acidic and had not yet reached a threshold suitable for nonacidophilic bacterial
27 communities.

28 [Pannek et al. \(2015\)](#) used a data set from seminatural grasslands found on acidic soils
29 along an N deposition gradient (2.4 to 43.5 kg N/ha/yr) in northwestern Europe to
30 examine the response of species frequency to N and other factors including soil
31 (0–10 cm) P, pH, NH₄⁺, and NO₃⁻ and geographical, climatic, and management factors.
32 Out of 44 studied species, 16 were affected by N deposition, with 12 of them exhibiting a
33 negative response (see also [Appendix 6.2.5](#) and [Appendix 6.3.5](#)).

5.5.3. Critical Loads and Exceedances

1 Since the 2008 ISA, critical load evaluations have been conducted in the northeastern
2 forests of the U.S., hardwood forests in Pennsylvania, forests in western Canada, and
3 arctic, subarctic, alpine, subalpine, and boreal systems. Studies also simulated target
4 loads and critical loads and exceedances into the future under different deposition and
5 climate scenarios, and evaluated the sensitivity of critical load estimates to varying
6 environmental conditions and forest management and uncertainties in critical load
7 estimates. See [Appendix 4.6.2.1](#) for more information on critical loads based on soil
8 acidification and [Appendix 6.5](#) for information on N critical loads in terrestrial systems.

9 [Duarte et al. \(2013\)](#) calculated critical loads of N and S for 4,057 forested plots in the
10 northeastern U.S. using the steady-state SMB model (see also [Appendix 4.5.1.2](#)) and soil
11 solution Bc:Al of 10.0 as the chemical indicator and threshold. In addition, the study
12 evaluated the influence of three different BCw rates on critical loads: minimum,
13 midpoint, and maximum. These BCw rates were determined using the clay
14 correlation-substrate method and the range of U.S. Department of Agriculture (USDA)
15 Natural Resources Conservation Service (NRCS) Soil Survey Geographic Database
16 (SSURGO) values for each soil series. Critical loads using the midpoint weathering rates
17 were found to range from 11 to 6,540 eq/ha/yr (over 80% within the range of
18 850–2,050 eq/ha/yr), and in comparisons with deposition estimated using the ClimCalc
19 model, were exceeded in 98% (calculated using minimum weathering rates), 45%
20 (calculated using midpoint weathering rates), and 15% (calculated using maximum
21 weathering rates) of plots. Similarly, [Phelan et al. \(2014\)](#) calculated critical loads of N
22 and S deposition for 51 hardwood forests in Pennsylvania using the SMB model, soil
23 solution Bc:Al of 10.0 as the chemical indicator, and the PROFILE model to estimate
24 BCw rates. They found that critical loads ranged from 4 to 10,503 eq/ha/yr, and that
25 critical loads at 53% of the sites were exceeded by the 2002 N and S deposition.

26 [Krzyzanowski \(2011\)](#) modeled deposition and soil acidification critical loads in
27 northeastern British Columbia, Canada using empirical methods described in [Spranger et
28 al. \(2004\)](#). Slow weathering of shale- and mudstone-derived feldspars, micas, and quartz
29 placed the soils of the study area in the “high-sensitivity” class of critical loads. Soil
30 acidification critical load was estimated to be 200 eq/ha/yr. Neither S nor N deposition
31 exceeded this critical load. The combined S and N deposition at the dominant point of
32 reception (i.e., near Blueberry River First Nation) was estimated to be 73.5 eq/ha/yr.

33 Estimates of S and N critical loads and exceedances for upland soils were generated for
34 the Georgia Basin in British Columbia, Canada using the SMB model and zero base
35 cation depletion as the chemical criterion and threshold ([Nasr et al., 2010](#)). The objective
36 of the study was to evaluate critical load and exceedance calculations in the context of

1 sustainable forest and soil management policies by using “no further changes in soil base
2 saturation” as the critical load criterion. Critical loads were found to range between 140
3 and 4,000 eq/ha/yr, and were generally lowest on ridge tops and increased towards the
4 valleys. Critical load exceedance ranged from 13% of the basin when exposed to wet
5 deposition to 32% under modeled total (wet and dry) deposition. With continued N and S
6 deposition, significant portions of the basin were predicted to experience
7 exceedance-enhanced base cation depletion rates greater than 200 eq/ha/yr.

8 [Forsius et al. \(2010\)](#) determined critical loads and exceedances for terrestrial ecosystems
9 in the arctic and subarctic regions (with latitudes north of 60°) for 1990, 2000, 2010, and
10 2020 using the SMB model and two different chemical indicators (soil solution Al:Bc of
11 1.0 and ANCle of 0.0). The Al:Bc indicator was hypothesized to protect against fine root
12 damage, and the ANCle indicator was hypothesized to preserve existing soil base cation
13 pools. The 2020 deposition scenario was based on the maximum feasible reduction
14 (MFR) emissions for 2020. Critical load estimates were generally comparable among the
15 three main regions (northern Europe, Russia, and North America) and were influenced by
16 the chemical indicator and associated threshold. The Al:Bc of 1.0 was less stringent than
17 ANCle of 0.0, with the median critical loads for the two indicators being 700 and
18 300 eq/ha/yr, respectively. In North America, the lowest critical loads occurred in eastern
19 Canada above latitudes of 60°. In general, low critical loads were found in areas with low
20 weathering rates associated with coarse soils on acidic parent material. Critical loads in
21 North America (above latitudes of 60°) were not exceeded by any of the deposition levels
22 for any of the years: The lowest critical load was 130 eq/ha/yr, while the maximum rates
23 of N and S deposition in North America were estimated to be 30 to 40 eq/ha/yr.

24 [Simkin et al. \(2016\)](#) quantified the effect of N deposition on species richness in the
25 continental U.S. using data from over 15,000 plots. N deposition had a strong effect on
26 species richness, but this effect differed between closed canopy and open ecosystems
27 (i.e., forests and nonforest). In nonforested ecosystems (grasslands, deserts, shrublands,
28 subalpine ecosystems), there was a positive relationship between N deposition and
29 herbaceous species richness at low rates of N deposition, then a decrease in species
30 richness with higher rates of N deposition over a threshold of 8.7 kg N/ha/yr. This study
31 focused N enrichment, but highlighted interactions with soil acidification. Vegetation on
32 acidic soils was more susceptible to species loss under elevated N. See [Appendix 6.2](#) and
33 [Appendix 6.5.3](#) for more information on this study.

5.5.3.1. Target and Future Critical Loads/Critical Load Exceedances

1 Target loads of S deposition were calculated for 44 watersheds and extrapolated to
2 1,320 acid-sensitive watersheds in the Adirondacks using MAGIC (see also
3 [Appendix 4.5.1.4](#)) and different soil chemical indicator and thresholds of base saturation
4 (5 and 10%), soil solution Bc:Al, and Ca:Al [1.0 and 10.0; ([Sullivan et al., 2011a](#))]. In a
5 comparison of target loads (out to Years 2050 and 2100) and the 2002 deposition, only
6 11.6 to 13.5% of the watersheds were simulated to be in exceedance of target loads to
7 protect soil base saturation to 5%. For target loads to protect soils to a base saturation of
8 10%, 79.7 to 87.5% of the watersheds were in exceedance. For soil solution Bc:Al, 7.8
9 and 98.1% of watersheds were exceeded by the 2002 deposition for target loads to protect
10 soil solution ratios of 1.0 and 10.0, respectively. For soil solution Ca:Al, 44.1 to 58.2% of
11 watersheds experienced exceedances of target loads associated with a soil solution ratio
12 of 1.0, and 98.1% of watersheds with target loads to protect Ca:Al ratios of 10.0 were
13 exceeded. Further investigations revealed that 58.2, 85.7, and 93.6% of watersheds could
14 not obtain threshold values of 10% base saturation, Bc:Al = 10, or Ca:Al = 10,
15 respectively, even if acidic deposition was held at zero, thereby demonstrating that these
16 chemical indicator threshold values were not useful for target load calculations using
17 MAGIC in the Adirondack Mountains.

18 [Sverdrup et al. \(2012\)](#) and [McDonnell et al. \(2014a\)](#) used the ForSAFE-VEG model (see
19 also [Appendix 4.5.1.3](#)) to evaluate potential long-term effects of climate change and
20 atmospheric N deposition on alpine/subalpine ecosystems. Critical loads in both studies
21 were defined as the amount of N deposition to protect against a change in plant
22 biodiversity of 5 to 10 Mondrian (M) units (i.e., 5–10% change in plant species cover).
23 [Sverdrup et al. \(2012\)](#) focused on a “generalized” alpine/subalpine site in the Rocky
24 Mountain National Park, and simulated plant responses to a future climate (IPCC
25 scenario A2) and four levels of N and S deposition (preindustrial background, Clean Air
26 Act [CAA] controls, no CAA controls, and no CAA controls + high deposition). Soil
27 base saturation decrease to less than 1% and soil solution Bc:Al were predicted to be less
28 than 10.0 after Year 2100, with the futures of no CAA emission controls and no CAA
29 controls + high deposition (indicating soil acidification). Future plant species coverages
30 were predicted to change in successively greater amounts in response to the altered
31 climate, CAA emission controls, no CAA emission controls, and no CAA emission
32 controls + high deposition. Critical loads of N deposition were calculated (based on a
33 change of 5 M) to be 1 kg N/ha/yr. Critical loads related to S deposition were not
34 discussed. All future N deposition scenarios (except preindustrial background N) were
35 simulated to result in critical load exceedance. [McDonnell et al. \(2014a\)](#) found similar
36 results in their study that evaluated the response of plants on a site in the Loch Vale
37 watershed, CO to 100 different scenario combinations of N deposition, precipitation, and

1 temperature. The estimated critical load of N to protect against future (average of
2 Years 2010–2100) change in biodiversity (10 M) was estimated to be between 1.9 and
3 3.5 kg N/ha/yr, depending on the temperature increase scenario. Current deposition levels
4 were found to exceed the critical load. Future increases in temperature were forecasted to
5 substantially impact plant community composition beyond the predicted changes in
6 response to N alone; N deposition was forecasted to result in approximately a 10- to
7 25-M change by 2100, whereas a +4.6°C increase in temperature was forecasted to result
8 in approximately a 38- to 48-M change by 2100. In both studies, plant community
9 response appeared to be attributed to N enrichment or eutrophication, as [McDonnell et al.](#)
10 [\(2014a\)](#) stated that the critical load adopted in their study was much lower than critical
11 loads to protect against NO₃⁻ leaching and soil acidification determined by other studies.

5.5.3.2. Sensitivity of Critical Load Estimates to Forest Management and Environmental Stresses

Influences of Forest Management

12 Removal of N and base cations with tree harvesting can be included in the calculation of
13 critical loads. Several recent studies evaluated the amounts of base cations removed
14 through different harvesting practices and determined that base cation removal can be
15 substantial and contribute to site acidification.

16 [Duchesne and Houle \(2008\)](#) determined base cation budgets in a managed boreal balsam
17 fir forest in Quebec, Canada according to six different scenarios, including two
18 harvesting scenarios (whole-tree and stem-only harvesting), and three scenarios of
19 mineral weathering. Whole-tree harvesting was found to remove twice as much Ca (1,358
20 vs. 664 mol/ha) and K (483 vs. 200 mol/ha) as stem only. In contrast to Ca and Mg,
21 immobilization of K within tree biomass (69 mol/ha/yr) was the main pathway of K
22 losses from the soil exchangeable reservoir, being five times higher than losses via soil
23 leaching (14 mol/ha/yr). The amounts of K contained within the aboveground biomass
24 and the exchangeable soil reservoir were 3.3 and 4.2 kmol/ha, respectively. Whole-tree
25 harvesting was estimated to remove 44% of the K that was readily available for cycling
26 in the short term.

27 Similar results were found by [Iwald et al. \(2013\)](#) in their evaluation of the removal of
28 base cations with the harvesting of tree stumps and logging residues for biofuels in
29 Sweden. Their study evaluated three levels of harvesting intensity that varied in the
30 amounts of stump and logging residues left on site (0–40%). Results from the study
31 indicated that harvesting of stumps and logging residues constituted 13 to 24% and 27 to

1 45% of total (stumps + stem wood + logging residues) base cation extraction,
2 respectively, depending on harvest intensity and tree species. The higher acidifying effect
3 of logging residue removal was explained by the higher contents of base cations in
4 needles and branches compared to stem wood. In a comparison between total net cation
5 extraction by tree harvesting and maximum levels of current acid deposition, the
6 acidifying effect of pine harvesting was found to be 57 to 108% of that of acid
7 deposition, the acidifying effect of spruce harvesting was 114 to 263%, and the acidifying
8 effect of birch harvesting was 60 to 171%.

9 In the northeastern U.S., [Lucas et al. \(2014\)](#) evaluated base cation extractions under three
10 different management scenarios that varied in management intensity and conservation
11 focus. The MaxGrowth management option, which involved site scarification, intensive
12 fertilization (ammonium nitrate), and short rotation lengths (60–100 years), resulted in
13 roughly 50 to 100% greater base cation removal than that associated with the other three
14 management scenarios. Additionally, removal of tree tops, branches, and stumps
15 consistently resulted in removal rates of Ca, Mg, and K three to four times greater than
16 conventional stem-only harvests.

17 [Johnson et al. \(2015a\)](#) used mass balance calculations to evaluate the impact of
18 harvesting on ecosystem balances of Ca, Mg, K, and acidification of forest soils at
19 40 sites in Ireland. Three harvesting scenarios were evaluated: stem-only harvest (SOH),
20 stem plus branch harvest (SBH), and whole-tree harvest (WTH). Mass balances for Ca,
21 Mg, and K were determined based on the difference between long-term inputs
22 (atmospheric deposition plus mineral weathering) and outputs (biomass removal plus
23 leaching losses). Soil acidification was calculated using a simplified acidity balance of
24 inputs (base cation and Na deposition and base cation weathering) and outputs (base
25 cation uptake, S deposition, and Cl⁻ deposition). Under the SOH and SBH management,
26 inputs of Ca, Mg, and K were predicted to be sufficient to meet outputs. Atmospheric
27 deposition was the most important source of Ca and Mg input. For K, inputs from soil
28 weathering were as important as deposition. Under the WTH scenario, Ca output
29 exceeded input at 19 of the 40 study sites. However, the differences were small relative to
30 the sizes of the Ca pools; at the 19 sites, exchangeable pools could support Ca removal
31 with WTH for a median of 220 years. Mg and K removal with WTH was balanced by
32 inputs through deposition and soil weathering. In contrast, for soil acidification budgets,
33 base cation removal with all scenarios of harvesting was much greater than that generated
34 by soil weathering, suggesting that soils will become acidified over the long term.
35 However, there was considerable uncertainty around the calculation of base cation fluxes.
36 For Ca balances, confidence intervals spanned positive and negative values at so many
37 sites that it was not possible to predict the balance of Ca budgets. In addition, uncertainty

1 in flux calculations was particularly important for K, as soil exchangeable pools were
2 small and could be depleted within one or two rotations.

3 [Zetterberg et al. \(2014\)](#) evaluated the long-term effects of whole-tree harvest (WTH) on
4 soil and stream water acidity in three forested catchments dominated by Norway spruce
5 in Sweden. Potential influences of varying the amounts of logging residues, Ca
6 concentrations in tree biomass, and site productivity on the model predictions were also
7 evaluated through a sensitivity analysis. The MAGIC model was used to simulate
8 changes in forest soil exchangeable Ca pools and stream water ANC from 1850 to 2100,
9 with WTH occurring in 2020. Large depletions in soil Ca supply and a reversal of the
10 positive trend in stream ANC were predicted for all three catchments sites after WTH.
11 However, the magnitude of impact on stream ANC varied depending on site and the
12 concentrations of mobile strong acid anions. Varying the tree biomass Ca concentrations
13 was found to have the largest impacts on modeled soil and stream chemistry. Site
14 productivity was the second most influential variable, and changing the amount of
15 harvest residues left on site only marginally affected soil exchangeable Ca and stream
16 water ANC. The results from this study suggest that future research should concentrate
17 on minimizing uncertainties in tree biomass Ca concentrations and performing studies on
18 biological feedback mechanisms that can increase Ca availability in the soils.

Influences of Environmental Stresses

19 Climate and other environmental stresses may also directly or indirectly alter ecosystem
20 parameters that are used in the SMB model to determine critical loads. The potential
21 influences of climate were examined by [McNulty and Boggs \(2010\)](#) in their case-study
22 evaluation of red spruce stands in western North Carolina that were experiencing low
23 versus high rates of mortality associated with a pine beetle outbreak. There were positive
24 relationships between site fertility (forest floor and soil measurements, foliar N
25 concentrations, and Mg:N ratios) and red spruce mortality. Annual basal area growth of
26 red spruce on more fertile plots was more sensitive to drought than on less fertile sites.
27 Based on these observations, critical loads of acidity could change as a result of episodic
28 stress (e.g., drought, insect infestations, frost injury, cold tolerance, etc.), and increased
29 growth due to higher fertility and/or nutrient imbalances caused by acidifying deposition
30 may make red spruce more susceptible to environmental stresses. Critical loads of N and
31 S, therefore, might be lower when environmental stresses are present.

5.5.3.3. Uncertainties in Critical Load Estimates

1 [Reinds and de Vries \(2010\)](#) evaluated the uncertainties in critical and target loads of S
2 and N for 182 European forest soil plots using the very simple dynamic (VSD) model
3 (see also [Appendix 4.5.2.2](#)). Target loads were defined as the deposition that leads to a
4 desired chemical state of the ecosystem in a given future year. The VSD model was
5 calibrated using Bayesian prior probability functions for model parameters based on
6 literature data, data from 200 Dutch forest sites and from simulated denitrification rates
7 from a detailed ecosystem model, which improved the model fit to observed soil
8 measurements. Critical loads determined by the calibrated model varied by chemical
9 criterion. Minimum critical loads of N ranged between 181 (5th percentile) and
10 1,606 eq/ha/yr (95th percentile), maximum critical loads of N ranged between 502
11 (5th percentile) and 31,247 eq/ha/yr (95th percentile), and maximum critical loads of S
12 ranged between 4 (5th percentile) and 9,670 eq/ha/yr (95th percentile), with the critical
13 loads based on Al:Bc = 1 being higher than those determined using the ANC = 0 eq/ha/yr
14 criterion. Uncertainty analysis also showed that the main drivers of uncertainty were
15 largely dependent on the chemical criterion used in the critical and target load
16 calculations. Base cation weathering, deposition, and the parameters describing the H-Al
17 equilibrium in the soil solution were the main sources of uncertainty in the estimates of
18 maximum critical loads for S (CL_{max}[S]) based on the Al:Bc criterion of 1.0, and
19 uncertainty in CL_{max}(S) based on ANC was completely determined by base cation
20 inputs. The denitrification fraction was the most important source of uncertainty for the
21 maximum critical loads of N (CL_{max}[N]). Calibration of VSD reduced the levels of
22 uncertainty for all critical loads and criteria. After calibration, the coefficient of variation
23 (CV) for CL_{max}(S) was below 0.4 for almost all plots, and target loads were not needed
24 in any of the simulations for 40% of the plots. According to the noncalibrated model,
25 there was a positive probability for the need of a target load for almost all plots.

5.6. Climate Modification of Ecosystem Response

26 The effect of acidifying deposition on terrestrial ecosystems can be modified by climate
27 shifts in temperature and precipitation. [Appendix 13](#) provides an overview on this topic
28 and [Appendix 4.7.1](#). provides information on climate modification of soil acidification.

29 Warmer temperatures increase decomposition and nitrification. Nitrification will also
30 increase with increased N supply caused by increased weathering or decomposition
31 ([Booth et al., 2005](#)). The process of nitrification generates protons that increase the rate
32 of nitrate and base cation leaching to drainage waters ([Murdoch et al., 1998](#)). The
33 combined increase of NO₃⁻ leaching and loss of base cations has the potential to magnify

1 acidification in forest soils ([Fernandez et al., 2003](#)). Soil weathering is typically the key
2 buffer to acidic deposition ([Li and McNulty, 2007](#)), and while weathering is increased by
3 both soil temperature and soil moisture ([Gwiazda and Broecker, 1994](#)), it is unclear
4 whether any future change in the magnitude of temperature and precipitation will be
5 enough to alter base cation supply or influence the acid-base balance of sensitive
6 ecosystems. Furthermore, it is unclear whether increased supply of N in soils from either
7 deposition, increased decomposition, or increased nitrogen fixation may negate the
8 ameliorative effect of enhanced weathering. Some studies show that climate change will
9 mitigate acidification through increased weathering ([Belyazid et al., 2011a](#)), while others
10 show that climate change will aggravate acidification although increased nitrification
11 outpaces enhanced weathering ([Wu and Driscoll, 2010](#)). In general, increased
12 temperature and precipitation will likely enhance inputs of buffering agents from
13 weathering and deposition, but also increase inputs of acidifying agents from deposition
14 and enhanced N cycling. The relative sensitivity of these opposing processes to a given
15 change in climate remains unresolved.

16 The mountainous regions of the Eastern U.S. are especially interesting to study because
17 of the both acidifying deposition and climate change interact in these areas. Recently,
18 [Wason et al. \(2017\)](#) studied the responses of red spruce and balsam fir to acidic
19 deposition and trends in climate on Whiteface Mountain in New York using tree ring
20 analysis in forests plots along an elevational gradient. They found that both species
21 increased growth with increased precipitation pH. Red spruce growth appeared to
22 increase growth with a warming climate and balsam fir did not. Despite the changes in
23 growth due to precipitation chemistry and climate, the authors did not detect changes in
24 the distribution in the spruce-fir forest and perhaps this is a longer-term process. The
25 study demonstrated the complexity of forest response as multiple environmental factors
26 change as these forests recover from acidifying deposition.

27 [Koo et al. \(2014\)](#) used the Annual Radial Model (ARIUM) to investigate projected
28 climate change effects and changing air pollution on red spruce growth in the Great
29 Smoky Mountain national park. The model estimated that high elevation (<1,700 m) red
30 spruce growth would decline 10.8% when a climate change interacted with a 10%
31 increase in air pollution. However, growth increased by 8.4% when air pollution
32 decreased 10% in air pollution with climate change. In contrast, low elevation red spruce
33 growth decreased with future climate change with decreased, increased and no change in
34 air pollution.

5.7. Summary

1 Since publication of the 2008 ISA, the overarching understanding of terrestrial
2 acidification has not appreciably changed. More recent research has confirmed and
3 strengthened this understanding and provided more quantitative information, especially
4 across the regional landscape. A number of studies have evaluated the relationships
5 between soil chemistry indicators of acidification and ecosystem biological endpoints
6 (see [Table 5-6](#)). Soil chemistry indicators examined in recent literature include
7 exchangeable base cations, soil pH, exchangeable acidity (H⁺ and Al), exchangeable
8 Bc:Al ratio, base saturation, and Al concentrations. Biological endpoints included in the
9 evaluations consisted of physiological and community responses of trees and other
10 vegetation, lichens, soil biota, and fauna.

5.7.1. Physiology and Growth

11 The physiological effects of acidification on terrestrial ecosystems in the U.S. were well
12 characterized at the time of the 2008 ISA. Consistent and coherent evidence from
13 multiple species and studies in 2008 showed that the biological effects of acidification on
14 terrestrial ecosystems were generally attributable to physiological impairment caused by
15 Al toxicity and decreased ability of plant roots to take up base cations (Section 3.2.2.3 of
16 the 2008 ISA). Acid deposition can also leach membrane-associated stores of Ca from
17 young red spruce needles, which affects membrane stability and freezing tolerance. New
18 information since the 2008 ISA has supported these conclusions ([Appendix 5.2](#)),
19 including further studies on the impact of acidifying deposition on sensitive tree species,
20 such as sugar maple and red spruce. Much of the new evidence for the negative effects of
21 acidifying deposition on these species comes from Ca addition experiments, in which the
22 addition of Ca has alleviated many of the negative plant physiological and growth effects.
23 Consistent with the findings of the 2008 ISA, **the body of evidence is sufficient to infer
24 a causal relationship between acidifying N and S deposition and the alteration of the
25 physiology and growth of terrestrial organisms and the productivity of terrestrial
26 ecosystems.**

27 In the 2008 ISA, acidifying deposition, in combination with other stressors, was found to
28 be a likely contributor to physiological effects that led to the decline of sugar maple trees
29 living at higher elevation in some portions of the eastern U.S. that have geologies
30 dominated by sandstone or other base-poor substrate, and that have base-poor soils.
31 Studies since the 2008 ISA support these findings (see [Appendix 5.2.1.1](#)). For example,
32 recent field studies demonstrated relationships between soil chemical indicator threshold
33 values and tree responses. Substantial declines in sugar maple regeneration were found at

1 soil base saturation levels <20%, which is consistent the range reported in the 2008 ISA.
2 In new studies, sugar maple showed positive growth and regeneration responses to
3 increasing exchangeable base cations, base saturation and soil pH, and negative
4 relationships with increasing exchangeable Al. Additional studies indicated that growth,
5 regeneration and physiological responses of sugar maple to soil conditions created by
6 acidifying N and S deposition were reversed or ameliorated by Ca additions. The
7 responses to Ca additions included increased growth and regeneration, decreased crown
8 dieback, increased foliar chlorophyll, and decreases in foliar metabolic indicators of
9 physiological stress.

10 The 2008 ISA reported that changes in soil chemistry, such as depletion of soil base
11 cations, increasing Al concentration, and leaching of base cations into drainage water,
12 have contributed to physiological stress, high mortality rates, and decreasing growth
13 trends of red spruce trees. New information since the 2008 ISA from Ca addition studies
14 supports the conclusion that depletion of base cations contributed to these effects in trees
15 ([Appendix 5.2.1.2](#)). Foliar biomass and physiological responses of red spruce to soil
16 conditions created by acidifying N and S deposition were reversed or ameliorated by Ca
17 additions. The responses included higher foliar antioxidant activity in the winter,
18 significantly greater foliar cold tolerance, and higher levels of foliar metabolic
19 compounds that indicate an increased tolerance of environmental stresses. ([Schaberg et](#)
20 [al., 2011](#); [Halman et al., 2008](#)).

21 In the 2008 ISA, there was a limited amount of information on acidification effects on
22 flowering dogwood. Since the 2008 ISA, no additional information on dogwood has been
23 published; however, other tree species that have been evaluated in studies relating soil
24 chemistry to tree physiology include yellow birch, white ash, American beech, black
25 cherry, northern red oak, hickories, American basswood, and eastern hophornbeam.
26 These species were reported to vary in their sensitivities to soil conditions associated with
27 acidifying deposition. Data are insufficient to draw general conclusions for other species.
28 New information was also published on the recovery of eastern redcedar since the 1980s
29 as SO₂ emissions declined. However, it is unclear whether this recovery was from acid
30 deposition, direct SO₂ effects, or a combination of each ([Appendix 5.2.1.3](#)).

31 New studies since the 2008 ISA have also added new information about acidifying
32 deposition on forest understory vegetation, grasslands, lichen communities, and higher
33 trophic-level organisms (snails and salamanders). These studies are not as numerous as
34 those from the decades of tree research; however, results of these studies support the
35 conclusions of the 2008 ISA regarding the effects of acid deposition on terrestrial
36 ecosystems.

5.7.2. Biodiversity

1 Consistent with the findings of the 2008 ISA, **the body of evidence is sufficient to infer**
2 **a causal relationship between acidifying N and S deposition and the alteration of**
3 **species richness, community composition, and biodiversity in terrestrial ecosystems.**

4 The physiological effects of acidifying deposition can result in changes in species
5 composition and biodiversity whereby sensitive species are replaced by more tolerant
6 species. For example, sugar maple was found to have greater growth and seedling
7 colonization with increasing soil cation availability, and American beech was more
8 prevalent on soils with lower levels of base cations—locations where sugar maple does
9 less well ([Appendix 5.2.1.3.1](#)). As noted above, studies have found increased
10 regeneration of sugar maple with Ca additions and less regeneration with increasing
11 exchangeable Al. Soil acid-base chemistry was found to be a predictor of understory
12 species composition. Fifty understory species were associated with the basic end of a soil
13 pH gradient, and these species could have value as indicators of sites with high base
14 cation status and potentially suitable habitat for acid-sensitive species like sugar maple.
15 In another set of studies, soil acid-base chemistry predicted and was correlated with soil
16 biota diversity and community composition. Proportions of soil bacteria, fungi, and
17 nematodes were found to be correlated to soil pH and Al concentrations. Fungi and
18 nematodes were more abundant in acidic soils. Ca additions resulted in a change in soil
19 bacterial community composition, and the bacterial community structure was found to be
20 significantly correlated with soil exchangeable Ca, pH, and P ([Appendix 5.2.4](#)).

5.7.3. National-Scale Sensitivity and Critical Loads

21 Sensitivity of soils to acidifying deposition is discussed in detail in [Appendix 4](#) and
22 summarized in [Chapter 1.5](#). In general, surficial geology is the principal factor governing
23 the sensitivity of terrestrial ecosystems soil to acidification from S and N deposition.
24 Other factors contribute to the sensitivity of soils to acidifying deposition, including
25 topography, soil chemistry, and land use. Forests of the Adirondack Mountains of New
26 York, Green Mountains of Vermont, White Mountains of New Hampshire, the Allegheny
27 Plateau of Pennsylvania, and mountain top and ridge forest ecosystems in the southern
28 Appalachians are the regions most sensitive to terrestrial acidification from atmospheric
29 deposition (Section 3.2.4.2 of the 2008 ISA). Sensitive ecosystems can also be
30 characterized by presence of acid-sensitive soils and plant species ([Appendix 5.3](#)).

31 Models used to determine critical loads of acidifying deposition included: SMB, STA,
32 MAGIC, ForSAFE-VEG, and empirical models. Several models and extrapolation
33 methods to estimate BCw rates were also investigated. The PROFILE model was

1 evaluated as a model to estimate soil BCw rates to support estimates of SMB critical
2 loads in the U.S. In general, recently published models used soil solution Bc:Al of 10.0 as
3 an indicator to estimate critical loads in North America. These models are described in
4 more detail in [Appendix 4.5](#).

5 Sensitivities of ecosystems to ambient N and S deposition were also characterized
6 through critical loads and exceedances ([Appendix 5.5](#)). Calculated critical loads for forest
7 sites based on the soil solution Bc:Al of 10.0 in the northeastern U.S. ranged from 11 to
8 6,540 eq/ha/yr (eq quantifies the supply of H⁺ ions available for acid-base reaction,
9 allowing the acidifying effects of N and S deposition to be combined into the same unit),
10 and 15–98% of these critical loads were exceeded by N and S deposition. In this region,
11 correlation analyses showed that the growth of 17 species and crown density of 4 species
12 were negatively correlated with critical load exceedance. In Pennsylvania, critical loads
13 based on the soil solution Bc:Al of 10.0 for hardwood forests ranged from 4 to
14 10,503 eq/ha/yr and were exceeded by the 2002 N and S deposition in 53% of the plots.
15 In comparison, critical loads for terrestrial ecosystems in the arctic and subarctic regions
16 of North America were not exceeded by estimated deposition in the Years 1900, 2000,
17 2010, and 2020. For these high latitude ecosystems, the lowest critical load was
18 130 eq/ha/yr, while the maximum N and S deposition was 30 to 40 eq/ha/yr.

19 In western Canada, critical loads ranged from 40 to 4,000 eq/ha/yr depending on the
20 study and location. Several studies evaluated the influence of BCw rates, soil chemical
21 indicators and thresholds, N retention, tree species-specific base cation uptake, and/or
22 bulk (i.e., wet) versus total deposition on critical load estimates. All of these parameters
23 were found to influence critical load and exceedance determinations, thereby
24 demonstrating the uncertainties and sensitivities associated with critical load estimates.

Table 5-6 Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Bardhan et al. (2012)	Forest Great Smoky Mountain National Park, TN, NC	Soil microbes (bacteria)	6 to 41 kg S/ha/yr modeled deposition classes (Weathers et al., 2006)	Soil pH and exchangeable Ca and Al, CEC and base saturation (O-, A-, and B-horizons)	Only minor differences in bacterial diversity among sites; the bacterial community did not change along the gradients of S deposition, soil pH, or exchangeable Ca:Al ratio. High elevation sites remain acidic and have not yet reached a threshold suitable for nonacidophilic bacterial communities.
Beier et al. (2012)	Forest Adirondack Mountains, NY (12 upland hardwood forests)	NA	14.57 to 19.7 kg/ha/yr as wet NO ₃ ⁻ ; 17.44 to 29.09 kg/ha/yr as wet SO ₄ ²⁻ , modeled (Ito et al., 2002) 1990–1999	Exchangeable Ca and pH (Oa- and B-horizons)	Increasing trends in snail community richness and abundance, live biomass of red-backed salamanders, and canopy tree basal area with increasing soil Ca. Land snail species richness and abundance were positively correlated with Oa-horizon Ca and negatively correlated to SO ₄ ²⁻ deposition. Salamander communities changed continuously along the Ca gradient. Several known calciphilic species of snails and plants were found only at the highest Ca sites. The proportion of basal area attributed to standing dead trees decreased significantly with Oa-horizon Ca.
Bilodeau-Gauthier et al. (2011)	Forest Quebec lakes network, Quebec, Canada (6 watersheds)	Sugar maple	NA	Soil pH, base saturation, exchangeable Ca:Al ratio, exchangeable Al, Ca, Mg, Mn, and K (forest floor and 0 to 15 cm of B-horizon)	Tree growth was positively correlated to concentrations of base cations (Ca, K, and Mg) in wood and soil, and negatively correlated to concentrations of acidic metals in wood (Al, Mn, and Cd) and soil (H ⁺ and exchangeable Al). Percentage base saturation was the best predictor of BAI (nonlinear) and explained 43% of variance. Multifactorial relationships indicated that tree age and soil exchangeable Al accounted for 51% and tree age and log of the ratio of base cations (Ca + Mg + K):Al in the soluble (water and acid soluble wood extracts) fractions accounted for 46% of the variation in sugar maple BAI.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Bondi et al. (2016)	White, Green, and Adirondack Mountains (34 forest sites)	Red-backed salamander (<i>Plethodon cinereus</i>)	NA	Soil pH (Oa-horizon—on 16 sites A-horizon). Soil pH range was 2.73–5.54.	Studied the relationships between soil pH (organic horizon) and the abundance and health of red-backed salamanders. No associations between soil pH and salamander metrics (abundance, body size, and body condition) were found, and the salamanders did not appear to select habitats based on soil pH. The strongest driver of the abundance of red-backed salamanders was the presence of dusky salamanders (<i>Desmognathus</i> spp.).
Cai et al. (2017a)	Semiarid grassland Inner Mongolia, China	Grasses (<i>Agropyron cristatum</i> , <i>Stipa krylovii</i>), forbs (<i>Artemisia frigida</i> , <i>Potentilla tanacetifolia</i> , <i>Potentilla bifurca</i>)	0, 5, 10, and 15 g N/m ² /yr and two water addition treatments	Soil pH and Al plant tissue Zn, Cu, Mn, and Fe concentrations	N additions resulted in decreased pH and increased soil available Fe, Mn, and Cu concentrations, with water additions partially counteracting the impacts of N. Nitrogen additions caused higher foliar Mn, Cu, and Zn and lower Fe concentrations, resulting in micronutrient imbalances. Similar to the soils, water additions partially offset the impacts of the N additions on foliar chemistry.
Chen et al. (2013)	Grassland Mongolian steppe, China	Soil microbes (bacteria, fungi, and nematodes)	Seven treatments of S additions as sulfuric acid (0, 2.76, 5.52, 8.28, 11.04, 13.8, and 16.56 mol H ⁺ /m ²) as three additions (2009–2010)	Soil pH and extractable cations (Al, Ca, Mg, and NA; 0 to 15 cm)	Fungal fatty acids were increased by 49% and fungi:bacteria ratio increased by up to 120% by the H ₂ SO ₄ additions, relative to the controls. The H ₂ SO ₄ treatments decreased total and bacterial fatty acids by up to 47 and 40%, respectively. These responses were attributed to soil pH and Al ³⁺ concentrations. High Al ³⁺ concentrations (51 to 83 mg/kg) were associated with decreased total fatty acids and decreases in bacterial and increases in fungal fatty acids. Soil nematode numbers were initially increased by the H ₂ SO ₄ treatments followed by changes in the nematode community. The shifts in the nematode community were attributed to decreased soil pH and changes in soil moisture.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Chen et al. (2016)	Alpine grasslands and global terrestrial biomes	Soil microbes (bacteria, fungi)	NA	Soil pH	Studied the relative importance of site, biotic, and climatic factors on soil microbial communities in two alpine grasslands in the Tibetan Plateau and across global terrestrial biomes. Microbial communities were characterized by phospholipid fatty acid (PFLA) and grouped as total microbial biomass, fungal biomass, arbuscular mycorrhizal fungi biomass, actinomycete biomass, and fungal:bacterial ratio. In the Tibetan grasslands, all measures of soil microbial communities were found to be negatively related to soil pH (soil pH ranged from ~6–10) and positively correlated with soil C:N ratio (C:N ratio range of 4–15). The fungal:bacterial ratio showed a positive relationship with pH at soil pHs that ranged from 7.5–10, and negative relationship with soil C:N. Across the global biomes, total microbial biomass was also found to be positively correlated with soil C:N and negatively correlated with soil pH. Soil variables (alone) accounted for 43.4% of the variation in total microbial biomass, while climatic and biotic variables (alone) only accounted for 4.5 and 0.2% of variation, respectively.
Cleavitt et al. (2014)	Forest Hubbard Brook Experimental Forest, NH	Sugar maple	NA	Exchangeable Ca (top 5 cm of B-horizon)	Soil Ca concentration exhibited a 9x change across the study sites and was positively correlated to sugar maple abundance and initial seedling densities. However, soil Ca concentration was not a significant predictor of first-year mortality, nor was it a factor that distinguished among the three main site types.
Duchesne and Quimet (2009)	Forest Southern Quebec, Canada (426 monitoring plots)	Sugar maple and American beech	NA	Soil pH, exchangeable K, Ca, Mg, H, and Al (upper B-horizon)	The basal area of sugar maple in the sapling stratum was positively correlated with soil exchangeable Ca and Mg. Basal area of American beech in the sapling stratum was negatively correlated with exchangeable Ca and Mg. However, the basal area of sugar maple in the sapling stratum was positively correlated with both the relative basal area of dead sugar maple and sugar maple in the tree stratum. The basal area of American beech was also positively correlated with the relative basal area of American beech in the tree stratum.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Elias et al. (2009)	Forest Monongahela National Forest, WV (FIA plots)	Hardwood and conifer tree species	NA	Soil pH, base saturation, exchangeable Ca:Al (A- and B-horizons)	The study authors found that hickories were the only species to be in significantly lower numbers on sites with base saturation below 20 (A-horizon) and 2.5% (B-horizon). Percentage of dead northern red oak was highest on sites with A-horizon Al concentrations above 43 cmol/kg of soil. Soil exchangeable Ca:Al and sum of base cations in the B-horizon were highest in stands that experienced the lowest species turnover rates (1989–2000). Periodic mean annual volume increment (whole stand) was positively correlated with A-horizon base saturation (range of 5 to 77%), Ca concentrations, and exchangeable Ca:Al (range of 0.17 to 10.2) and B-horizon pH. The exchangeable Ca:Al of the A-horizon accounted for over 30% of the variation in the periodic mean annual volume increment.
Gilliam et al. (2011b)	Forest Fernow Experimental Forest, WV	Soil microbes (bacteria and fungi)	NA	Soil pH (5 cm)	Fungi were dominant at the most weathered, low NO ₃ ⁻ site, while Gram-negative bacteria were significantly higher at the less weathered, moderate and high NO ₃ ⁻ sites. Accordingly, the fungi:bacteria ratio increased in the direction of the low NO ₃ ⁻ plots in ordination space. Correlations between the soil parameters and PLFA results suggest that low soil pH and NO ₃ ⁻ concentrations supported fungal dominance, although other factors including differences in plant community and clay and organic matter content may have also influenced the soil microbial community.
Horsley et al. (2008)	Forest Pennsylvania, New York, New Hampshire, and Vermont (86 northern hardwood stands)	234 forest understory species	NA		The study authors found that a base cation-acid cation nutrient gradient accounted for 71.9% (in NH and VT) and 63% (in PA and NY) of the variation in the nonmetric multidimensional scaling ordination analyses of plant community composition. Sugar maple foliar Mg and Ca had the strongest association with the base end of the gradient. Exchangeable Al (in NH and VT) and foliar Mn (in PA and NY) were strongly associated with the acid end of the gradient. A total of 50 of the 234 understory species were associated with the base end of the base cation-acid cation nutrient gradient.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Huang et al. (2017)	Forest Eastern China	Soil microbes (Archaeal diversity)	NA	Soil pH and Al concentrations	Studied influence of Al additions on the archaeal diversity in red soils. Three Al treatments of 0, 100, or 200 mg Al/kg soil (as AlCl ₃ ·6H ₂ O); pH maintained at pretreatment level. Al additions were found to increase the abundance but decrease the evenness of the Archaea. Abundances of Crenarchaeota increased while those of Euryarchaeota decreased in response to higher Al concentrations, suggesting that Crenarchaeota is more tolerant of Al than is Euryarchaeota
Kunito et al. (2016)	Forest Japan (27 sites)	Soil microbes	NA	pH and Al (soluble and exchangeable) concentrations in 0–15 cm of soil	Evaluated the relationship between soil chemistry (Al concentrations and pH) and soil microbial biomass and enzymes involved with C, N, and P cycling (β -D-glucosidase, polyphenol oxidase, L-asparaginase, acid phosphatase). The researchers found that β -D-glucosidase and polyphenol oxidase were reduced with higher amounts of soluble and exchangeable Al, acid phosphatase shared an inverse relationship with soil pH, and L-asparaginase increased as pH increased. Microbial biomass was also found to decrease as organically bound Al and Fe increased.
Li et al. (2016a)	Natural steppe ecosystem Inner Mongolia, China	Soil microbes (bacteria)	<u>Elevated N</u> 5–15 g N/m ² /yr as urea applied in May and June since 2005	Soil pH (0–15 cm)	Evaluated: (1) the impacts of N and water additions on soil microbial community (0–15 cm of soil), (2) the linkages between the variation in belowground bacterial community and aboveground vegetation community, and (3) relationships between soil/plant factors and soil microbial community. In general, bacterial alpha diversity was positively correlated with total N and pH and negatively correlated with soil C:N ratio and concentrations of NH ₄ and NO ₃ . Beta diversity of the bacterial community was significantly correlated with C/N ratio, inorganic N, and pH. The relative abundances of Proteobacteria, Firmicutes, TM7, and OD1 increased with N addition gradient. The relative abundances of Proteobacteria Firmicutes, TM7 and OD1 were positively correlated with inorganic N and negatively correlated with soil pH.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Long et al. (2009)	Forest Pennsylvania, New York, New Hampshire, and Vermont (76 sites)	Sugar maple and black cherry	NA	Soil Ca:Al (threshold of 0.03; upper B-horizon)	Exchangeable Ca, Mg, and pH in upper B-horizon were positively correlated with sugar maple BAI growth in 1987–1996. Generally, in long-term trends (1937–1996), sugar maple in stands with below-threshold amounts of foliar Ca or Mg and above-threshold amounts of Mn had decreasing BAI trends, while stands with above-threshold Ca and Mg and below-threshold Mn showed a leveling off of the BAI. Black cherry consistently showed greater growth on stands with below-threshold foliar Ca and Mg compared with above-threshold stands. Black cherry BAI was also greater in stands with below-threshold Ca:Al molar ratios in the upper B-horizon.
Lucash et al. (2012)	Forest 19 sites in northeastern U.S. (New York and New Hampshire)	Hardwood and conifer tree species	NA	Exchangeable Ca, Mg, and Al (Oie, Oa 0 to 10 cm, 10 to 30 cm, and 30 cm to top of C-horizon)	Concentrations of Ca and Mg in foliage were correlated with exchangeable Ca and Mg concentrations in the upper mineral soil; for most tree species they were also correlated to acid-extractable Ca and Mg in the parent material (C-horizon). Foliar Al was insensitive to soil Al concentrations.
Medeiros et al. (2016)	Greenhouse study	Red maple and white oak	N and P treatments (control and low N/P—90% of control N/P levels), pH (4.5 and 6)	pH	Studied the influence of pH (simulated acid rain) on leaf, xylem, and hydraulic trait coordination responses of 1-yr old red maple and white oak seedlings in a greenhouse study. The researchers found interactions between nutrient levels and pH; low pH reduced the ability of both species to adjust xylem traits and leaf water relations (i.e., hydraulic acclimation) in response to changes in nutrient availability.
McEathron et al. (2013)	Forest Ha-De-Ron-Dah Wilderness Area in Adirondack Mountains, NY (seven subwatersheds)	Sugar maple, black cherry, American beech, red maple, and yellow birch	NA	Soil pH and exchangeable Ca and Al (0 to 10 cm mineral soil horizon)	Evaluated the relationships between species-specific basal area and soil and stream water chemistry. Sugar maple basal area was positively correlated with mineral soil pH, and yellow birch basal area was positively correlated with mineral soil exchangeable Ca. Sugar maple basal area was also negatively correlated with stream water DOC.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Mueller et al. (2016)	Sugar maple dominated forests Michigan	Soil microbes	NA	Soil pH	Studied the relationships between soil bacterial and fungal community activity and soil pH and C:N gradients in the litter from sugar maple stands in Michigan. The proportion of active bacteria were found to increase along the soil pH gradient, but decreased along the soil C:N gradient. In contrast, no significant correlations were detected for the fungal community. Similarly, no significant correlations were between temperature and the fungal or bacterial communities.
Pabian and Brittingham (2012)	Forest Pennsylvania (14 forest sites)	NA	NA	Exchangeable Ca and pH (Oa-horizon). Mean soil exchangeable Ca and pH for the 14 study sites ranged from 5.28 to 23.5 meq/100 g and 3.6 to 5.1, respectively.	Bird community composition (species richness and species abundances) varied with soil Ca and pH, with 10 bird species having the highest abundances in forests with high-Ca soils, and 5 species having the highest abundances with low-Ca soils. Bird species associated with low-Ca soils were associated with high densities of acid-loving mountain laurel (<i>Kalmia latifolia</i>) and five tree species with basal area explained by low soil pH and Ca, whereas bird species associated with high-Ca soils were associated with high densities of saplings and high basal area of acid-sensitive tree species.
Page and Mitchell (2008)	Forest Adirondack Mountains, NY (11 sites)	Sugar maple, American beech, American basswood, and white ash	NA	Exchangeable Ca, exchangeable Ca:Al (forest floor and upper [0 to 10 cm] mineral soil)	Evaluated the relationships between exchangeable soil Ca concentrations and tree basal area. There were no observed trends relating total basal area to mineral soil (0 to 10 cm) exchangeable Ca concentrations; however, the relative basal areas of sugar maple and American basswood were positively correlated with mineral soil exchangeable Ca, and relative basal area of American beech was negatively correlated. Relative basal area of white ash was not correlated to soil exchangeable Ca.
Perakis et al. (2013)	Forest Oregon (coastal range)	Douglas fir (plantations)	NA	None	Nitrate leaching (at 20 and 100 cm) increased, soil pH declined (from 5.8 to 4.2), and exchangeable soil Ca, Mg, and K decreased (10x declines) along the soil N gradient. Exchangeable Ca and Mg (in both 0 to 20 cm and 0 to 100 cm) and K (0 to 20 cm) declined with increasing nitrate leaching. Mean soil profile pH declined logarithmically with nitrate leaching at 20 and 100 cm. The sum of exchangeable Ca, Mg, and K was positively correlated with soil pH at 20 and 100 cm. Aboveground tree biomass contained an increasing percentage of total ecosystem Ca, Mg, and K as soil N increased.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Pitel and Yanai (2014)	Forest Massachusetts, Vermont, and New York	Sugar maple	NA	Soil pH, exchangeable Ca:Al, Al, and cations (Ca, Mg, K), cation (Ca, Mg, K, and total) saturation, and effective CEC (A- and upper B-horizons)	Evaluated the mortality of dominant and codominant sugar maple in 47 stands that had experienced defoliation by native forest tent caterpillar (<i>Malacosoma disstria</i>). Mortality was found to be highest in stands with the greatest amount of crown dieback the previous year. Drought, cold winter temperatures, concave microrelief and soil base cation availability were also significant predictors of mortality. Concentrations of exchangeable Ca, Mg, and K in the upper B soil horizon were inversely correlated with sugar maple mortality, with exchangeable K having the strongest relationship with mortality. Site with above-average sugar maple mortality (>3 or 4%) occurred on soils with low concentrations of exchangeable Ca (0.31 to 0.46 cmol _e /kg), Mg (0.06 to 0.10 cmol _e /kg), and K (0.03 to 0.05 cmol _e /kg). Stands defoliated in 2005 that had low Mg saturation (A-horizon) suffered higher rates of mortality, suggesting an interaction between low base cations and defoliation events.
Sridevi et al. (2012)	Forest Hubbard Brook Experimental Forest, NH	Soil microbes (bacteria)	NA	Soil pH, exchangeable cations, Al, Fe, P, Mn, Zn, exchangeable acidity, and CEC (0 to 15 cm)	Ca additions of 1,000 kg Ca/ha applied in 1999. The bacterial community structure in the Ca treated and nontreated reference soils was found to be significantly different, with differences among communities being more pronounced in the mineral soils. Calcium additions resulted in a change in bacterial community composition of 23% in the organic and 22% in the mineral soil horizons. Numbers of detectable taxa in some families were lower in the Ca amended soils, while some families were higher. Analyses of relationships between soil chemistry and the bacterial communities indicated that only Ca, pH, and P were significantly correlated with bacterial community structure.
Stevens et al. (2010b)	Grassland U.K. (68 sites)	Grassland species	6.2 to 36.3 kg N/ha/yr Centre for Ecology and Hydrology (CEH) National Atmospheric Deposition Model	Ellenberg R (reaction-soil pH) and N (soil nutrient) scores	Data from a national survey were used to evaluate species richness of 68 U.K. grasslands along an N deposition gradient. The results suggest that soil acidification (instead of eutrophication) was contributing to changes in species diversity and composition. Soil acidification may have led to reduced nutrient availability and increased Al solubility preventing the “fertilizing” effects of N addition from being apparent.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Sullivan et al. (2013)	Forest Adirondack Mountains, NY (50 plots in 20 small watersheds with sugar maple overstory)	Sugar maple	75 to 112 meq/m ² /yr as N + S NADP (wet deposition); CASTNET (dry deposition) 2000–2004 (average)	Soil pH, exchangeable Ca, exchangeable Mg, and base saturation (forest floor, A- and upper B- (0 to 10 cm) horizons)	The study found that plots with lower soil base saturation did not have sugar maple regeneration (these same plots also received higher N and S deposition levels); proportion of sugar maple seedlings dropped substantially at base saturation levels less than 20%. Canopy vigor was positively correlated with soil pH and exchangeable Ca and Mg. Mean growth rates (BAI) were positively correlated with exchangeable Ca and base saturation at the watershed level.
Tian et al. (2016b)	Temperate steppe Inner Mongolia, China	Grassland species; <i>Stipa krylovii</i> and <i>Artemisia frigida</i>	<u>Elevated N</u> 9 yr of urea additions at 0, 1, 2, 4, 8, 16, 32, and 64 g N/m ² /yr	Soil pH, exchangeable Mn and Al (three soil depths: 0–10, 10–20, 20–30 cm)	Long-term N additions increased total above-ground plant biomass but decreased species richness; N additions significantly reduced forb species richness, while the diversity of grass species was not affected. Soil chemistry was influenced by the N additions; soil pH was reduced and concentrations of exchangeable Mn, ferric Fe, and Al were increased. Foliar concentrations of Mn in both <i>A. frigida</i> and <i>S. krylovii</i> were increased by N additions. A greenhouse study showed that the biomass of <i>A. frigida</i> seedling shoots and roots were significantly reduced with MnCl ₂ additions, but the treatments had no effect on <i>S. krylovii</i> seedlings.
Tu et al. (2016)	Forest types across North America	Soil diazotrophs (N ² fixing microbes)	NA	Soil pH (0–10 cm)	The soil diazotrophic community structure was found to differ significantly across the six forests; lower microbial spatial turnover and greater community diversity were found in rainforests relative to temperate forests. In addition, community diversity was strongly correlated with latitude, mean annual temperature, plant species richness, and total annual precipitation. Diazotrophic community diversity was weakly correlated with soil pH and moisture.
Ying et al. (2017)	Grassland Inner Mongolia, China	Soil microbes (ammonia-oxidizing bacteria and Archaea)	<u>Elevated S</u> H ₂ SO ₄ additions started in 2009; 0, 2.76, 5.52, 8.28, 11.04, 13.80, 16.56 mol H/m ²	Soil pH and NH ₄ ⁺ -N and NO ₃ ⁻ -N	Study evaluated the impacts of soil pH on the abundance and structure of soil ammonia-oxidizing bacteria (AOB) and Archaea (AOA) communities. Decreasing soil pH was found to be correlated with decreases in AOB abundance (pH range of 5.0–7.3) and increases in AOA (pH range of 5.3–7.3) abundance, except at the lowest pH (pH 5.0), which negatively influenced AOA abundance. Soil acidification did not significantly influence AOA or AOB community composition.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Yuan et al. (2016)	Alpine tundra Niwoot Ridge, Colorado Rocky Mountain National Park	Soil bacteria	<u>Elevated N</u> 20 yr of N and P additions—0 and 20 g N/m ² /yr and 0 and 2 g P/m ² /yr (1993–1995), 0 and 10 g N/m ² /yr and 2 g P/m ² /yr (1996–1997), same application rates every 2 yr (1998–2009), 10 g N/m ² /yr was added as Ca(NO ₃) ₂ to address soil acidification	Soil pH (0–10 cm)	Soil bacterial communities differed by plant community type, with bacterial alpha diversity being significantly correlated with plant richness and production of forbs. N additions also influenced soil bacteria, with bacterial communities treated with N (and N + P) being significantly different than those in the control and P treatments. Chloroflexi and Bacteroidetes responded positively to the additions of N, while Acidobacteria and Verrucomicrobia responded negatively to N. The N additions resulted in reduced soil pH; from wet to dry systems, the relative importance of N additions on soil pH increased. Of the soil variables, pH shared the strongest correlations with plant and bacterial diversity metrics. Structural equation modeling showed that the indirect effects (as opposed to direct effects) of N additions—changes in soil pH and plant communities—were the strongest determinants of soil bacterial community responses.
Zeng et al. (2016)	Temperate steppe Inner Mongolia, China	Soil microbial communities	<u>Elevated N</u> 6 yr of NH ₄ NO ₃ additions at 0, 60, 120 and 240 kg N/ha/yr	Soil pH (0–10 cm and 10–20 cm)	Plant community biomass was found to significantly increase, species richness decrease, and N concentrations increase with N additions. Seven bacterial phyla (mainly rare phyla) in the 0–10cm soil depth were significantly changed with N additions, while only 1 phylum in the 10–20-cm depth was affected by the additions of N. Hierarchical structural equation modeling revealed that changes in bacterial community composition were due to changes in soil pH and plant composition, while shifts in bacterial richness were attributed to NH ₄ concentrations.

Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
Zhang et al. (2016b)	Temperate steppe Inner Mongolia, China	57 vascular plant species	Elevated N 6 yr of NH ₄ NO ₃ additions at 0, 1, 2, 3, 5, 10, 15, 20, and 50 g N/m ² /yr (2x and 12x per year)	Soil pH (0–10 cm)	N additions, at both frequencies, significantly decreased the number of new species gained and increased the number of old species lost. However, the number of new species gained was lower on the low frequency of N addition plots compared to the high frequency, while the number of old species lost was not affected by N addition frequencies. There was a negative correlation between the cumulative gain of new species and soil pH, NH ₄ concentrations and community biomass accumulation, while cumulative loss of old species was positively correlated with these variables.
Basto et al. (2015b)	Grassland Peak District National Park, U.K.	261 grassland species; seed bank	NA	Soil pH (gradient with soil pH range of 3.5 to 6.5)	Studied seed bank and seed germination, viability, and damage (through seed burial experiment conducted with <i>Scabiosa columbaria</i> , <i>Hypericum pulchrum</i> , and <i>Campanula rotundifolia</i>) along a natural pH gradient from acidic to calcareous grasslands. Increasing soil pH was found to be correlated with decreases in total and grass seed abundance, declines in the persistence of <i>H. pulchrum</i> seed, and declines in damage to <i>C. rotundifolia</i> seed. Seed germination was not influenced by pH. In soil with pH higher than 5.6, indirect effects of pH (through increased fungal pathogens) appeared to decrease the persistence of the seed of all three grassland species. This study suggested that: acidic soils are associated with increased seed persistence; the longevity and size of grassland seed banks decline as soil pH increases; and that pH indirectly influences seed persistence.

Al = aluminum; BAI = basal area increment; Ca = calcium; CASTNET = Clean Air Status and Trends Network; Cd = cadmium; CEC = cation exchange capacity; CEH = Centre for Ecology and Hydrology; cm = centimeter; DOC = dissolved organic compound; Fe = iron; FIA = Forest Inventory and Analysis; g = grams; H⁺ = hydrogen; ha = hectare; K = potassium; kg = kilograms; m = meter; meq = milliequivalent; mg = milligrams; Mg = magnesium; Mn = manganese; mol = mole; N = nitrogen; NA = not applicable; NADP = National Acid Deposition Program; P = phosphorus; PLFA = phospholipid fatty acid; NO₃⁻ = nitrate; S = sulfur; SO₄²⁻ = sulfate; yr = year; Zn = zinc.

APPENDIX 6. TERRESTRIAL ECOSYSTEMS: NITROGEN ENRICHMENT EFFECTS ON ECOLOGICAL PROCESSES

1 [Appendix 5](#) examined the biological effects of terrestrial acidification from nitrogen (N)
2 and sulfur (S) deposition. This appendix characterizes the biological effects of terrestrial
3 N enrichment that can be caused by atmospheric N deposition. Following an introduction
4 ([Appendix 6.1](#)), this appendix is composed of five major sections: effects on physiology,
5 growth, and productivity ([Appendix 6.2](#)); changes in biodiversity and community
6 composition ([Appendix 6.3](#)); climate modifications of N enrichment effects
7 ([Appendix 6.4](#)); critical loads ([Appendix 6.5](#)); and a summary ([Appendix 6.6](#)). The first
8 two sections begin with an introduction ([Appendix 6.2.1](#) and [Appendix 6.3.1](#)) reviewing
9 the previous causal determination and presenting the current causal determination.
10 Following this introduction, an overview is presented of the mechanisms operating across
11 ecosystems to link N enrichment to biological change ([Appendix 6.2.2](#) and
12 [Appendix 6.3.2](#)). [Appendix 6.2](#), [Appendix 6.3](#), and [Appendix 6.5](#) are further divided into
13 subsections based on ecosystem type (e.g., forests, grasslands, etc.) or functional group
14 (e.g., lichens, trees, herbaceous plants). Finally, [Appendix 6.6](#) provides a summary of the
15 new information generated since the *2008 ISA for Oxides of Nitrogen and*
16 *Sulfur—Ecological Criteria* (hereafter referred to as the “2008 ISA”).

6.1. Introduction

17 Nitrogen (N) is a key element required by all organisms in order to build amino acids and
18 nucleic acids, the basic biochemical subunits needed to synthesize the proteins, enzymes,
19 RNA, and DNA sustaining all biological processes. By the second half of the 19th
20 century, before these biochemical pathways had been identified, it was already
21 understood that N was a component of plant and animal tissues and a supply of N was
22 essential for plant growth ([Galloway et al., 2004](#)). Indeed, the ability of added N to
23 stimulate plant growth had been recognized by science (and commerce) for over a
24 century ([Galloway et al., 2004](#); [Galloway and Cowling, 2002](#)) prior to the 2008 ISA. By
25 2008, it was already clear that N availability broadly limited productivity in terrestrial
26 ecosystems.

27 By 2008, it was also clear N availability could alter the biodiversity of terrestrial
28 ecosystems. Broadly, the effects of N deposition on the diversity of terrestrial ecosystems
29 stem from four mechanisms [*sensu* ([Bobbink et al., 2010](#))]: (1) eutrophication,
30 (2) acidification, (3) direct toxicity and damage, and (4) increased susceptibility to

1 secondary stress. Multiple mechanisms likely operate simultaneously to alter diversity
2 within a particular community or ecosystem. As described in [Appendix 5](#), N deposition
3 may lead to soil acidification, which can have negative effects on plants and
4 microorganisms. Direct toxicity and damage from N deposition often comes from an
5 accumulation of NH_4^+ in soils and plant tissues. Increased susceptibility to secondary
6 stressors includes greater impacts of pathogens ([Bobbink et al., 2010](#)) and shifts in
7 herbivory as a result of altered tissue chemistry([Throop and Lerdau, 2004](#)). Among these
8 four major mechanisms, eutrophication is perhaps the most complex because it can
9 change the physiology of individual organisms, alter the relative growth and abundance
10 of species, transform relationships between species, and indirectly affect the availability
11 of other essential resources such as light, water, and nutrients [([Hautier et al., 2009](#); [Clark
12 et al., 2007](#); [Suding et al., 2005](#)); see also [Appendix 4](#)]. These can lead to biodiversity
13 shifts, including community compositional changes, the loss of species, and decline in
14 species richness.

15 Since the 2008 ISA, the effects of N deposition on terrestrial ecological processes and
16 biodiversity have continued to be widely studied. With the increasing volume of research,
17 a number of new studies have been conducted using meta-analysis to synthesize
18 published observations or using continental or global data sets to understand broad-scale
19 patterns. New studies have provided a more detailed understanding of how N influences
20 terrestrial ecosystem growth and productivity; community composition and biodiversity;
21 and sensitive organisms and ecosystems. Further, a large body of work has been
22 published on critical loads (CLs) for N since 2008. Together with the information
23 available in the 2008 ISA, **this body of evidence is sufficient to infer a causal
24 relationship between N deposition and (1) the alteration of the physiology and
25 growth of terrestrial organisms and the productivity of terrestrial ecosystems; and
26 (2) the alteration of species richness, community composition, and biodiversity in
27 terrestrial ecosystems.**

6.2. Linking Nitrogen Deposition to Changes in Physiology, Growth, and Productivity in Terrestrial Ecosystems

6.2.1. Introduction

28 In the 2008 ISA, evidence was sufficient to infer a causal relationship between N
29 deposition and the alteration of the terrestrial carbon (C) and N biogeochemical cycles.
30 These effects included not only changes in soil C and N pools and fluxes (described in
31 [Appendix 4](#)), but also significant alterations of plant and microbial growth and

1 physiology. The 2008 ISA built upon the conclusions of the 1993 Oxides of Nitrogen Air
2 Quality Criteria Document. By 1993, a series of hypotheses regarding the effects of
3 chronic N deposition on northern temperate forests had already been developed from
4 early field observations ([Aber et al., 1989](#)). Briefly, N deposition was expected to
5 increase tree growth in most forests, but once plant demand for N had been satisfied
6 (biological and physical sinks had reached “N saturation”), further N deposition could
7 lead to nitrification, soil cation leaching, acidification, nutrient deficiencies, and
8 decreased tree growth ([Aber et al., 1989](#)) (described in [Appendix 4](#) and [Appendix 5](#)). A
9 revised form of these N saturation hypotheses ([Aber et al., 1998](#)) provided much of the
10 conceptual foundation in the 2008 ISA for understanding how N deposition influenced
11 plant physiology, growth, and ecosystem productivity.

12 The effects of N deposition on terrestrial ecological processes have been widely studied
13 since 2008. Research on N deposition has continued in North America and Europe, with
14 other areas receiving less attention [e.g., temperate forests in Asia and the Southern
15 Hemisphere ([Gilliam, 2016](#))]. A significant new body of research has developed in the
16 boreal, arid, and subtropical ecosystems of Asia, particularly in China [e.g., ([Zhang et al.,
17 2015e](#); [Du et al., 2014a](#); [Du et al., 2014b](#); [Du and Fang, 2014](#); [Sun et al., 2014](#))]. New
18 meta-analyses have provided a more detailed understanding of how added N affects
19 productivity responses in different biomes ([LeBauer and Treseder, 2008](#)), growth among
20 plant functional types ([Xia and Wan, 2008](#)), growth of individual plant parts ([Xia and
21 Wan, 2008](#)), root growth ([Li et al., 2015](#)), and ecosystem C storage ([Liu and Greaver,
22 2009](#)), while other broad-scale analyses have examined changes in plant N concentrations
23 ([Xia and Wan, 2008](#)), microbial biomass ([Treseder, 2008](#)), and belowground C cycling
24 ([Liu and Greaver, 2010](#)). This expanded body of research has created a better
25 understanding of how N influences processes at molecular to global scales. Together with
26 the information available in the 2008 ISA, this body of evidence is sufficient to infer a
27 causal relationship between N deposition and the alteration of the physiology and growth
28 of terrestrial organisms and the productivity of terrestrial ecosystems.

6.2.2. Mechanisms Operating across Terrestrial Ecosystems

29 The 2008 ISA evaluated a large number of studies assessing how N deposition has
30 changed terrestrial C cycling and found an array of ecological responses. The most
31 extensive evidence of the effect of N deposition on C cycling was available for forests in
32 North America and Europe. In experimental N addition studies, moderate to high
33 additions of N led to either no significant change in tree growth rates or transient growth
34 increases (generally at deposition rates lower than 10 kg N/ha/yr), followed by increased
35 mortality, especially at higher rates of N addition. This group of studies showed

1 coherence in effects and indicated the presence of a biological gradient in responses with
2 increasing N deposition.

3 Some of the broad-scale changes caused by N additions to terrestrial ecosystems have
4 been quantified by meta-analysis, a data synthesis tool that started to become common in
5 ecological research beginning in the late 1990s ([Gurevitch et al., 2001](#)). Using this tool to
6 understand the effects of N additions on herbaceous plant communities, ([Gough et al.,
7 2000](#)) found that N additions stimulated aboveground plant productivity by an average of
8 53%. In a broader synthesis, ([Elser et al., 2007](#)) conducted a meta-analysis of N addition
9 effects on plant community productivity and observed average increases in productivity
10 of 20–30% in grasslands, forests, tundra, and wetlands. In addition to changes in plant
11 growth, ([Koricheva et al., 1998](#)) identified via meta-analysis that added N could alter the
12 chemistry of plant tissues, including increasing tissue concentrations of N and free amino
13 acids, while decreasing concentrations of starch and C based secondary compounds
14 (important for defense against herbivores), including phenylpropanoid compounds. In a
15 meta-analysis of the belowground effects of N, [Treseder \(2004\)](#) found N additions
16 decreased both the abundance of mycorrhizal fungi and the percentage of plant roots
17 colonized by mycorrhizal fungi. In addition, multiple lines of evidence showed that N
18 deposition increases the performance of insect herbivores, and potentially, insect
19 populations ([Throop and Lerdau, 2004](#)). In a synthesis of 500 observations of the effect
20 of N on litter decomposition rates, [Knorr et al. \(2005\)](#) found that added N stimulated
21 decomposition at sites with low rates of ambient N deposition (<5 kg N/ha/yr), but
22 slowed decomposition at sites with moderate rates of N deposition [5–10 kg N/ha/yr;
23 [Knorr et al., 2005](#)] and that N additions at rates from 2 to 20 times ambient N
24 deposition inhibited decomposition by 8 to 16%.

25 These changes can cause a cascade of ecological consequences. For instance, the
26 inhibition of decomposition can increase soil C content, but the accumulation of plant
27 litter on the soil surface can inhibit the establishment of some plant species ([Patterson et
28 al., 2012](#); [Cleavitt et al., 2011b](#); [Xiong and Nilsson, 1999](#); [Facelli and Pickett, 1991](#)). In
29 the western U.S., [Fenn et al. \(2003a\)](#) suggested greater plant growth caused by N
30 deposition could increase plant litter accumulation, in turn increasing the susceptibility of
31 forests and other wildlands to severe wildfires. Nitrogen deposition also affects the
32 patterns of C allocation because most of the additional plant growth occurs aboveground.
33 This increases the shoot-to-root ratio, which can be detrimental to plants because of
34 decreased resistance to environmental stressors, such as drought and wind ([Braun et al.,
35 2003](#); [Krupa, 2003](#); [Minnich et al., 1995](#); [Fangmeier et al., 1994](#)). Thus, it was recognized
36 in the 2008 ISA that the effects of N deposition on biological and ecological processes in
37 terrestrial ecosystems were pervasive, complex, and difficult to fully understand and
38 predict.

1 Although evidence showed plant productivity responses to N deposition as of the 2008
2 ISA, the extent to which N increased forest C content in C budget measurements
3 (quantified input and output of C to the ecosystem) was uncertain. A prominently
4 reported estimate of >600 kg C sequestered per kg of N deposited to forests, which was
5 based on a regional gradient technique ([Magnani et al., 2007](#)), was widely criticized.
6 Subsequent reassessments of these data suggested that forest C sequestration was an
7 order of magnitude lower ([Sutton et al., 2008](#)). [Liu and Greaver \(2009\)](#) found in a
8 meta-analysis that N additions ranging from 25.5 to 200 kg N/ha/yr increased forest
9 ecosystem C content (+6%).

10 In addition, fewer studies had examined the effects of N deposition on the eutrophication
11 of nonforested ecosystems. [Mack et al. \(2004\)](#) examined C and N pools in a long-term N
12 addition experiment at the Arctic Long-Term Ecological Research site near Toolik Lake,
13 AK. Plant growth increased as a result of N additions, but the N additions enhanced
14 decomposition of belowground C pools in deep soil layers more than it increased primary
15 production, leading to a substantial net loss of C from this ecosystem. More broadly, [Liu](#)
16 [and Greaver \(2009\)](#) conducted a meta-analysis of 16 observations from nine publications
17 to evaluate the relationship between N addition (16 to 320 kg N/ha/yr) and C
18 sequestration in nonforest ecosystems and did not find a significant effect on net
19 ecosystem exchange (NEE, kg C/ha/yr).

20 [Xia and Wan \(2008\)](#) identified nearly 1,600 observations of plant biomass growth in
21 response to N additions, excluding agricultural and horticultural species ([Figure 6-1A](#)).
22 Overall, plant biomass increased by 54%, with a larger gain in seeded plants (+55%) than
23 spore plants (+21%; not shown). Among the seeded plants, grasses showed the largest
24 biomass response, followed by trees, forbs, and shrubs. Annual herbs (+92%) showed a
25 stronger response than perennial herbs (+56%). Overall, biomass responses to N
26 increased linearly with mean annual precipitation (MAP). The studies included in the
27 analysis had addition rates ranging from 10 kg N/ha/yr to 1,000 kg N/ha/yr. When the N
28 additions were divided into low (<100 kg N/ha/yr) and high (>100 kg N/ha/yr) groups,
29 there were only a few differences among functional groups. The response of woody
30 species was lower than for herbaceous species at the low addition rate (+25 vs. +51%),
31 but the groups had similar responses at the high N addition rate. Among herbaceous
32 plants, both legumes and nonlegumes had positive responses to low rates of N additions
33 (19 and 23%, respectively), while the high rate of N additions increased nonlegume
34 biomass (+43%), but did not significantly affect legume growth. The authors also
35 examined how these responses varied in response to the rate of N additions. The N
36 addition studies were divided into 50 kg N/ha/yr increments from 0 to 300 kg N/ha/yr,
37 but aside from increasingly positive growth responses for trees and woody plants with
38 greater N additions, there were few apparent trends, and sample sizes were inconsistent.

1 In their analysis, [Xia and Wan \(2008\)](#) separated plant growth data into aboveground
2 (887 observations) and belowground (340 observations) components. Across almost all
3 functional groups, there were greater increases in biomass in aboveground than
4 belowground components ([Figure 6-1A](#)) (see also [Appendix 4](#)). In a subsequent
5 meta-analysis of plant C pools, [Lu et al. \(2011b\)](#) also found that N additions to plants in
6 nonagricultural systems stimulated shoot C by 28.5% (n = 146) and root C by 20%
7 (n = 77). These results indirectly suggest that plant C allocation changes in response to N
8 addition. These changes were also shown by a more direct analysis of a much smaller
9 meta-analysis data set (n = 15) in which [Li et al. \(2015\)](#) observed a significant 11%
10 decrease in the root:shoot biomass ratio. Together, these results provide further support to
11 the conclusion in the 2008 ISA that N additions can alter plant C allocation and result in
12 elevated shoot:root ratios. Further, [Lu et al. \(2011b\)](#) analyzed the response of some
13 individual plant parts to added N and observed a 1.6% increase in leaf C mass.

14 Belowground processes are important components of terrestrial ecosystems. As detailed
15 in [Appendix 5](#), soils are often the largest ecosystem pools of both C and N; soil
16 respiration can be the largest ecosystem efflux of CO₂; and soils can be important sources
17 and sinks for the greenhouse gases N₂O and CH₄. Biologically, the large C fluxes plants
18 allocate belowground for root exudation, the growth and maintenance of roots, and the
19 support of mycorrhizal fungi help support complex belowground foodwebs. Less
20 information is available about belowground responses to N additions than aboveground
21 responses. However, [Li et al. \(2015\)](#) recently conducted a meta-analysis of how root traits
22 respond to N additions. Notably, [Li et al. \(2015\)](#) found that although total root biomass
23 increased (+20%; n = 74), fine root biomass declined (-13%; [Figure 6-2B](#)). This
24 discrepancy is apparently accounted for by an increase in the biomass of coarse roots
25 (+57%; n = 7), which are typically structural and conductive tissues. Morphological traits
26 of fine roots, such as length (n = 25), diameter (n = 10), and specific root length (n = 22),
27 were unaffected by N additions. Fine root turnover rate was 21% higher (n = 12), but fine
28 root production was not significantly affected by the N additions [n = 22; ([Li et al.](#),
29 [2015](#))].

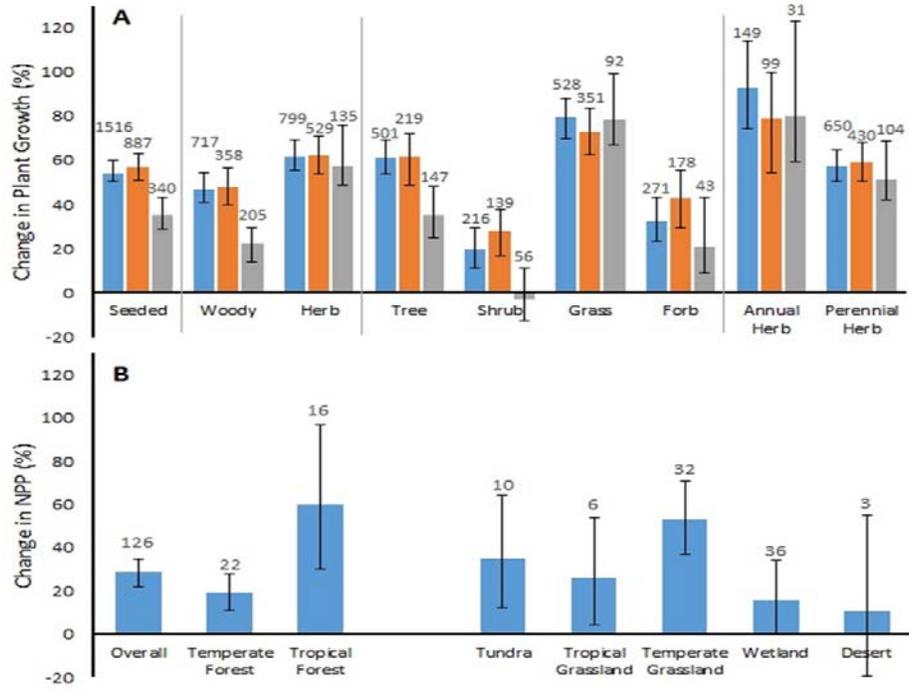

30 Aboveground net primary productivity (NPP), which measures aboveground plant growth
31 at the community scale, was less responsive on average (+29%) than individual plant
32 growth to N additions [([LeBauer and Treseder, 2008](#)); [Figure 6-1B](#) and [Figure 6-2A](#)].
33 Consistent with the plant functional group analysis conducted by [Xia and Wan \(2008\)](#),
34 [LeBauer and Treseder \(2008\)](#) observed a large stimulation of aboveground NPP in
35 grass-dominated ecosystems such as temperate grasslands (+53%), tropical grasslands
36 (+26%), and tundra (+35%), whereas NPP increased only 19% in temperate forests.
37 There were also significant NPP increases in tropical forests and wetlands. Added N did

1 not significantly increase NPP in deserts, but the analysis only included three
2 observations.

3 More recently, [Tian et al. \(2016a\)](#) synthesized aboveground NPP data from studies that
4 had experimentally added N at more than one rate in order to examine how plant growth
5 responses per unit N changed with increasing levels of N. Their metric, termed “N
6 response efficiency” ($100\% \times [\text{ANPP}_{\text{treatment}} - \text{ANPP}_{\text{control}}] / \text{ANPP}_{\text{control}} / \text{N addition rate}$) did
7 not significantly differ across the three ecosystem types (wetlands, forests, grasslands),
8 with an average increase of 3 to 4% in NPP per g of added N. The N response efficiency
9 decreased with N addition rates above 50 kg N/ha/yr, consistent with a saturating
10 response to N.

11 [Liu and Greaver \(2009\)](#) had smaller data sets, with 16 observations of net ecosystem
12 exchange (NEE; all in nonforested systems) and 17 observations of ecosystem C content
13 ([Figure 6-2](#)). There were no significant effects of added N on NEE overall or within the
14 individual biomes included in the analysis (grasslands, wetlands, tundra). However,
15 added N did increase forest ecosystem C content by 6%. Belowground NPP responses
16 have not been synthesized, at least in part, because data are lacking ([LeBauer and](#)
17 [Treseder, 2008](#)).

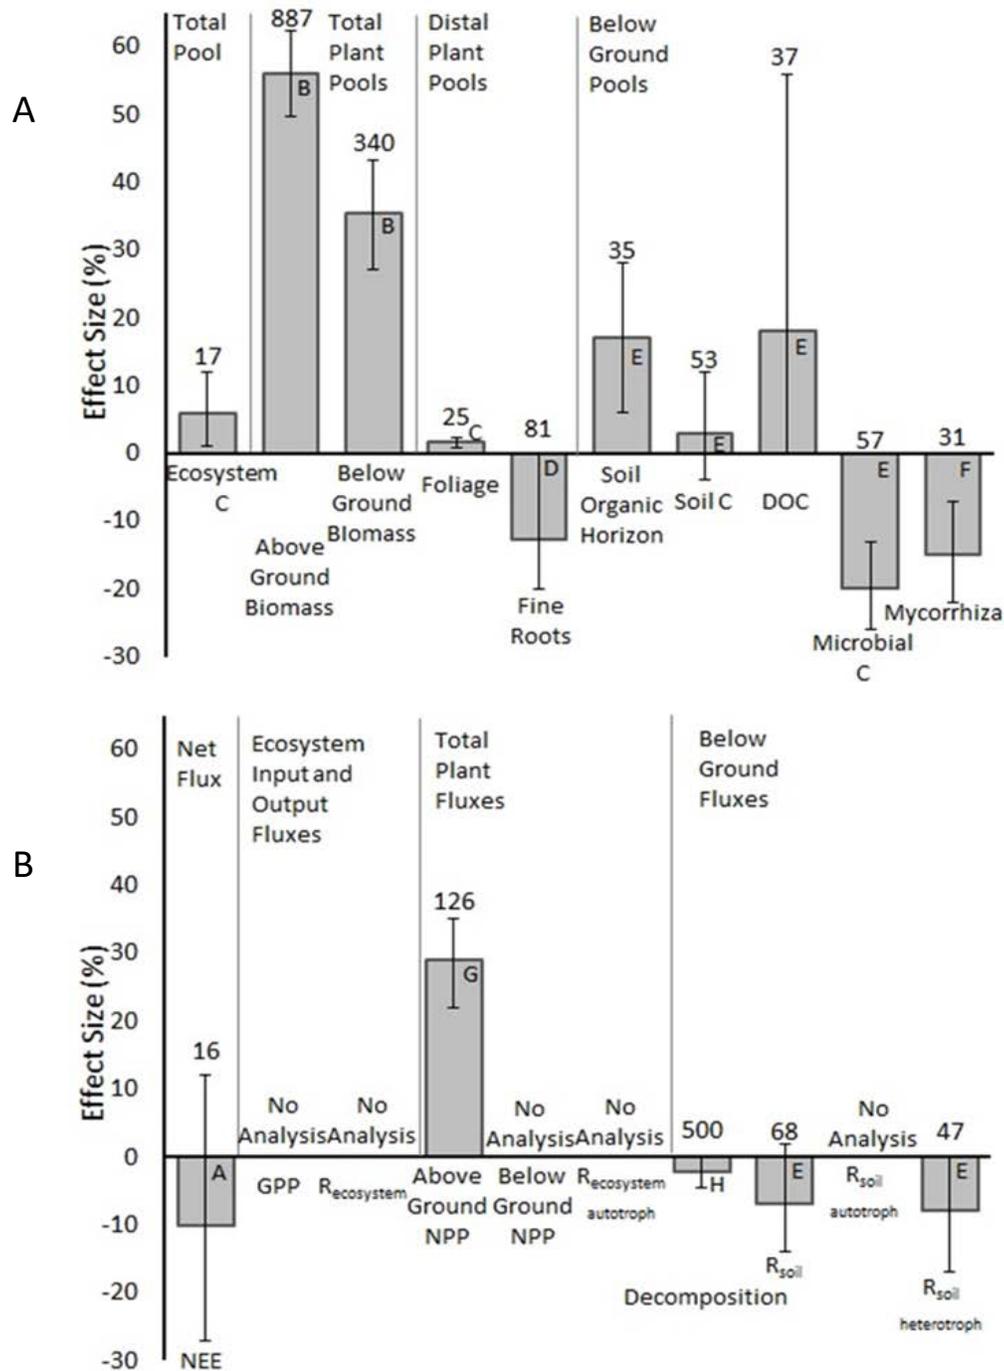

18 In terms of altered physiology, there is also widespread evidence that N additions
19 increase plant tissue N concentrations. The meta-analysis by [Xia and Wan \(2008\)](#)
20 included changes in plant N concentrations overall, aboveground, and belowground.
21 Overall, N additions increased plant N concentrations by an average of 28.5% ([Xia and](#)
22 [Wan, 2008](#)). Although there was significant variation among plant functional groups, the
23 average increase in tissue N concentration among seeded plants was much more similar
24 across functional groups than the biomass growth response, ranging only from +24 to
25 +35% once legumes (+7%) and the two broader functional groups containing legumes
26 (forbs, +14%; perennial herbs: +22%) were excluded. Likewise, belowground and
27 aboveground plant tissues had a similar change in N concentration, in contrast to the
28 varying biomass growth responses to N ([Xia and Wan, 2008](#)). [Li et al. \(2015\)](#) also
29 observed that N additions significantly increased root N concentrations in a root trait
30 meta-analysis (+18%; n = 84). Because of these increased N concentrations, N additions
31 can significantly decrease plant C:N ratios ([Yue et al., 2017](#)).

NPP = net primary productivity.

Notes: (A) Mean change in plant biomass growth in response to N additions redrawn from [Xia and Wan \(2008\)](#), with blue bars representing the overall response, orange bars representing aboveground growth, and grey bars representing belowground growth. Vertical grey lines identify different ways the data were parsed (i.e., all seeded plants; woody vs. herbaceous plants, etc.). (B) Mean change in aboveground net primary productivity, from [LeBauer and Treseder \(2008\)](#). Error bars represent the 95% confidence interval. Numbers above the error bars indicate the number of observations included in the analysis.

Figure 6-1 Effects of nitrogen additions on plant growth and net primary productivity.

DOC = dissolved organic carbon, NEE = net ecosystem exchange, GPP = gross primary production, R_{ecosystem} = ecosystem respiration, NPP = net primary production; R_{ecosystem autotroph} = plant respiration, R_{soil} = soil respiration, R_{soil heterotroph} = heterotroph soil respiration.

Notes: mean effect sizes from meta-analyses of N addition experiments on ecosystem, plant, and soil pools ([a] top panel) and fluxes ([b] bottom panel). Error bars represent 95% confidence intervals. Numbers above the bars are the sample sizes for each analysis. Letter with each bar denote the data source. No Analysis denotes a pool or flux that has not yet been meta-analyzed.

Data sources: (A) [Liu and Greaver \(2009\)](#), (B) [Xia and Wan \(2008\)](#), (C) [Lu et al. \(2011b\)](#); (D) [Li et al. \(2015\)](#); (E) [Liu and Greaver \(2010\)](#), (F) [Treseder \(2004\)](#); (G) [LeBauer and Treseder \(2008\)](#); (H) [Knorr et al. \(2005\)](#).

Figure 6-2 Effects of added nitrogen on ecosystem carbon pools and fluxes.

1 The 2008 ISA linked enhanced terrestrial productivity to increases in photosynthesis and
2 gross primary productivity. Gross primary productivity (GPP) can increase as a result of
3 either a greater amount of photosynthetic tissue (more light absorption) or a higher rate of
4 photosynthesis per leaf. There is a strong mechanistic and conceptual link between
5 greater foliar N concentrations, higher leaf concentrations of the C assimilating enzyme
6 rubisco ([Evans, 1989](#)), and greater maximum rates of leaf-level photosynthesis in
7 vascular plants ([Wright et al., 2004](#)). Consequently, the increase in foliar N caused by N
8 additions has been linked to increases in the leaf-level rate of photosynthesis for decades
9 [e.g., ([Teskey et al., 1994](#)) and references therein]. Alternately, evidence cited in the 2008
10 ISA suggests that much of the increased foliar N observed when N is added may be
11 physiologically inactive because it manifests as an increase in storage compounds such as
12 free amino acids ([Bauer et al., 2004](#)). While increases in photosynthesis in response to N
13 additions have been observed in trees, grasses, and shrubs, these increases have not been
14 consistent [e.g., ([Pivovarov et al., 2016](#); [Talhelm et al., 2011](#); [Elvir et al., 2006](#); [Chen et](#)
15 [al., 2005b](#); [Newman et al., 2003](#); [Lajtha and Whitford, 1989](#); [Gulmon and Chu, 1981](#))]
16 and there does not appear to be a meta-analysis or other synthesis on the response of
17 leaf-level photosynthesis or GPP ([Figure 6-2B](#)) to N additions. Similarly, there is a strong
18 fundamental relationship between tissue N concentration and respiration rates in plants
19 ([Reich et al., 2008](#); [Reich et al., 2006](#); [Ryan et al., 1996](#)), such that this relationship is
20 used to model respiration rates [e.g., ([Hanson et al., 2004](#); [Amthor, 2000](#))]. However,
21 there is evidence that this relationship can breakdown in N addition studies [e.g., ([Burton](#)
22 [et al., 2012](#); [Drake et al., 2008](#); [Schaberg et al., 1997](#))], and there are currently no broad
23 analyses on the effects of N additions on ecosystem or plant-scale autotrophic respiration
24 ([Figure 6-2B](#)).

25 The 2008 ISA noted some observations of decreased microbial biomass as a result of
26 added N, particularly for mycorrhizal fungi [([Treseder, 2004](#)); [Figure 6-2B](#)]. Since 2008,
27 however, it has become increasingly clear that N deposition can greatly impact microbial
28 communities, often including a decrease in microbial biomass. Meta-analyses conducted
29 across all ecosystem types have found that N additions can decrease microbial biomass
30 ([Treseder, 2008](#)), microbial biomass C ([Liu and Greaver, 2010](#)), and microbial biomass N
31 ([Lu et al., 2011b](#)) and that the effects of added N on microbial biomass increase with the
32 duration of N additions and the total amount of N added ([Treseder, 2008](#)). These changes
33 are noteworthy given the diverse role of microorganisms in nutrient cycling, greenhouse
34 gas fluxes, and other ecosystem services. Although N additions frequently decrease
35 microbial biomass, the results are not always consistent ([Liu and Greaver, 2010](#);
36 [Treseder, 2008](#)). The effects of N were not significant at the level of individual microbial
37 domains (bacteria, fungi), although there were trends toward increasing negative effects
38 of N additions on fungal biomass as duration and cumulative N load increased ([Treseder,](#)
39 [2008](#)). In a meta-analysis, [Carey et al. \(2016\)](#) observed that N additions increased the

1 abundance of ammonia-oxidizing bacteria across nonagricultural ecosystems, but did not
2 affect the abundance of ammonia-oxidizing archaea. Recently, [Li et al. \(2015\)](#) provided a
3 new meta-analysis of N addition effects on mycorrhizal colonization of fine root tips and
4 observed an overall 17% decline (n = 21). While this reinforces the conclusions of an
5 earlier meta-analysis by [Treseder \(2004\)](#), there are important qualifiers to this finding: the
6 sample only included observations from forests and grasslands in temperate and
7 subtropical climates; significant decreases were only observed in temperate and forested
8 ecosystems, after more than 3 years of N additions, or at N addition rates
9 >100 kg N/ha/yr ([Li et al., 2015](#)).

10 Changes in mycorrhizae in turn can affect plant productivity. Mycorrhizal fungi provide
11 benefits to plants, yet also carry costs. In exchange for nutrients and water from the
12 fungus, the plant provides C from photosynthesis ([Högberg et al., 2010](#); [Rillig, 2004](#)). In
13 many cases, this tradeoff works to the plant's advantage. For instance, [Van Der Heijden](#)
14 [et al. \(1998\)](#) observed higher biomass for most of the individual plant species in their
15 study when inoculated with arbuscular mycorrhizae versus when mycorrhizae were
16 absent. They suggested the mycorrhizal acquisition of a limiting nutrient, in this case
17 phosphorus (P), for the plant in exchange for C explained this finding. However, under
18 conditions in which the nutrient limitation of the plant is relieved (e.g., high N
19 availability), mycorrhizae may no longer be as needed by the plant for nutrient
20 acquisition, yet concomitantly still impose a C cost. In this case, the tradeoff is no longer
21 as beneficial to the plant. With increased N availability, plants that make fewer
22 mycorrhizal associations can benefit both from the physiological advantages
23 accompanying an alleviation of N limitation (e.g., increases in photosynthesis, changes in
24 plant chemistry) and from incurring a lower C cost for mycorrhizae ([Johnson et al.,](#)
25 [2008](#)). Indeed, shifts in C allocation away from mycorrhizae may be a mechanism to
26 support increased plant productivity in situations where plants do not show gains in
27 photosynthesis [e.g., ([Talhelm et al., 2011](#))].

28 There are numerous mechanisms through which N deposition could impact microbial
29 biomass, including changes in soil chemistry, changes in the rates of aboveground and
30 belowground plant C inputs (including litter production, root exudates, and C supplied to
31 mycorrhizal fungi), and changes in plant tissue chemistry ([Treseder, 2008](#)). Nitrogen
32 additions can change the chemistry of litter inputs by altering the tissue composition of
33 plant species ([Throop and Lerdau, 2004](#)) or by changing the composition of plant
34 communities contributing to the ecosystem flux of plant litter [e.g., ([Manning et al.,](#)
35 [2008](#))]. Within a particular species, N additions can cause changes in both of the
36 dominant forms of plant litter: leaf litter and fine roots [e.g., ([Xia et al., 2015](#))]. These
37 changes can be relatively direct, such as increases in tissue concentrations of inorganic
38 and organic forms of N [e.g., ([Bauer et al., 2004](#); [Koricheva et al., 1998](#))]. While leaf

1 litter N concentrations are not as widely measured as green leaf N, increases in leaf litter
2 N concentrations due to added N are also likely to be widespread because increased N
3 availability often either decreases or has no effect on the fraction of N plants absorb from
4 leaves during senescence ([Aerts, 1996](#)). Other changes in litter chemistry, such as
5 increases in condensed tannins, soluble phenolics, and nonstructural carbohydrates ([Xia
6 et al., 2015](#)), likely involve more complex biological mechanisms. In a meta-analysis of
7 plant biochemistry data, [Liu et al. \(2016a\)](#) observed different effects of added N on trees
8 and herbs. For the live tissues of trees, N additions decreased concentrations of lignin,
9 cellulose, and nonstructural carbohydrates, and increased the concentration of protein. In
10 the live tissues of herbs, added N decreased the concentrations of nonstructural
11 carbohydrates and hemicellulose, but increased lignin, cellulose, and protein
12 concentrations. These changes have implications for herbivores and detritivores, as well
13 plant growth dynamics.

14 In a litter decomposition meta-analysis, [Knorr et al. \(2005\)](#) observed that the effects of
15 added N also differed based on the length of the study and the initial litter lignin content.
16 Added N stimulated decomposition in studies lasting less than 2 years, but reduced
17 decomposition in studies lasting more than 2 years. High-lignin litter decomposed more
18 slowly than low-lignin litter. Because lignin concentrations tend to increase during litter
19 decomposition, both of these results were considered to be consistent with earlier
20 evidence that increased N supplies stimulate microbial activity responsible for the
21 decomposition of labile litter constituents, while suppressing the microbial production of
22 extracellular enzymes responsible for the degradation of lignin ([Knorr et al., 2005](#)) (see
23 also [Appendix 4](#)). In a meta-analysis of biochemistry data for decomposing litter, [Liu et
24 al. \(2016a\)](#) observed that N additions increased the concentration of lignin in
25 decomposing litter for herbs and shrubs, but did not have a significant effect on
26 decomposing tree litter. In comparison, N additions decreased cellulose concentrations in
27 decomposing tree litter, but did not significantly affect cellulose concentrations in
28 decomposing herb litter. In another meta-analysis, [Liu and Greaver \(2010\)](#) found that
29 although N additions increased aboveground litter production (+20%; n = 37; not shown)
30 across all biomes and N addition rates, there were no significant overall changes in either
31 total soil respiration ([Figure 6-2B](#)) or heterotrophic soil respiration ([Figure 6-2B](#)). In fact,
32 both forms of soil respiration tended to decline. Currently, no similar cross-biome
33 analysis has been conducted for changes in autotrophic soil respiration (respiration from
34 roots and mycorrhizal fungi), but [Janssens et al. \(2010\)](#) noted in a meta-analysis that
35 autotrophic respiration was suppressed by N additions in forests.

36 Because some biogeochemical processes involve specific chemical forms of N
37 (e.g., denitrification, ammonium toxicity) (see [Appendix 4](#)), there is the potential that
38 biological responses to N deposition (or N addition) could depend on whether the

1 dominant form of deposited N is oxidized (NO_y) or reduced (NH_x). A number of studies
2 have specifically addressed this issue, either by conducting experiments directly testing
3 additions of different forms of N or indirectly through syntheses comparing the effects of
4 NO_y and NH_x in different experiments. Different responses to individual forms of N have
5 been observed for some endpoints, such as increases in dissolved organic C, decreases in
6 ecosystem N retention, increases in soil N_2O emissions, plant growth, and defense against
7 pathogens ([Mur et al., 2016](#); [Yue et al., 2016](#); [Templer et al., 2012](#); [Verhoeven et al.,](#)
8 [2011](#); [Liu and Greaver, 2010, 2009](#)) (see also [Table 4-13](#)). By contrast, other studies have
9 failed to observe a difference between the effects of N forms. One direct test occurred in
10 the Front Range of the Rocky Mountains in Colorado, where [Ramirez et al. \(2010a\)](#)
11 investigated whether soil microbes respond differently to additions of NH_4^+ versus NO_3^-
12 and found that the total amount of N added was correlated with a decrease in soil
13 respiration, not the form of the N (NH_4^+ vs. NO_3^-). A more comprehensive understanding
14 is available by reviewing the results of meta-analyses comparing the responses of N
15 addition experiments conducted with different forms of N ([Table 6-1](#)). With notable
16 exceptions, most often differences in the effect of the form of N were not observed in
17 these meta-analyses. Moreover, studies finding differences tended to occur where sample
18 sizes were small [e.g., belowground C pools in ([Yue et al., 2016](#))].

Table 6-1 The effects of different forms of inorganic nitrogen on biological endpoints according to meta-analyses.

See [Table 4-13](#) for the effects of different forms of inorganic nitrogen on biogeochemical processes and indicators.

Reference	Endpoint	Effect of NO _y vs. NH _x Forms
Yue et al. (2016)	Aboveground plant C pool	Not significant
LeBauer and Treseder (2008)	Aboveground plant productivity	Not significant
Yue et al. (2016)	Aboveground plant productivity	Not significant
Treseder (2008)	Bacteria biomass	Not significant
Yue et al. (2016)	Belowground plant C pool	Increase with NH ₄ ⁺
Liu and Greaver (2009)	Ecosystem C content	Not significant
Liu and Greaver (2010)	Fine root litter production	Not significant
Treseder (2008)	Fungal biomass	Not significant
Liu and Greaver (2010)	Leaf litter production	Insufficient data
Yue et al. (2016)	Leaf litter production	Insufficient data
Knorr et al. (2005)	Litter decomposition	Not significant
Yue et al. (2016)	Litter decomposition	Not significant
Treseder (2008)	Microbial biomass	Not significant
Liu and Greaver (2010)	Microbial biomass C	Decrease with NH ₄ ⁺
Yue et al. (2016)	Microbial biomass C	Not significant
Treseder (2004)	Mycorrhizal abundance	Not significant

C = carbon; ¹⁵N = tracer isotope of nitrogen; N₂O = nitrous oxide; NH₄⁺ = ammonium; NH₄NO₃ = ammonium nitrate; NH_x = sum of reduced forms of N; NO₃⁻ = nitrate; NO_y = the sum of oxidized forms of nitrogen. Notes: References ordered by endpoint. Only statistically significant differences between the effects of forms of N listed as increases or decreases.

1 Before the 2008 ISA, neither terrestrial N cycling nor anthropogenic N deposition had
 2 been widely incorporated into Earth systems models (ESMs) used to understand and
 3 forecast global climate and biogeochemical cycling. [Thornton et al. \(2007\)](#) made the first
 4 effort to understand how both coupled C and N cycling and anthropogenic N deposition
 5 would impact ESM predictions for terrestrial C uptake by inserting a new land
 6 biogeochemistry model into a coupled climate system model. In the resulting model
 7 output, N limitation greatly decreased the amount of terrestrial C uptake predicted from

1 future increases in atmospheric CO₂ and decreased the sensitivity of terrestrial C
2 sequestration to increases in temperature and precipitation ([Thornton et al., 2007](#)).
3 Including N deposition within the model directly increased terrestrial C uptake and also
4 indirectly increased terrestrial C uptake by removing some of the N limitation predicted
5 to occur under increased atmospheric CO₂ ([Thornton et al., 2007](#)). Subsequently, efforts
6 to model biogeochemical processes at regional and global scales have expanded ([Thomas](#)
7 [et al., 2015](#); [Zaehle and Dalmonech, 2011](#)). Although the integration of terrestrial N
8 cycling into ESMs remains relatively weak, more ESMs are incorporating the coupling of
9 terrestrial C and N cycling as overall model development and sophistication advances
10 ([Thomas et al., 2015](#); [Arora et al., 2013](#); [Zaehle and Dalmonech, 2011](#); [Bonan and Levis,](#)
11 [2010](#); [Gerber et al., 2010](#)). Consistent with the findings of [Thornton et al. \(2007\)](#),
12 inclusion of coupled C-N cycling in ESMs has two primary effects: decreasing the
13 stimulatory effects of elevated atmospheric CO₂ on terrestrial productivity and decreasing
14 the sensitivity of terrestrial C sequestration to climate warming because increased soil N
15 mineralization stimulates plant productivity ([Arora et al., 2013](#); [Zaehle and Dalmonech,](#)
16 [2011](#); [Zhang et al., 2011b](#); [Arneeth et al., 2010](#); [Bonan and Levis, 2010](#); [Gerber et al.,](#)
17 [2010](#); [Yang et al., 2010](#); [Zaehle et al., 2010](#); [Thornton et al., 2009](#)). However, the ESMs
18 that do include basic terrestrial C-N coupling lack more recently identified interactions
19 such as plant organic N uptake, soil priming (root exudation), and the suppression of litter
20 decomposition at high soil N availability, all of which could increase terrestrial C uptake
21 to varying extents ([Thomas et al., 2015](#); [Zaehle and Dalmonech, 2011](#)). In addition, the
22 interactions between and the net effects of N, precipitation, and temperature on
23 ecosystem C response in soils are unknown in many cases (see [Appendix 13.1.2.1](#)).

24 In the few ESMs that have directly included the effects of N deposition, the additional N
25 increased terrestrial C uptake and increased the extent to which elevated atmospheric CO₂
26 stimulates terrestrial C uptake ([Devaraju et al., 2016](#); [Bonan and Levis, 2010](#); [Yang et al.,](#)
27 [2010](#)). In addition, N deposition in the Northern Hemisphere (particularly in the U.S.)
28 apparently compounded the increase in C sequestration caused by the regrowth of
29 secondary forests during the late 20th century following agricultural abandonment and
30 timber harvest ([Gerber et al., 2013](#); [Yang et al., 2010](#)). However, ESMs that do not
31 include potential N saturation may overestimate the effect of N deposition on terrestrial C
32 uptake in regions experiencing high N deposition rates ([Lu et al., 2016](#)). In addition, it
33 should be noted that although N deposition and the overall anthropogenic production of
34 reactive N increases terrestrial C sequestration, they are not the only influence of
35 anthropogenic N on global climate. It is difficult to quantify the overall climate impact of
36 anthropogenic N [e.g., ([Pinder et al., 2013](#))] because reactive N can change the planetary
37 albedo by enhancing aerosol formation, stimulate the production of biogenic greenhouse
38 gases, alter the production and destruction of methane and tropospheric ozone in the
39 atmosphere, and indirectly decrease terrestrial productivity due to the phytotoxic effects

1 of ozone ([Lu and Tian, 2013](#); [Pinder et al., 2013](#); [Pinder et al., 2012](#); [Arneeth et al., 2010](#);
2 [Zaehle et al., 2010](#)). Many of these effects are discussed further in the atmospheric
3 chemistry and terrestrial biogeochemistry portions of this ISA (see [Appendix 2](#) and
4 [Appendix 4](#)).

5 In addition to the global-scale analyses conducted using ESMs, biogeochemical process
6 models have been used to assess the impact of N deposition on terrestrial productivity
7 and C sequestration at national and regional scales. [Tian et al. \(2012\)](#) used the Dynamic
8 Land Ecosystem Model (DLEM) to model the influence of climate, tropospheric ozone,
9 fertilizer use, land use/land cover change, atmospheric CO₂, and N deposition on
10 terrestrial C storage over the 20th century in the southeastern U.S. (encompassing Texas
11 and Oklahoma to Florida and Virginia). Terrestrial C storage increased from 1951–2007,
12 with the model identifying atmospheric CO₂ and N deposition as the environmental
13 factors responsible for the increase in C sequestration ([Tian et al., 2012](#)). In China, a
14 series of papers has been published using biogeochemical process models to identify how
15 this same set of environmental factors influenced terrestrial C cycling in that country.
16 Rates of N deposition in China grew rapidly during the late 20th century and were
17 considerably higher than in the U.S. by the early 21st century, with nationwide average
18 rates of approximately 20 kg N/ha/yr and rates in southeast China averaging 35–40 kg
19 N/ha/yr ([Lu and Tian, 2013](#); [Lu et al., 2012](#)). [Tian et al. \(2011\)](#) applied the Terrestrial
20 Ecosystem Model and the DLEM model to China using data from 1961–2005. In both
21 models, China was a C sink during this time period, with the combination of N deposition
22 and agricultural fertilizer use accounting for 61% of the increase in C sequestration.
23 Notably, the responsiveness of terrestrial C sequestration to N deposition has declined
24 since the 1980s as N deposition in China increased, providing evidence that terrestrial
25 ecosystems are becoming less N limited in China ([Tian et al., 2011](#)). [Lu et al. \(2012\)](#)
26 conducted a similar analysis, using DLEM to understand how multifactor environmental
27 change influenced terrestrial C sequestration in China from 1901–2005. Like [Tian et al.](#)
28 [\(2011\)](#), [Lu et al. \(2012\)](#) observed that N deposition increased terrestrial C sequestration in
29 China throughout much of the late 20th century, but that the responsiveness of terrestrial
30 C sequestration to N deposition has declined since the 1980s. Moreover, [Lu et al. \(2012\)](#)
31 reported that all areas of China, aside from some shrublands and portions of western
32 China, are becoming N saturated.

6.2.3. Forests

6.2.3.1. Aboveground Processes

1 The 2008 ISA noted a wide range of forest productivity responses to added N. Responses
2 to low levels of N were often positive because N availability tends to limit growth in
3 terrestrial ecosystems ([LeBauer and Treseder, 2008](#)). However, forest productivity
4 responses to higher rates of N addition were neutral or negative [e.g., ([Magill et al.,](#)
5 [2004](#))]. The effects of N deposition were variable across species. Conifer species,
6 particularly at high elevations, were more likely to exhibit negative growth responses or
7 mortality in response to added N. Conifer species were less likely to demonstrate
8 increased growth in response to additional N and more often exhibited decreased growth
9 and increased mortality [e.g., ([McNulty et al., 2005](#); [Beier et al., 1998](#); [Boxman et al.,](#)
10 [1998a](#))]. Differences between broadleaf and conifer species were especially clear in
11 long-term N addition experiments: [Elvir et al. \(2003\)](#) observed increased sugar maple
12 (*Acer saccharum*) basal area growth in response to long-term (NH₄)₂SO₄ (25 kg N/ha/yr
13 for 10 years) additions, but red spruce (*Picea rubens*) growth was unchanged. At Harvard
14 Forest, oak (*Quercus velutina*, *Q. rubra*) increased growth in response to chronic N
15 additions (50 or 150 kg N/ha/yr for 15 years), while red pine (*Pinus resinosa*) growth
16 slowed and mortality increased ([Magill et al., 2004](#)). Most empirical observations of the
17 effects on atmospheric N deposition on forest productivity came from chronic N addition
18 experiments in temperate forests in the U.S. [e.g., ([Pregitzer et al., 2008](#); [Magill et al.,](#)
19 [2004](#); [Elvir et al., 2003](#); [McNulty et al., 1996](#); [Aber et al., 1995](#))] and temperate and
20 boreal forests in Europe ([Hyvönen et al., 2008](#); [Högberg et al., 2006](#); [Beier et al., 1998](#);
21 [Boxman et al., 1998a](#)). Empirical analyses of the effects of atmospheric N deposition on
22 forest productivity in the U.S. were lacking.

23 Research published since 2008 has reinforced many of the ideas in the 2008 ISA. There is
24 considerable evidence from deposition gradient studies, forest modeling, and long-term N
25 addition experiments that N deposition broadly stimulates tree growth and the
26 productivity of forested ecosystems. Using forest inventory data from the early 1980s
27 through the mid 1990s for 23 species growing in a region stretching from Ohio to Maine,
28 [Thomas et al. \(2010\)](#) found that N deposition accelerated growth in 11 species, including
29 3 of the 4 most abundant species (red maple [*Acer rubrum*], sugar maple, and northern
30 red oak [*Quercus rubra*]). Negative effects on growth were seen in three species, all of
31 which were evergreen conifers (red pine [*Pinus resinosa*], red spruce, northern white
32 cedar [*Thuja occidentalis*]). All five of the arbuscular mycorrhizal tree species included
33 in the analysis exhibited increased growth. [Xia and Wan \(2008\)](#) observed positive effects
34 of added N on growth for both broadleaf and coniferous trees in a meta-analysis, with

1 broadleaf trees (+73%) more responsive than conifers (+37%). Eight species exhibited
2 higher mortality rates with increasing N deposition in the [Thomas et al. \(2010\)](#) analysis,
3 notably several oak species, including northern red oak. Only three species showed
4 increased survival. Examining forest stand-level responses, [Hember et al. \(2017\)](#)
5 concluded N deposition had increased forest stand growth in one of the five Canadian
6 ecozones (Montane Cordillera), decreased it in another (Boreal Plain), and did not
7 significantly affect stand growth in the remaining three (Pacific Maritime, Boreal Shield,
8 and Atlantic Maritime). They similarly found differences in forest stand mortality, with N
9 deposition decreasing mortality in three of the five ecozones (Pacific Maritime, Montane
10 Cordillera, and Boreal Plain) and no significant effect in the remaining two. In an
11 analysis of forest inventory data from across the entire eastern U.S. from the 1970s
12 through early 2000s, [Dietze and Moorcroft \(2011\)](#), as noted in [Appendix 5](#), found N
13 deposition was linked to decreased tree mortality in 9 of 10 plant functional types and
14 increased mortality only in the northern midsuccessional hardwoods functional type.
15 Across a smaller gradient within the Adirondacks, [Bedison and McNeil \(2009\)](#) found a
16 significant positive overall effect of N deposition on tree growth from 1984–2004, but
17 positive growth effects only for red maple, balsam fir (*Abies balsamea*), and red spruce at
18 the species level. Thus, it appears from these inventory analyses that while tree growth
19 has generally been enhanced by N deposition over the last several decades, individual
20 species have exhibited variable responses to N deposition in mortality and growth.

21 Many of the species exhibiting notable responses in the broad northeastern U.S. inventory
22 analysis have also been included in long-term simulated N deposition experiments, but
23 the results in these studies have not always been consistent with the observations of
24 [Thomas et al. \(2010\)](#). Overstory sugar maple trees increased growth in response to added
25 N in Michigan [[Pregitzer et al., 2008](#)]; N added at 30 kg N/ha/yr] and Maine [[Elvir et](#)
26 [al., 2003](#)]; 25 kg N/ha/yr], but mature sugar maple and red maple did not respond in the
27 Catskills [[Lovett et al., 2013](#)]; 50 kg N/ha/yr]. Northern red oak increased growth at
28 Harvard Forest [[Frey et al., 2014](#)]; 50 and 150 kg N/ha/yr] but showed no growth
29 response at two sites in New York state [[Wallace et al., 2007](#)]; 75 kg N/ha/yr, [[Lovett et](#)
30 [al., 2013](#)]; 50 kg N/ha/yr], with increased mortality at one of the New York sites ([Wallace](#)
31 [et al., 2007](#)). A 13-year study in a young forest in West Virginia included the two species
32 with the most positive growth responses in the [Thomas et al. \(2010\)](#) analysis and found
33 that N addition (35 kg N/ha/yr of $[\text{NH}_4]_2\text{SO}_4$) generally decreased growth of black cherry
34 (*Prunus serotina*) and tulip poplar (*Liriodendron tulipifera*), although these changes were
35 not statistically significant ([May et al., 2005](#)). Red pine at Harvard Forest exhibited
36 decreased growth and higher mortality in response to chronic N additions [[Frey et al.,](#)
37 [2014](#)]; 50 and 150 kg N/ha/yr], while red spruce showed no growth response in Maine
38 [[Elvir et al., 2003](#)]; 25 kg N/ha/yr]. Notably, the rates of N additions in these studies

1 were often considerably greater than the typical rates of N deposition observed in the
2 U.S.

3 Other studies have also observed similarly mixed results on tree growth and mortality in
4 U.S. forests. At the same sites in Michigan where long-term N additions increased growth
5 of mature sugar maple ([Pregitzer et al., 2008](#)), N additions decreased the growth and
6 survival of sugar maple saplings ([Talhelm et al., 2013](#); [Patterson et al., 2012](#)). Notably,
7 this negative effect occurred without increase in overstory leaf area that would reduce
8 light availability or a decrease in soil pH ([Talhelm et al., 2013](#)). More recently, [Ibanez et](#)
9 [al. \(2016\)](#) observed that although small overstory trees (5–10 cm diameter at breast
10 height) at these sites were growing faster, they were also experiencing increased
11 mortality. As with sugar maple saplings in Michigan, N deposition appears to be
12 decreasing growth among northern red oak saplings in the Chicago area, potentially
13 contributing to the inability of this species to regenerate in that region ([Bassirad et al.,](#)
14 [2015](#)). In Vermont, 2 years of N addition at 150 kg N/ha/yr increased growth in four
15 hardwood species (including sugar maple and northern red oak), decreased growth in one
16 conifer, and had no effect on two other hardwoods ([Finzi, 2009](#)). [Allen et al. \(2010\)](#)
17 reported higher mortality and a decrease in ectomycorrhizal root tips ([Table 6-2](#)), with N
18 addition (100 kg N/ha/yr) in ectomycorrhizal piñon pine in New Mexico, while no
19 change in the mortality of arbuscular mycorrhizal juniper. [Allison et al. \(2010\)](#) observed
20 a 2.5-fold increase in aboveground net primary productivity in response to several years
21 of N additions (100 kg N/ha/yr) in central Alaska in a recently burned boreal forest. At
22 two mixed conifer forests in the Sierra Nevada, 2 years of N additions (12 or
23 24 kg N/ha/yr) had a positive effect on herb community biomass at one site
24 (24 kg N/ha/yr) and a negative effect at the other site (12 kg N/ha/yr); shrub biomass was
25 unaffected ([Hurteau and North, 2008](#)). Modeling 50 years into the future based on these
26 results, a lower rate of N deposition (12 kg N/ha/yr) was expected to increase herb
27 biomass, while the high rate of N deposition (24 kg N/ha/yr) led only to a small increase
28 in shrub biomass. In combination with a wetter precipitation regime, both N deposition
29 rates were predicted to increase shrub and herb biomass ([Hurteau et al., 2009](#)). In a
30 greenhouse study, N additions of up to 120 kg N/ha/yr had no effect on the N fixing tree
31 black locust (*Robinia pseudoacacia*) when grown in a monoculture or in competition
32 with the sawtooth oak (*Quercus acutissima*), but N additions increased the height and
33 total biomass of the sawtooth oak when grown in competition with black locust ([Luo et](#)
34 [al., 2014](#)).

Table 6-2 Growth, productivity, and carbon cycle responses of ectomycorrhizal fungi to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Högberg et al. (2010)	Sweden	Scots pine (<i>Pinus sylvestris</i>)	Addition	100	2	¹³ C labeling of EM biomarker PLFA 18:2ω6,9	Decrease
Näsholm et al. (2013)	Sweden	Scots pine (<i>Pinus sylvestris</i>)	Addition	100	0 (2 weeks)	¹³ C labeling of EM biomarker PLFA 18:2ω6,9	Not significant
Parrent and Vilgalys (2009)	North Carolina	Loblolly pine (<i>Pinus taeda</i>)	Addition	112	1	Ectomycorrhizal 18S RNA expression	Not significant
Högberg et al. (2011)	Sweden	Scots pine (<i>Pinus sylvestris</i>)	Addition	120	20; 15 yr recovery	Ectomycorrhizal biomarker 18:2ω6,9	Not significant
Högberg et al. (2011)	Sweden	Scots pine (<i>Pinus sylvestris</i>)	Addition	30, 70	35	Ectomycorrhizal biomarker 18:2ω6,9	Decrease
Näsholm et al. (2013)	Sweden	Scots pine (<i>Pinus sylvestris</i>)	Addition	100	0 (2 weeks)	Fine root chitin concentration	Not significant
Kjøller et al. (2012)	Denmark	Norway spruce (<i>Picea abies</i>)	Ambient	27–43	n/a	Mycelium production	Decrease
Bahr et al. (2013)	Sweden	Norway spruce (<i>Picea abies</i>)	Ambient	0.9–24.6	n/a	Mycelium production	Decrease
Bahr et al. (2015)	Sweden	Norway spruce (<i>Picea abies</i>)	Addition	200 (once)	1	Mycelium production	Decrease
Hasselquist et al. (2012)	Sweden	Scots pine (<i>Pinus sylvestris</i>)	Addition	20, 100	6	Mycorrhizal respiration	<u>Low dose</u> : increase <u>High dose</u> : decrease

EM = ectomycorrhizal fungi; ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; PLFA = phospholipid fatty acids; RNA = ribonucleic acid; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 A number of studies on the effects on N deposition or chronic N additions have been
2 conducted in temperate and boreal forests in Europe, and these studies have more
3 consistently found positive effects of N on tree growth (e.g., [\(Nair et al., 2016; Ferretti et](#)
4 [al., 2014; Solberg et al., 2009\)](#). [Ferretti et al. \(2014\)](#) observed a positive relationship
5 between N deposition and tree growth across 26 forest plots in Italy. A positive effect of
6 N deposition on tree growth was also found on 135 Swiss long-term observation plots for
7 mature beech and spruce from the mid 1980s through late 2000s ([Braun et al., 2010](#)).
8 Further N additions decreased tree growth at three of seven experimental sites, yet these
9 changes were linked to P deficiencies ([Braun et al., 2010](#)). [Eastaugh et al. \(2011\)](#) took a
10 more complex approach to understand growth trends of Norway spruce (*Picea abies*) in
11 the Austrian National Forest Inventory from 1960–2008. Using the Biome-BGC model to
12 isolate growth trends from variation in climate, the authors found a positive relationship
13 between tree growth and N deposition. Using data from long-term N addition
14 experiments in Norway spruce and Scots pine (*Pinus sylvestris*) forests throughout
15 Sweden and Finland, [Hyvönen et al. \(2008\)](#) found increased tree growth at 11 of 12 sites.
16 The effects of added N on forest productivity appear to persist for decades and carry over
17 through major ecosystem disturbances. [From et al. \(2015\)](#) studied young Norway spruce
18 and Scots pine forests planted in the late 1990s after the original forests were clear-cut.
19 The original forests had received N additions of 150 kg N/ha/yr (as NH₄NO₃) either twice
20 (in 1977 and 1985), once (1985), or never. Tree height growth of the young forests was
21 positively related to the amount of previous N additions, with significantly greater height
22 growth in the forests that had received two N additions. Foliar N concentrations were also
23 significantly higher in the forests that had received N additions ([From et al., 2015](#)).
24 Biomass of understory shrubs and bryophytes decreased in response to N additions
25 (100 kg N/ha/yr for 6 years) on boreal forest islands in Sweden, although one of three
26 shrub species increased in growth ([Wardle et al., 2016](#)).

27 The 2008 ISA tied greater tree growth and forest productivity to increases in foliar N,
28 photosynthesis, and gross primary productivity. In addition, foliar N was identified as a
29 sensitive indicator of changes in forest N availability ([Aber et al., 1989](#)). Since the 2008
30 ISA, increases in foliar N continue to have been linked to N deposition in forests in the
31 U.S., Europe, and Asia in pollution gradient studies ([Sardans et al., 2016; Talhelm et al.,](#)
32 [2012; Jones et al., 2011; Cox et al., 2010; Thimonier et al., 2010; Fenn et al., 2008](#)) and N
33 addition experiments ([Du, 2017; Fusaro et al., 2017; Gilliam et al., 2016a; Wardle et al.,](#)
34 [2016; Fowler et al., 2015; Du and Fang, 2014; Lovett et al., 2013; Talhelm et al., 2013;](#)
35 [Lovett and Goodale, 2011; Talhelm et al., 2011; Allen et al., 2010; Braun et al., 2010](#)).
36 For instance, [Cox et al. \(2010\)](#) observed a 40% increase in foliar N (from 15 mg/g to
37 21 mg/g) in Scots pine forests in Germany and the U.K. along an N deposition gradient of
38 4.6 to 28 kg N/ha/yr. In addition to trees, forest bryophytes and lichens also show
39 increased tissue N concentrations when exposed to additional N ([Maaroufi et al., 2016](#);

1 [McMurray et al., 2015](#); [McMurray et al., 2013](#); [Gundale et al., 2011](#); [Fenn et al., 2008](#);
2 [Glavich and Geiser, 2008](#)). Increased foliar N is not universally observed in N addition
3 studies [e.g., ([Zhang et al., 2017](#); [Zhang et al., 2015c](#); [Lovett et al., 2013](#))] or along N
4 deposition gradients ([Watmough and Meadows, 2014](#)), but a meta-analysis found that N
5 additions generally increase foliar N in trees ([Lu et al., 2011b](#)).

6 Although there are clear links between N deposition and increased foliar N and between
7 higher foliar N and increased photosynthesis, there is only limited evidence that chronic
8 N deposition directly increases leaf-level photosynthesis in forests. For instance, in
9 long-term simulated N deposition experiments in Massachusetts and Maine, only one of
10 four species exhibited increased photosynthesis with N additions ([Elvir et al., 2006](#);
11 [Bauer et al., 2004](#)). Research on photosynthesis since the 2008 ISA has been similarly
12 mixed. [Talhelm et al. \(2011\)](#) did not observe a significant increase in either
13 photosynthesis or canopy leaf area in mature sugar maple trees at four sites in Michigan
14 in response to N additions (30 kg N/ha/yr as NaNO₃ for 14 years). Using a
15 canopy-applied N treatment at two Swiss forests, [Wortman et al. \(2012\)](#) found that N
16 additions improved photosynthetic processes in oak at one site, but did not significantly
17 influence photosynthetic parameters in spruce or beech at the other site. In Swedish
18 boreal forests, higher tissue N concentrations resulting from N additions (20 or
19 100 kg N/ha/yr for 4 years) increased the amount of ¹³CO₂ assimilated into shrub
20 (*Vaccinium*) foliage but decreased the amount of C assimilated by bryophytes
21 ([Hasselquist et al., 2016](#)). At a broader scale, [Fleischer et al. \(2013\)](#) analyzed the effect of
22 N deposition on photosynthesis using observations from 80 forest eddy covariance C flux
23 measurement sites predominantly located in the eastern U.S. and western Europe. In this
24 data set, canopy photosynthetic capacity was positively correlated to N deposition for
25 conifer forests when N deposition was below an observed critical load of approximately
26 8 kg N/ha/yr ([Fleischer et al., 2013](#)). Most of the stimulus provided by N deposition
27 occurred in boreal forests, with little to no influence of N deposition in broadleaf forests
28 or forests in the temperate climate zones ([Fleischer et al., 2013](#)). [Leonardi et al. \(2012\)](#)
29 compiled a global data set of published tree ring ¹³C chronologies and found that the rate
30 of N deposition had a significant linear effect on intrinsic water-use efficiency (iWUE)
31 and ¹³C discrimination ($\Delta^{13}\text{C}$) in conifers and a quadratic effect in angiosperms. This
32 change in ¹³C discrimination suggests that the additional N either stimulated
33 photosynthesis or stimulated growth to the extent that the trees became more water
34 limited.

35 The apparent contradiction between the wide observations that N deposition can increase
36 both tree growth and foliar N concentrations and the inconsistent effects of N deposition
37 on leaf-level photosynthesis could be explained by two other physiological responses to
38 N. First, plants can store excess N in foliage as free amino acids and other

1 physiologically inactive forms of N ([Bauer et al., 2004](#)). Increases in foliar amino acid
2 concentrations, particularly arginine, have been observed in forests in chronic N addition
3 experiments ([Bauer et al., 2004](#)) and along N deposition gradients ([Braun et al., 2010](#)). In
4 these cases, the added foliar N would have no impact on photosynthesis. Second, plants
5 can respond to added N by altering C allocation. As noted in the 2008 ISA, higher N
6 availability often causes trees to allocate less photosynthate to roots and belowground
7 processes and more toward aboveground growth ([Vicca et al., 2012](#); [Högberg et al.,
8 2010](#); [Janssens et al., 2010](#); [Litton et al., 2007](#); [Aerts and Chapin, 1999](#); [Minnich et al.,
9 1995](#)). Research since the 2008 ISA has provided further evidence that N deposition is
10 likely capable of causing such a shift in forests. In a greenhouse experiment, N additions
11 (2, 5, and 10 kg N/ha/yr) resulted in more biomass allocated to leaves than to roots at all
12 four N addition levels for oak and black locust trees. At the same Michigan sites where
13 [Talhelm et al. \(2011\)](#) observed that chronic N additions had no effect on leaf-level
14 photosynthesis or stand leaf area, the combination of increased aboveground growth, no
15 change in root production or respiration, and decreased mycorrhizal abundance led the
16 authors to conclude that a change in C allocation away from mycorrhizae was the likely
17 cause for enhanced tree growth. More broadly, [Vicca et al. \(2012\)](#) found that across
18 49 forest sites, higher site fertility increased both the fraction of biomass that was
19 allocated aboveground and the fraction of photosynthate that was allocated toward
20 biomass production. The increase in C allocated to biomass production was thought to
21 most likely result from less C being allocated to root symbionts such as mycorrhizae
22 ([Vicca et al., 2012](#)). Likewise, [Janssens et al. \(2010\)](#) conducted a meta-analysis of
23 20 forest N addition experiments and found that N additions decreased the fraction of C
24 allocated to belowground processes but did not affect root biomass. As an example of
25 this, [Högberg et al. \(2010\)](#) conducted a short-term (~2 hour) $^{13}\text{CO}_2$ canopy labeling
26 experiment in a young Scots pine forest in northern Sweden to determine how N
27 additions (two 100 kg N/ha additions over 2 years) altered the allocation of recent
28 photosynthate belowground. In the 3 weeks following the canopy labeling, the total soil
29 respiratory efflux of the ^{13}C label was 62% lower in the plots that had received the N
30 additions. Other observed physiological responses to N include delayed bud burst ([De
31 Barba et al., 2016](#)), tree ring width, and xylem conduit density ([Borghetti et al., 2017](#)).

32 The effects of N addition on forest productivity have the potential to be moderated by
33 increases in herbivory, particularly among insects ([Throop and Lerdau, 2004](#)). For
34 instance, [Andersen et al. \(2010\)](#) observed that N additions increased foliar N and
35 photosynthetic rates within a tropical forest in Panama, but that tree growth rates were
36 unaffected because of increased herbivory. At Harvard Forest in Massachusetts, northern
37 red oak regeneration declined with N additions (50 and 100 kg N/ha/yr) ([Bogdziewicz et
38 al., 2017](#)). Acorn production increased, but so did weevil infestation of the acorns, and
39 germination rates declined. In a Pennsylvania common garden experiment with northern

1 red oak, saplings receiving N additions (200 kg N/ha/yr) tended to have greater herbivore
2 damage, but the effects of N addition on herbivory and the link between herbivory and
3 decreased growth both varied by the type of herbivore, the tree lineage (breeding family),
4 and the study location ([Cha et al., 2010](#)). Similarly, [Jones et al. \(2008\)](#) and [Jones et al.](#)
5 [\(2011\)](#) observed that the most abundant herbivore of bracken fern (*Pteridium aquilinum*)
6 and a beetle herbivore of California black oak (*Quercus kelloggii*) were increased by N
7 addition at a heavily polluted site, but not at a drier, less polluted site. However, there
8 was a positive correlation between leaf NO₃⁻ concentrations and the abundance of several
9 groups of black oak herbivores.

6.2.3.2. Belowground Processes

10 The 2008 ISA analysis of how belowground processes in forests reacted to N deposition
11 focused on fine root dynamics, aboveground litter inputs, decomposition, soil respiration,
12 and soil C. [Johnson \(2001\)](#) had found a significant increase in forest soil C in response to
13 N additions as part of a meta-analysis, but only a single long-term N addition field study
14 had observed a significant increase in forest soil C [[Pregitzer et al., 2008](#)]; see
15 [Appendix 4](#). For fine roots, [Nadelhoffer \(2000\)](#) hypothesized that N deposition would
16 decrease biomass, but stimulate turnover and production. The 2008 ISA found little
17 evidence with which to evaluate this hypothesis. There was more available research on N
18 effects on decomposition and soil respiration. As noted earlier, [Knorr et al. \(2005\)](#)
19 observed in a meta-analysis that N additions increased decomposition at sites receiving
20 low rates of ambient N deposition (<5 kg N/ha/yr), but N additions suppressed
21 decomposition at sites receiving moderate rates of N deposition (5–10 kg N/ha/yr).

22 Research completed since the 2008 ISA has advanced our understanding of how N
23 affects belowground processes in forests. In two meta-analyses, [Liu and Greaver \(2010\)](#)
24 did not find a consistent effect of N additions on forest fine root production, while [Li et](#)
25 [al. \(2015\)](#) observed a decrease (–13.5%) in forest fine root biomass. Broadly, some of the
26 results discussed in the 2008 ISA that appeared inconsistent at the time were likely a
27 reflection of how N additions interacted with other ecological processes. In young,
28 rapidly expanding forests, N addition may increase root biomass as a consequence of an
29 overall enhancement of plant growth ([Janssens et al., 2010](#)). For instance, N additions
30 (150 kg N/ha/yr for 3 years) to a young bamboo forest increased fine root growth by
31 >30%, even though this forest already received high rates of atmospheric N deposition
32 [95 kg N/ha/yr of wet deposition; [Tu et al., 2015](#)]. However, as noted in the
33 “Aboveground Processes” section ([Appendix 6.2.3.1](#)), increases in N deposition tend to
34 decrease the proportion of C allocated to roots relative to aboveground growth ([Li et al.,](#)
35 [2015](#); [Vicca et al., 2012](#); [Janssens et al., 2010](#); [Litton et al., 2007](#); [Minnich et al., 1995](#)).

1 Thus, in more mature forests, root biomass and production are not consistently affected
2 by N deposition. For instance, there were no effects of chronic N additions on fine root
3 biomass in four mature hardwood forests in Michigan [30 kg N/ha/yr for over 15 years;
4 ([Burton et al., 2012](#))], and in two mature mixed oak (*Quercus*) stands at Harvard Forest
5 [50 or 150 kg N/ha/yr for over 20 years ([Frey et al., 2014](#))]. Likewise, N addition
6 (50 kg N/ha/yr) did not cause significant changes in root biomass in a tropical forest in
7 Puerto Rico ([Cusack et al., 2010](#)). Root turnover did not respond to N addition
8 (30 kg N/ha/yr for 3 years) across 13 successional (20–40 years old) and mature
9 (>90 years old) hardwood stands in central New Hampshire ([Kang et al., 2016](#)). In
10 contrast with the mixed oak stands, fine root biomass decreased in two red pine stands at
11 Harvard Forest [50 or 150 kg N/ha/yr for over 10 years; ([Frey et al., 2014](#))], and root
12 biomass also decreased with N additions (50 or 150 kg N/ha/yr for 3 years) in a
13 subtropical, broadleaf forest in China ([Peng et al., 2017](#)).

14 Observations of how other belowground processes respond to N additions provide further
15 evidence of an increase in the ratio of tree C allocated to aboveground growth and
16 productivity versus the C allocated belowground. In a meta-analysis of forest soil
17 respiration responses to N addition, [Janssens et al. \(2010\)](#) noted that N additions
18 decreased soil respiration overall, with a portion of this effect caused by a decrease in
19 autotrophic respiration. Within forests, autotrophic respiration may make up more than
20 50% of total soil respiration ([Hasselquist et al., 2012](#)). Much of this autotrophic
21 respiration is mycorrhizal respiration, with the C allocated to and respired by
22 mycorrhizae estimated to account for 9 to 34% of forest soil respiration ([Hasselquist et](#)
23 [al., 2012](#); [Heinemeyer et al., 2007](#)).

24 Mycorrhizal fungi have long been observed to be sensitive to increased forest N
25 availability, particularly ectomycorrhizae because these fungi have direct roles in plant N
26 acquisition, and their production of aboveground fruiting bodies (sporocarps) makes it
27 easier to observe changes in abundance ([Treseder, 2004](#); [Lilleskov et al., 2002](#); [Wallenda](#)
28 [and Kottke, 1998](#)). As noted in [Appendix 4](#), when N supply increases, C allocation to
29 ectomycorrhizal fungi decreases, and their abundance and activity decline. In a
30 meta-analysis, [Li et al. \(2015\)](#) found that N additions decreased mycorrhizal colonization
31 of fine root tips by 19% (n = 12). In contrast to the widespread increases in aboveground
32 tree growth, studies of ectomycorrhizal growth and productivity responses to added N
33 have documented nearly universally negative or neutral effects on metrics such as
34 mycorrhizal root colonization, sporocarp abundance, and the abundance of the fungal
35 lipid biomarker 18:2ω6,9 in the soil ([Table 6-2](#)). Although this research is consistent,
36 these studies have limitations because nearly all of this research has been conducted on
37 conifer species and most of the negative effects occur in studies using unrealistically high
38 rates of N addition (>100 kg N/ha/yr). However, two studies of ectomycorrhizae in

1 Norway spruce forests in Europe have documented significant declines along gradients of
2 ambient N deposition ([Bahr et al., 2013](#); [Kjøller et al., 2012](#)). In particular, ([Kjøller et al.,](#)
3 [2012](#)) observed an 80 and 90% decrease in ectomycorrhizal root tip abundance and
4 mycelial production, respectively, across a canopy throughfall N deposition gradient of
5 27 to 43 kg N/ha/yr in Denmark. [Morrison et al. \(2016\)](#) also observed a decline in the
6 relative abundance of ectomycorrhizal fungal DNA within the soil of the N addition (50
7 or 150 kg N/ha/yr for 25 years) plots at the oak (*Quercus*)-dominated Harvard Forest in
8 Massachusetts.

9 Given these decreases in ectomycorrhizal growth and productivity in response to added
10 N, it is not surprising that the amount of C allocated belowground by plants to
11 mycorrhizae can be sensitive to N availability. [Högberg \(2012\)](#) twice added N
12 (100 kg N/ha) over a period of two growing seasons to boreal Scots pine forests in
13 Sweden as part of a short (~2 hour) ¹³C canopy labeling experiment. In the 5 weeks
14 following the labeling, 48% less of the ¹³C label was found in an ectomycorrhizal fungal
15 lipid biomarker in the soil of the N amended plots. [Hasselquist et al. \(2012\)](#) found that in
16 Scots pine forests in northern Sweden, 6 years of N additions at a rate of 100 kg N/ha/yr
17 decreased respiration from ectomycorrhizae by 40%, but N additions at a rate of
18 20 kg N/ha/yr increased this respiration by 120%. However, the low N addition did not
19 change the fractional contribution of ectomycorrhizae to total soil respiration. The low N
20 addition treatment also had no effect on ectomycorrhizal sporocarp production, but the
21 high N addition treatment nearly eliminated sporocarp production [99% decrease;
22 ([Hasselquist et al., 2012](#))]. The availability of N also appears to influence the transfer of
23 N from mycorrhizal fungi to plants. In a boreal Scots pine forest in Sweden, [Näsholm et](#)
24 [al. \(2013\)](#) observed that a single N dose (100 kg N/ha) shifted the dominant sink for a ¹⁵N
25 tracer added 2 weeks later from the cytoplasm of ectomycorrhizal fungi and other soil
26 microorganisms to the pine foliage.

27 Although ectomycorrhizae are important in many high latitude and temperate
28 ecosystems, particularly forests, most species of terrestrial plants form arbuscular
29 mycorrhizae ([Rillig, 2004](#)). The impact of N deposition on arbuscular mycorrhizae has
30 received less research attention, perhaps partly because these fungi are best known for
31 their role in plant P acquisition ([Rillig, 2004](#)). Arbuscular mycorrhizae community
32 composition and production can be sensitive to added N [([van Diepen et al., 2010](#);
33 [Egerton-Warburton and Allen, 2000](#)); [Table 6-3](#)], but these effects may not be consistent.
34 [van Diepen et al. \(2010\)](#) reviewed eight previous studies of how intraradical (within root)
35 and extraradical arbuscular mycorrhizal biomass responded to N additions,
36 predominantly in forests, and found inconsistent effects. Intraradical biomass
37 significantly declined in response to N in three studies and increased in two studies,
38 including in the work of ([Garcia et al., 2008](#)). In comparison, extraradical biomass was

1 either unresponsive or declined ([van Diepen et al., 2010](#)). Aside from the work of [Garcia](#)
2 [et al. \(2008\)](#), other researchers since 2008 have found either neutral or negative effects on
3 metrics of arbuscular mycorrhizal biomass and abundance ([Table 6-3](#)). Observations of
4 decreased arbuscular mycorrhizal biomass span from a subtropical broadleaf evergreen
5 forest in China that experienced a single year of N additions (25 or 50 kg N/ha/yr) ([Shi et](#)
6 [al., 2016a](#)) to a subalpine Englemann spruce (*Picea engelmannii*) forest in Rocky
7 Mountain National Park that had received more than 15 years of N additions
8 (25 kg N/ha/yr) ([Boot et al., 2016](#)).

9 Notably, the arbuscular mycorrhizal species studied by [Garcia et al. \(2008\)](#) were all
10 understory or subdominant canopy species growing beneath ectomycorrhizal loblolly
11 pines. The increased growth of these larger trees in response to added N may have
12 imposed other resource limitations on the arbuscular mycorrhizal plant species. In
13 general, the response of arbuscular mycorrhizae to N additions may depend upon the
14 relative availability of P or other nutrients. [Johnson et al. \(2003\)](#) found N additions
15 decreased arbuscular mycorrhizae when the soil N:P ratio was low (i.e., P-rich soils),
16 while increasing arbuscular mycorrhizae under high soil N:P (i.e., P-poor soils). Where P
17 is more limiting, plants may allocate more carbon to arbuscular mycorrhizae in order to
18 acquire it ([Egerton-Warburton et al., 2007](#); [Johnson et al., 2003](#)). Thus, the varying
19 availability of soil P may explain in part the seemingly inconsistent response of
20 arbuscular mycorrhizae to N additions.

Table 6-3 Growth, productivity, and carbon cycle responses of arbuscular mycorrhizal fungi to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
van Diepen et al. (2010)	Michigan (four sites)	Sugar maple (<i>Acer saccharum</i>)	Addition	30	13	Extraradical biomass production	Decrease

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

- 1 Aside from mycorrhizal respiration, the other dominant component of autotrophic soil
- 2 respiration is root respiration. Although [Janssens et al. \(2010\)](#) observed a decrease in

1 autotrophic soil respiration in the presence of N, this decrease was not apparently related
2 to changes in root respiration. In a long-term N addition experiment (30 kg N/ha/yr for
3 +15 years) in four northern hardwoods forests, [Burton et al. \(2012\)](#) found that although
4 root N concentration was a strong predictor of the root respiration rate and N additions
5 had increased root N concentrations, N additions had not increased root respiration
6 because the added N changed the relationship between root N and respiration. [Drake et](#)
7 [al. \(2008\)](#) made a similar observation in loblolly pine forests in North Carolina: N
8 additions (100 kg N/ha/yr for 2 years) increased fine root N concentrations but did not
9 impact fine root respiration rates, resulting in an altered tissue N respiration relationship.
10 [Frey et al. \(2014\)](#) also reported that root respiration was unresponsive to long-term N
11 additions (50 or 150 kg N/ha/yr) in oak forests and pine forests in Massachusetts.
12 However, [Hasselquist et al. \(2012\)](#) found that a relatively modest N addition rate
13 (20 kg N/ha/yr for 6 years) increased both root and mycorrhizal respiration in a boreal
14 forest in Sweden that received relatively low rates of ambient N deposition
15 (<5 kg N/ha/yr). Thus, it appears that C allocation to mycorrhizae is more sensitive to N
16 availability than C allocation to root respiration.

17 In a meta-analysis of the effects of N additions on microbial biomass, [Treseder, 2008](#))
18 found that changes in soil respiration were significantly and positively correlated with the
19 response of microbial biomass. Mycorrhizal fungi are major components of forest soil
20 microbial communities, with [Högberg et al. \(2010\)](#) estimating that ectomycorrhizal
21 mycelium made up 39% of total soil microbial biomass in a Swedish boreal forest. At
22 Harvard Forest, [Morrison et al., 2016](#)) observed that 59–72% of all fungal operational
23 taxonomic units (OTUs) belonged to ectomycorrhizal fungi. Given the widespread
24 negative effects of added N on mycorrhizal fungi, the results of [Treseder \(2008\)](#)
25 meta-analysis and the broadly negative or neutral effects of N additions on microbial
26 biomass in the studies published since 2008 are unsurprising ([Table 6-4](#)).

Table 6-4 Abundance and carbon cycle responses of forest soil microorganisms and soil invertebrates to nitrogen added in experimental treatments.

C = carbon; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 However, forest soil microbial communities are taxonomically and functionally diverse
2 (see [Appendix 6.3.3.3](#)) and have exhibited varying responses to added N ([Zhang et al.](#)
3 [2015c](#); [Treseder, 2008](#)). For instance, [Wang et al. \(2015a\)](#) added N (50, 100, or
4 150 kg N/ha/yr for 9 years) to pine, broadleaf, and mixed pine-broadleaf forests in
5 southern China; the 50 kg N treatment increased microbial biomass C in the pine forests

1 and the 150 kg N treatment decreased microbial biomass C in the broadleaf forests, but
2 there were no other significant treatment effects. Elsewhere in China, a single year of N
3 additions (25 or 50 kg N/ha/yr) in a subtropical broadleaf evergreen and temperate
4 broadleaf deciduous forest had no effect on total microbial biomass in either forest, but
5 decreased the abundance of Gram-negative bacteria, actinomycetes, and saprotrophic
6 fungi in the subtropical evergreen forest ([Shi et al., 2016a](#)). The addition of
7 100 kg N/ha/yr to a regenerating Alaskan boreal forest decreased the microbial biomass
8 and the C:N ratio of microbial biomass ([Allison et al., 2010](#); [Allison et al., 2008](#)), while
9 N additions (50 kg N/ha/yr) in Indiana mixed hardwood forests decreased microbial
10 biomass without affecting the microbial C:N ratio ([Midgley and Phillips, 2016](#)). In
11 Sweden, the addition of 100 kg N/ha/yr to boreal forests for 6 years decreased bacterial
12 biomass, but did not significantly affect fungal biomass ([Wardle et al., 2016](#)). The
13 opposite result was observed in pine and hardwood stands at Harvard Forest and in
14 subalpine spruce-fir forests in Rocky Mountain National Park (RMNP). There, N
15 additions decreased fungal biomass, but bacterial biomass was unaffected (50 and 150 kg
16 N/ha/yr for 14 years at Harvard Forest; 25 kg N/ha/yr for 17 years in RMNP) ([Boot et al.,
17 2016](#)). In Michigan, long-term (+15 years) N additions (30 kg N/ha/yr) to northern
18 hardwood forests decreased the abundance of actinobacteria in the surface mineral soil,
19 but not in the soil organic horizon ([Eisenlord and Zak, 2010](#)). Relative to mycorrhizal
20 fungi, there is less information available regarding the growth and biomass responses of
21 individual domains and other taxonomic groupings within microbial communities
22 [Table 6-4](#)). Of this finer scale information, most observations are for fungi (sometimes
23 including mycorrhizal fungi), with positive, neutral, and negative effects of added N.

24 Atmospheric N deposition may affect forest microbial communities and litter
25 decomposition by altering litter chemistry through shifts in forest community
26 composition, increasing litter N concentrations, or changing the secondary chemistry of
27 litter. The two dominant forms of forest plant litter, leaves and fine roots, can each be
28 altered by N additions ([Xia et al., 2015](#)). As noted in the aboveground processes section
29 of this appendix, there is abundant evidence that N deposition can increase foliar N
30 concentrations in trees and there is also a large body of research that the increase in foliar
31 N concentrations will result in increased leaf litter N concentrations ([Aerts, 1996](#)). Since
32 the 2008 ISA, there have been new observations of increased leaf litter N concentrations
33 both in long-term N addition experiments ([van Diepen et al., 2015](#); [Xia et al., 2015](#); [Zak
34 et al., 2008](#)) and along an N deposition gradient [6.8–11.8 kg N/ha/yr; ([Talhelm et al.,
35 2012](#))]. Increases in leaf litter N concentrations with greater N deposition are not
36 universal [e.g., ([Watmough and Meadows, 2014](#))], but in a meta-analysis, [van Diepen et
37 al. \(2015\)](#) observed a >20% increase in tree leaf litter N concentrations in response to N
38 additions. Other changes in forest litter chemistry likely involve changes in more
39 complex physiological and biogeochemical mechanisms ([Du and Fang, 2014](#)). In an old

1 growth boreal forest in China, N additions (20, 50, or 100 kg N/ha/yr for 3 years)
2 decreased leaf litter P concentrations, an effect that could have been caused by changes in
3 either physiological or biogeochemical processes ([Du and Fang, 2014](#)). In a
4 meta-analysis, [van Diepen et al. \(2015\)](#) found that simulated N deposition significantly
5 decreased leaf litter concentrations of P, calcium, manganese, aluminum, and zinc, but
6 did not find significant changes in concentrations of potassium (K), magnesium, boron,
7 iron, or copper. It is not entirely understood how all of these changes in elemental
8 composition impact the composition and function of soil microbial communities, but
9 manganese and calcium are needed for the production of extracellular enzymes that
10 degrade lignin ([van Diepen et al., 2015](#)).

11 There is a large volume of research about how major biochemical constituents of plant
12 litter such as lignin, cellulose, condensed tannins, and phenolics impact leaf litter
13 decomposition, but less information about how N additions change the abundance of
14 these compounds. [Xia et al. \(2015\)](#) researched the effects of long-term N additions
15 (30 kg N/ha/yr for +15 years) on sugar maple leaf litter and fine root chemistry in four
16 mature northern hardwood forests in Michigan. The N additions increased concentrations
17 of condensed tannins in leaf litter and in fine roots. At three of the four sites, N additions
18 increased the fraction of nonstructural cell wall material and decreased both cellulose and
19 lignin in leaf litter. On an ecosystem basis, N additions decreased total annual litter
20 (leaf + fine root) fluxes of condensed tannins and soluble protein and increased the fluxes
21 of nonstructural carbohydrates (sugars + starch) and N ([Xia et al., 2015](#)). Based on broad
22 decomposition chemistry patterns observed elsewhere, these changes in litter chemistry
23 were expected to increase initial rates of litter decomposition, which contrasts with the
24 decrease in litter turnover rates observed at these sites ([Xia et al., 2015](#)). However,
25 changes in tissue chemistry are not ubiquitous; for example, [Griepentrog et al. \(2015\)](#)
26 observed that the abundance and composition of fatty acids in leaf and root tissues in
27 spruce and beech trees in Switzerland were not influenced by added N (70 kg N/ha/yr).
28 Further, while N additions can change plant tissue chemistry, links between litter
29 chemistry and microbial abundance and microbial function are complex [e.g., ([Baumann
30 et al., 2009](#))].

6.2.3.3. Forest Lichens

31 Lichens are widely used as indicators of N deposition impacts on ecosystems, particularly
32 in forests. However, lichens also are important for ecosystem function. For insects, birds,
33 and mammals, lichens represent camouflage, building materials for nests, and a source of
34 food ([Brodo et al., 2001](#)). Lichens absorb N, sulfur (S), and other elements from
35 atmospheric deposition and throughfall, and lichens that host cyanobacteria can add

1 significantly to ecosystem N inputs, providing N to other plants ([Kobylnski and Fredeen,](#)
2 [2015](#)). In addition, lichens also have a role in hydrologic cycling, have many traditional
3 human uses, and have high potential for pharmaceutical use ([McCune and Geiser,](#)
4 [1997](#)). Lichens are symbioses comprised of fungi (mycobiont) and a green alga and/or
5 cyanobacterium [photobiont; ([Sundberg et al.,](#) [2001](#); [Palmqvist,](#) [2000](#))]. Much of the
6 lichen biomass is comprised of fungal (mycobiont) tissue, but the photobiont synthesizes
7 organic compounds, supplying the energy and structural C needed for growth of the
8 lichen. Both the photobiont and the mycobiont require N for growth ([Palmqvist,](#) [2000](#)),
9 but the supply of C and N must be coordinated for the development of lichen thalli
10 ([Sundberg et al.,](#) [2001](#)). Lichens with a cyanobacterial photobiont are N fixing, but those
11 with a green algal photobiont depend on atmospheric deposition for N.

12 Lichens can be classified based on their response to N pollution. Lichens occurring in
13 areas that receive high N deposition are considered nitrophytic or eutrophic; lichens
14 common in areas receiving low N input are designated acidophytic or oligotrophic ([Gaio-](#)
15 [Oliveira et al.,](#) [2005](#); [van Herk,](#) [2001](#)). Atmospheric N deposition can impact lichens
16 through changes in physiological function caused by an increased supply of N or by
17 altering the pH of tree bark hosting the lichen ([Jovan,](#) [2008](#)). Although lichens with a
18 green algal photobiont depend on atmospheric deposition as a source of N, these lichens
19 can also be negatively impacted by N deposition via the accumulation of toxic
20 concentrations of NH_4^+ within the thallus. Cyanobacteria can grow on either NO_3^- or
21 NH_4^+ sources when administered at nontoxic concentrations, but more rapid growth has
22 been observed with NH_4^+ than NO_3^- ([Von Rückert and Giani,](#) [2004](#)). Ammonium is more
23 easily assimilated by lichens; both NO_3^- and nitrite must first be reduced to NH_4^+ before
24 assimilation can occur ([Von Rückert and Giani,](#) [2004](#)). The 2008 ISA noted that lichens
25 with a cyanobacterial photobiont appear to be more sensitive to adverse effects from
26 atmospheric N deposition than most other lichens ([Dahlman et al.,](#) [2002](#); [Hallingbäck and](#)
27 [Kellner,](#) [1992](#); [Hallingbäck,](#) [1991](#)). In part, the sensitivity of lichens to increasing N
28 deposition is a function of the mechanisms with which that lichen can respond to high N
29 supply, such as decreasing N uptake or assimilating N into nontoxic forms such as
30 arginine ([Gaio-Oliveira et al.,](#) [2005](#); [Dahlman et al.,](#) [2002](#)).

31 Since the 2008 ISA, new research on the impact of N deposition on the growth and
32 physiology of forest lichens has both confirmed that lichen abundance is sensitive to N
33 deposition and provided further insight on the growth and physiological changes that
34 occur when lichens are exposed to exogenous N ([Table 6-5](#)). For example, previous
35 research had suggested that lichens were most sensitive to N as ammonia ([Sheppard et](#)
36 [al.,](#) [2011](#); [Jovan,](#) [2008](#)). However, a study of lichen communities on California black oak
37 (*Quercus kelloggii*) forests at 22 sites in the Los Angeles Basin in California, [Jovan et al.](#)
38 [\(2012\)](#) found that the abundance of eutrophic lichen species was only weakly related to

1 gaseous NH₃ concentrations. Instead, the strongest N pollution-related predictor of
2 eutrophic lichen abundance was total N deposition (as canopy throughfall). Further, at the
3 relatively neutral bark pHs in the Los Angeles Basin, there was no influence of pH on the
4 abundance of eutrophic lichen species. The abundance of eutrophic lichens was also best
5 correlated with total throughfall N deposition in southeastern Alaska ([Schirokauer et al.,
6 2014a](#)). This research provides strong evidence that total N deposition, not the deposition
7 of a particular form of N, is the primary driver of changes in the growth, physiology, and
8 composition of epiphytic lichens.

9 Increases in lichen thalli N concentrations in response to added N have been widely
10 observed in the U.S. and Europe ([Table 6-5](#)), even at relatively low rates of atmospheric
11 N deposition. For instance, [McMurray et al. \(2013\)](#) measured throughfall N deposition
12 and sampled lichen thalli N concentrations at sites near the Bridger-Teton National Forest
13 Wilderness that were at increasing distances downwind of a major oil and natural gas
14 production field. Although the observed rates of N deposition were only 0.8 to
15 4.1 kg N/ha/yr along this gradient, thalli N concentrations in *Usnea lapponica*
16 approximately doubled from ~1.2 to 2.4%. In southeastern Alaska, [Schirokauer et al.
17 \(2014a\)](#) found increases in thalli N concentrations along an even smaller range of N
18 deposition (0.05 to 1.05 kg N/ha/yr), a pollution gradient attributed to cruise ship
19 emissions.

20 In southern California, [Riddell et al. \(2008\)](#) transplanted thalli from the oligotrophic
21 lichen *Ramalina menziesii* from relatively unpolluted sites into fumigation chambers
22 under moderate and high HNO₃ concentrations (19.9–25 µg/m³ and 26.4–35.3 µg/m³,
23 respectively). The HNO₃ fumigation caused significant declines in chlorophyll content
24 and C exchange capacity compared to thalli in control chambers. This research was later
25 expanded to six species known to vary in sensitivity to N pollution ([Riddell et al., 2012](#)).
26 Fumigation with HNO₃ (daily peaks near 50 ppb) decreased chlorophyll content,
27 chlorophyll fluorescence, gross photosynthesis, and dark respiration in three of the five N
28 sensitive species; while only photosynthesis declined in the other two N sensitive species.
29 Four of the N sensitive species were tested for fumigation effects on cell membrane ion
30 leakage; overall ion leakage, and specifically K⁺ ion leakage, were increased by HNO₃
31 fumigation in all species.

Table 6-5 Growth and physiology responses of forest epiphytic lichens to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen

Notes: single studies are reported more than once if multiple endpoints were measured. References are ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 Johansson and colleagues conducted a series of experiments in Sweden intended to
2 understand the physiological responses of epiphytic lichens to added N ([Johansson et al.](#)
3 [2012](#); [Johansson et al., 2011](#); [Johansson et al., 2010](#)). In a whole-tree N addition
4 experiment in a spruce forest in boreal Sweden, low rates of N addition (6,
5 12.5 kg N/ha/yr for 3 years) increased total lichen abundance, but higher N addition rates
6 (25, 50 kg N/ha/yr) decreased total lichen abundance ([Johansson et al., 2012](#)). However,
7 there was considerable variation among lichen species in the N addition treatment rate
8 that resulted in optimal growth. For two of the lichen species in that experiment,
9 *Alectoria sarmentosa* and *Platismatia glauca*, [Johansson et al. \(2010\)](#) quantified
10 physiological responses to N additions. Thalli N concentrations increased in both species
11 at the two highest N addition rates (25, 50 kg N/ha/yr). There was a significant positive
12 relationship between cumulative N dose and chlorophyll content, but the N additions did
13 not affect thalli P concentrations. In a separate experiment with a single much higher N
14 addition rate (300 kg N/ha/yr for one season), [Johansson et al. \(2011\)](#) examined the

1 physiological and growth responses of three lichen species. All three lichen species
2 exhibited increased tissue N concentrations, increased chlorophyll concentrations,
3 increased photosynthesis, and increased growth of the photobiont. However, mycobiont
4 growth decreased in two species and was unchanged in the third. Total biomass changes
5 among the three species were positive, neutral, and negative.

6 In another experiment in Scandinavia, lichens collected from Sweden and Norway were
7 exposed to added N (50 kg N/ha/yr for one season) to understand whether this addition
8 altered the concentrations of the C based secondary compounds (CBSCs) thought to
9 protect lichens from herbivores and whether it affected feeding preferences of gastropod
10 herbivores ([Asplund et al., 2010](#); [Nybakken et al., 2009](#)). The N additions decreased the
11 concentrations of CBSCs in one species, but had no effect on the other three lichen
12 species ([Nybakken et al., 2009](#)). The gastropod herbivores preferred to feed on lichens
13 from the control treatment for three of the four species, while preferring the thalli from
14 the N addition treatment for the fourth lichen species ([Asplund et al., 2010](#)). Notably, the
15 species exhibiting the decrease in CBSCs was not the species that was more preferable to
16 herbivores in the N addition treatment. Together, these results suggest that N deposition
17 may alter lichen community composition by shifting herbivore feeding preferences.

6.2.3.4. Net Ecosystem Production and Carbon Sequestration Response

18 The 2008 ISA concluded that N deposited onto terrestrial ecosystems increased net
19 primary productivity (NPP) and ecosystem C storage (kg C/ha). However, the extent to
20 which this additional N stimulates forest C sequestration was a topic of debate [e.g., ([De
21 Schrijver et al., 2008](#); [de Vries et al., 2008](#); [Sutton et al., 2008](#); [Magnani et al., 2007](#);
22 [Nadelhoffer et al., 1999b](#))]. [Magnani et al. \(2007\)](#) correlated net ecosystem production
23 (NEP; kg C/ha/yr) with estimated rates of N deposition for 20 forested sites in North
24 America and Europe, which resulted in an estimate of 725 kg C sequestered per kg of
25 added N (i.e., kg C/kg N). However, this estimate was widely criticized and a reanalysis
26 of these data produced an estimate of C sequestration more than an order of magnitude
27 lower [68 kg C/kg N; ([Sutton et al., 2008](#))].

28 Since the 2008 ISA, several new syntheses and a number of field experiments and
29 modeling studies have provided further evidence that N deposition increases NPP, NEP,
30 and ecosystem C content, and that have more tightly constrained estimates of the
31 response of plant, soil, and ecosystem C content to N deposition. [Nave et al. \(2009b\)](#)
32 estimated that up to 15% of the N needed to support NPP in a northern Michigan aspen
33 forest was supplied by atmospheric N deposition. In China, N additions of 20, 50, or
34 100 kg N/ha/yr to an old growth boreal forest stimulated aboveground tree productivity

1 by 5, 7, and 23% during the second and third years of the experiment ([Du and Fang,](#)
2 [2014](#)). [Chen et al. \(2011\)](#) found that a Douglas-fir stand in the Pacific Northwest
3 increased NEP by 2,500 kg/ha (+83%) in the first year after receiving 200 kg N/ha of
4 urea, both from decreased respiration (930 kg/ha) and increased gross primary production
5 (157 kg/ha). Increases in ecosystem C content have been noted in long-term N addition
6 experiments in Massachusetts ([Frey et al., 2014](#)), Michigan ([Pregitzer et al., 2008](#)), and
7 New York ([Lovett et al., 2013](#)). Using a process model that neglected changes in stand
8 ontogeny, disturbances, and shifts in forest management, [de Vries and Posch \(2011\)](#)
9 concluded that N deposition was a dominant determinant of European forest productivity
10 throughout the 20th century.

11 Since the 2008 ISA, a variety of techniques have been used to quantify the C
12 sequestration response of forests to N deposition, particularly in Europe ([Frey et al.,](#)
13 [2014](#)). Using a ¹⁵N-labeling technique, [Gundale et al. \(2014\)](#) observed a linear
14 relationship between C sequestration and N additions of up to 50 kg N/ha/yr that had a
15 slope of 16 kg C/kg N in a Swedish boreal forest. [Hyvönen et al. \(2008\)](#) synthesized soil
16 and plant C sequestration data from 15 long-term (14–30 year) N addition experiments in
17 boreal (*Picea abies*, *Pinus sylvestris*) forests in Sweden and Finland and estimated that C
18 sequestration averaged 23 kg C/kg N for *Picea* and 30 kg C/kg N for *Pinus*, with an
19 additional 11 kg C/kg N within the soil. Also in Sweden, [Eliasson and Ågren \(2011\)](#)
20 applied an ecosystem model to Scots pine (*Pinus sylvestris*) forests and estimated that
21 ecosystem C stocks increased by 24,123 kg/ha in response to a cumulative 224 kg N/ha
22 added over a century (108 kg C/kg N). Based on the stimulation of photosynthesis and
23 assumptions about the fraction of photosynthate that is ultimately transformed into tree
24 biomass, [Fleischer et al. \(2013\)](#) estimated that N deposition stimulates C sequestration by
25 25 kg C/kg N.

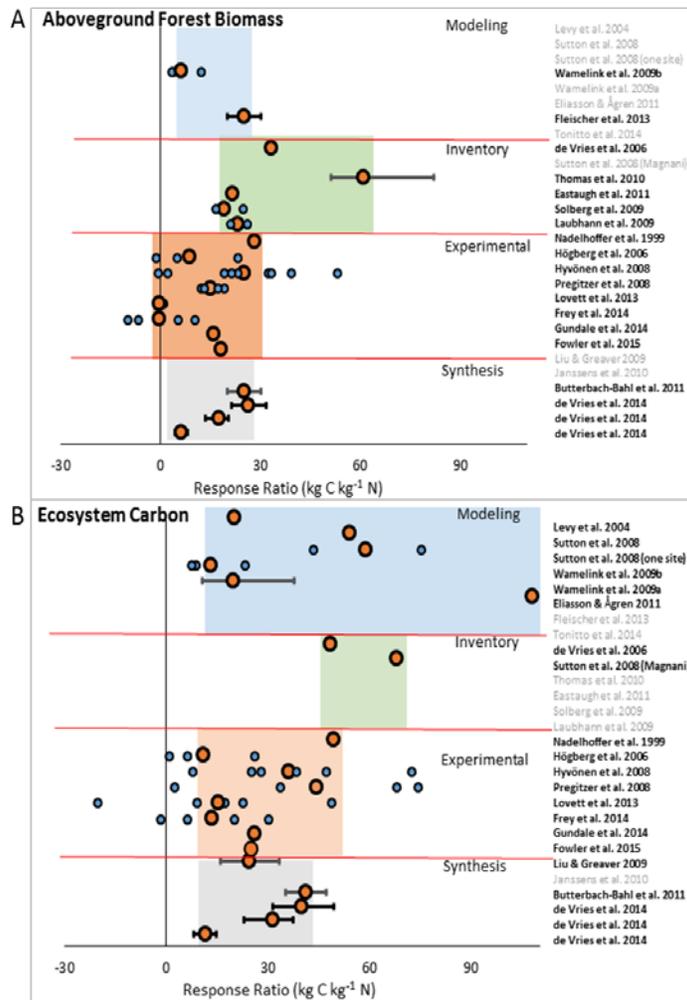

26 Forest inventory studies typically make use of one or more decades of tree growth data
27 from national or continental monitoring networks and relate the variation in this growth
28 to differences in N deposition and other environmental factors. Across western and
29 northern Europe, [Solberg et al. \(2009\)](#) found that variation in tree volume increment was
30 positively related to N deposition and summer temperature, particularly for pine (*Pinus*)
31 and spruce (*Picea*), with similar, but weaker, relationships for beech (*Fagus*) and oak
32 (*Quercus*). The overall model estimated C sequestration was 19 kg C/kg N. [Eastaugh et](#)
33 [al. \(2011\)](#) analyzed Norway spruce (*Picea abies*) growth data from the Austrian National
34 Forest Inventory and estimated that N deposition sequestered 21.6 kg C/kg N in
35 aboveground tree biomass during the latter half of the 21st century. [Etzold et al. \(2014\)](#)
36 and [Ferretti et al. \(2014\)](#) took similar approaches with 18 inventory plots in Switzerland
37 and 25 inventory plots in Italy, respectively. Both studies found a positive relationship
38 between N deposition and NPP, but were unable to isolate NPP effects from other

1 environmental factors. Within the U.S., the analysis of forest inventory data in the
2 northeastern U.S. by [Thomas et al. \(2010\)](#) estimated that N deposition increased
3 aboveground tree biomass at 61 kg C/kg N; a rough estimate including belowground C
4 increased this to 73 kg C/kg N. [Pinder et al. \(2012\)](#) modified the estimates of [Thomas et](#)
5 [al. \(2010\)](#), using alternate values for N deposition, more complex belowground biomass
6 estimates, and changes in soil C pools, to produce an enhancement of 65 kg C/kg N. One
7 criticism of the inventory and modeling studies is that they match variation in growth
8 only to current levels of N deposition and neglect the potential effects of previous N
9 deposition at that site. Thus, the influence of current N deposition may be exaggerated
10 ([Högberg, 2012](#)). In addition, estimates of tree growth and biomass production typically
11 rely on the application of equations that predict tree biomass based on measurements of
12 tree stem diameter, either alone or in combination with tree height measurements. [Ibanez](#)
13 [et al. \(2016\)](#) observed that at the sites in Michigan where N additions had increased tree
14 growth ([Pregitzer et al., 2008](#)), the N additions had also altered the allometric patterns of
15 sugar maple tree growth so that at a given tree stem diameter at breast height (1.4 m), the
16 trees receiving N additions were taller than those in the control plots. This meant that
17 stemwood biomass equations underestimated tree size for trees receiving N additions
18 ([Ibanez et al., 2016](#)). If these results apply in other environments and with other tree
19 species, this implies that allometric biomass equations may be underestimating tree
20 biomass in regions experiencing high rates of atmospheric N deposition and that
21 estimates of C sequestration due to tree growth increases [e.g., ([Thomas et al., 2010](#))]
22 may be too low.

23 In the long-term N addition experiment at Harvard Forest ([Frey et al., 2014](#)), the C
24 response to N deposition ranged from -2 to 30 kg C/kg N among the four treatment types
25 (50 or 150 kg N/ha/yr; *Pinus* or *Quercus* forests) and the amount of C sequestered in the
26 soil was equal to or greater than the amount of C sequestered in trees. Similar results
27 showing more C sequestration in the soil than in trees were found in N addition
28 experiments at four Michigan forests (23 kg C/kg N soil vs. 17 kg C/kg N tree; ([Pregitzer](#)
29 [et al., 2008](#)) and in the Catskills ([Lovett et al., 2013](#)). Several syntheses of forest C
30 sequestration changes in response to N deposition have been conducted ([Tian et al.,](#)
31 [2016a](#); [Frey et al., 2014](#); [Pinder et al., 2013](#); [Pinder et al., 2012](#); [Butterbach-Bahl et al.,](#)
32 [2011](#); [Janssens et al., 2010](#); [Liu and Greaver, 2009](#)), producing estimates of 12–41 kg
33 C/kg N. Often these synthesis studies are meta-analyses; however, [de Vries et al. \(2014a\)](#)
34 took a novel approach of combining estimates of ecosystem N retention with N allocation
35 and C:N ratios to develop stoichiometric estimates of N deposition for tropical,
36 temperate, and boreal ecosystems. Although this approach involves a number of
37 important assumptions about biogeochemistry and tree physiology, estimates for tree and
38 soil C sequestration response rates were similar to values from other syntheses
39 ([Figure 6-3](#)). In their study of aboveground NPP responses per unit of added N, [Tian et](#)

1 [al. \(2016a\)](#) found that the average forest response was a 3.75% increase in NPP per g of
2 N.

3 Variation in these estimates is likely influenced by the research approach. For instance,
4 the model used by [Eliasson and Ågren \(2011\)](#) predicted almost no N losses from the
5 forests due to leaching or denitrification, which are both widely reported at high rates of
6 N deposition. However, environmental and ontological factors also appear to influence
7 the sensitivity of forest C sequestration to N deposition. Using the G'DAY model, [Dezi et](#)
8 [al. \(2010\)](#) found recent forest harvests, shifts in plant C allocation away from roots, and
9 canopy N uptake all increased the C sequestration response to N deposition. Among the
10 15 experiments synthesized by [Hyvönen et al. \(2008\)](#), the amount of C sequestered
11 ranged from -0.8 to 61 kg C/kg N, with greater increases in kg C/kg N at lower N doses.
12 The amount of additional tree C sequestered was small in plots that had low soil
13 O-horizon C:N ratios (near 25) and the amount of C sequestered by added N increased
14 with O-horizon C:N until C:N reached 35. Among *Picea* forests, young stands were more
15 responsive than old stands, but no such effect was apparent for *Pinus*. In addition, C
16 sequestration increased more in plots simultaneously supplied with K and P ([Hyvönen et](#)
17 [al., 2008](#)). [Janssens et al. \(2010\)](#) acknowledged the role of stand age in altering the
18 dynamic of C cycling, explicitly removing young, rapidly expanding forests from some
19 portions of the meta-analysis.

C = carbon; kg = kilogram; N = nitrogen.

Notes: studies are grouped by research approaches, including process modeling, forest inventory analyses, long-term N addition experiments, or data syntheses. The citations to the right represent studies that quantified at least one of three aspects of forest C sequestration responses to N (forest biomass, soil C, or ecosystem C). Studies that quantified (A) forest biomass and (B) ecosystem carbon are shown in black text; N deposition C sequestration studies that quantified other C pools are shown in grey. The large orange circles represent the mean response for each study and the smaller blue circles represent individual estimates (replicate plots, study sites, or model simulations). The colored boxes bound the range of mean responses.

Figure 6-3 Studies reporting the response of forest (A) aboveground biomass carbon sequestration and (B) ecosystem carbon sequestration to nitrogen deposition or long-term nitrogen additions.

6.2.4. Arctic and Alpine Tundra and Grasslands

1 Tundra areas in the U.S. are concentrated in high-elevation alpine areas in the western
2 U.S. and high-latitude areas in Alaska. Although alpine ecosystems are limited in their
3 spatial extent, these ecosystems are important components of many national parks
4 (e.g., Rocky Mountain, Yosemite, Sequoia-Kings Canyon, Mount Rainier) and other
5 Class I areas within these regions. Nitrogen deposition rates in Arctic tundra areas are
6 generally low, but there is a distinct impact of anthropogenic pollution on N cycling that
7 could increase with further industrial development at high latitudes ([Holtgrieve et al.,
8 2011](#)). In addition, although baseline rates of N deposition in Arctic deposition tend to be
9 low, isolated precipitation events carrying air masses from industrialized or agricultural
10 regions can result in high rates of deposition ([Kuhnel et al., 2011](#)). In Svalbard (north of
11 Norway), 10% of precipitation events were responsible for 93% of all N deposited in
12 snow or rain ([Kuhnel et al., 2011](#)).

13 For Arctic tundra ecosystems, the 2008 ISA identified a single N addition experiment and
14 cited two studies from the 1980s on the effects of decreased N availability. The two
15 studies on plants grown under conditions of low N availability found that tundra plants
16 responded by increasing root growth ([Bloom et al., 1985](#)) or increasing N use efficiency
17 ([Chapin, 1980](#)). The N addition (50 or 100 kg N/ha/yr) experiment began in 1981 and
18 caused changes in plant community composition ([Shaver et al., 2001](#)) and increases in
19 aboveground plant growth, but losses in soil C pools that resulted in decreased ecosystem
20 C content ([Mack et al., 2004](#)).

21 The 2008 ISA reported that alpine plant species are often sensitive to N enrichment
22 because many are adapted to low nutrient availability ([Bowman et al., 2006](#)) and that N
23 deposition may increase alpine plant productivity and alter plant community composition
24 ([Neff et al., 2002](#); [Seastedt and Vaccaro, 2001](#); [Bowman et al., 1995](#)). Some alpine plants
25 in the southern Rocky Mountains exhibit greater growth in response to increased N, but
26 this species-specific growth response to N deposition is one of the mechanisms that can
27 change community composition ([Bowman et al., 1993](#)). Many of the dominant plant
28 species do not respond to additional N supply with increased production. Rather, many
29 subdominant species increase in abundance when the N supply is increased ([Fenn et al.,
30 2003a](#)). The 2008 ISA also noted that the effects of N deposition can be spatially
31 heterogeneous in alpine tundra ecosystems, with areas that accumulate wind-blown snow
32 receiving higher rates of winter N deposition ([Bowman and Steltzer, 1998](#)). Further, the
33 2008 ISA also cited evidence that chronic N additions to alpine ecosystems can
34 accelerate the decomposition of some soil C fractions, while preserving other C fractions
35 ([Neff et al., 2002](#)).

36 Research since 2008 on the effects of added N on alpine and Arctic ecosystems has
37 included broad syntheses, a number of experiments in both Europe and Asia, and

1 additional research in North America. [Bouskill et al. \(2014\)](#) conducted a meta-analysis of
2 high-latitude N addition experiments and compared these results with model simulations
3 from the Community Land Model (CLM), the land component of the Community ESM
4 (CESM). [Bouskill et al. \(2014\)](#) identified 37 N addition field experiments from 14 sites in
5 North America and Europe. In this synthesis, N additions significantly stimulated gross
6 primary production (GPP; $+44 \pm 7\%$, mean \pm standard error), while soil respiration
7 declined by $12 \pm 7\%$. Total aboveground plant biomass was not significantly affected by
8 N additions (increase of $15 \pm 22\%$), but vascular plant biomass increased by $33 \pm 8\%$.
9 Notably, the modeled responses produced from CLM matched observations only for two
10 parameters: soil organic matter and GPP. These matches occurred only under the lowest
11 rates of N addition (<1 kg N/ha/yr), suggesting that N cycling processes or parameters are
12 not well characterized in tundra ecosystems.

13 Three multiyear experiments span the period before and after the 2008 ISA was
14 published ([Table 6-6](#)). In a subalpine shrub heathland in Scotland, [Britton and Fisher](#)
15 [\(2007\)](#) examined the effects on plant communities of burning, clipping, and N additions
16 of 0, 10, 20, or 50 kg N/ha/yr as NH_4NO_3 for 5 years. Since the 2008 ISA was published,
17 [Britton et al. \(2008\)](#) observed that N additions increased shoot N concentration in the
18 dominant shrub *Calluna vulgaris*, with significant increases only at the two highest levels
19 of N addition. In assessing plant growth, [Britton and Fisher \(2008\)](#) found increased
20 growth of the dominant alpine shrub *Calluna vulgaris* and of *Vaccinium vitis-idaea* with
21 N additions of 20 and 50 kg N/ha/yr, but no effect with 10 kg N/ha/yr or with N at any
22 level on three other shrub species. Notably, in a greenhouse study with *Calluna vulgaris*
23 plants from four different geographic populations, [Meyer-Gruenefeldt et al. \(2016\)](#)
24 observed that N additions (35 kg N/ha/yr for 2 years) increased aboveground biomass in
25 all populations, but that responses varied by factor of two between populations.
26 Belowground biomass was unresponsive to N addition in the greenhouse study, resulting
27 in decreased root:shoot ratios and potentially making the plants more susceptible to
28 drought. In a second study within Scotland, [Britton and Fisher \(2010\)](#) found that N
29 additions of 7.5, 12.5, and 22.5 kg N/ha/yr increased thallus N concentration in three of
30 four alpine lichen species, but decreased growth of two species and did not significantly
31 affect growth in three other species.

Table 6-6 Alpine and Arctic tundra plant productivity and physiology responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate kg N/ha/yr	Duration yr	Endpoint	Effect of Additional Nitrogen

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; NEE = net ecosystem exchange; yr = year.

Notes: single studies are reported more than once if multiple endpoints or ecosystems were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 In subalpine tundra in Sweden, a long-term experiment was started in 1989 to understand
2 how alleviating nutrient limitations altered ecological processes, including productivity,
3 decomposition, and the development of plant communities ([Wardle et al., 2013](#); [Nilsson
4 et al., 2002](#)). The experimental design included six treatments, including additions of
5 NO_3^- and NH_4NO_3 at rates of 50 kg N/ha/yr. After the first 9 years, there were negative
6 effects of both NO_3^- and NH_4NO_3 on the percentage cover of the dominant ericaceous
7 shrub *Empetrum hermaphroditum*, but increased cover of two ericaceous *Vaccinium*
8 shrub species ([Nilsson et al., 2002](#)). An even stronger positive response was exhibited by
9 the bunchgrass *Deschampsia flexuosa*, which became the dominant plant in plots
10 receiving N additions. The N additions also had varying effects on the cover of the
11 dominant bryophyte species. *Dicranum* spp. decreased in cover in response to added N
12 and *Pleurozium schreberi* disappeared entirely from some N addition plots, while *Polia*
13 spp., *Bryum* spp. and *Barbilophozia lycopodioides* were not significantly affected by N
14 additions. The dominant lichen, *Cladina* spp., decreased in response to added N ([Nilsson
15 et al., 2002](#)). The N addition treatments did not impact vascular plant diversity, but moss
16 species richness was decreased by NH_4NO_3 and lichen species richness was decreased by
17 NO_3^- . Decomposition of pine needles in litterbags was followed for 4 years, but no
18 significant effects of the N addition treatments were observed ([Nilsson et al., 2002](#)). In
19 2010, [Wardle et al. \(2013\)](#) reassessed the changes in plant cover caused by the N addition
20 treatments. The N addition treatments increased cover of vascular plants, but decreased
21 bryophyte cover and lichen cover. Specifically, N additions repeatedly increased cover of
22 *Deschampsia* and decreased cover of *Empetrum*, although these changes were not always
23 significant. Within the soil microbial community, NH_4NO_3 additions decreased the
24 abundance of fungal phospholipid fatty acids (PLFAs; a marker of microbial abundance),
25 while bacterial PLFAs were increased by NO_3^- additions. However, NO_3^- and NH_4NO_3
26 each decreased the fungal-to-bacterial PLFA ratio in the soil. Humus mass and C content
27 were increased by NH_4NO_3 additions, but not significantly affected by NO_3^- .

28 Also spanning the period before and after the 2008 ISA was a 7-year N deposition study
29 in a subalpine grassland in the Swiss Alps, with rates of N addition of 0, 5, 10, 25, or
30 50 kg N/ha/yr (as NH_4NO_3). The initial analysis of the first 3 years of data found that N
31 additions increased aboveground plant productivity ([Bassin et al., 2007](#)). Among
32 functional groups, sedge growth was consistently stimulated, forb growth increased
33 strongly in the first year of the experiment, and grasses and legumes were unresponsive
34 to N. Species richness was not influenced by the N additions, but N did alter the relative
35 abundance of the 11 most frequently occurring species. A subsequent analysis of this
36 experiment [Bassin et al. \(2009\)](#) focused on the physiological responses of these
37 11 species to the 50 kg N/ha/yr treatment. The N addition treatment increased leaf
38 concentrations of N and chlorophyll in 9 of the 11 species. Notably, the species
39 exhibiting the largest growth response (*Carex sempervirens*) also showed the largest

1 increase in foliar concentrations of N and chlorophyll. Four years into the experiment,
2 [Volk et al. \(2011\)](#) measured changes in ecosystem C fluxes in response to the 10 and
3 50 kg N/ha/yr treatments. Although aboveground plant growth increased, there were no
4 significant changes in gross primary productivity or ecosystem respiration. Net
5 ecosystem production was unaffected by the lower rate of N addition, but declined with
6 the 50 kg N/ha/yr treatment, which suggests decreases in belowground C pools.

7 [Bassin et al. \(2013\)](#) and [Volk et al. \(2014\)](#) reassessed this Swiss Alps grassland N
8 addition experiment after 7 years when the experiment concluded. [Volk et al. \(2014\)](#)
9 observed that N additions had a strong positive effect on aboveground productivity,
10 ranging from a 31% stimulation caused by 5 kg N/ha/yr to a 60% increase caused by
11 50 kg N/ha/yr. Effects on belowground biomass were smaller, ranging from a 19%
12 increase for the 5 kg N treatment to a 24% increase for the 50 kg N treatment. Thus, N
13 additions increased the ratio of shoot-to-root biomass ([Volk et al., 2014](#)). This is
14 consistent with a ¹⁵N tracer study at the site, in which the N addition treatment increased
15 the proportion of the ¹⁵N tracer found in aboveground biomass ([Bassin et al., 2015](#)).
16 However, the stimulation of plant N pools was relatively similar among aboveground
17 biomass (+31%), roots (+31%), necromass (+41%), and litter [+30%; ([Bassin et al.,](#)
18 [2015](#))]. Among functional groups, the longer term results were both similar and different
19 from the results observed after the initial 3 years ([Bassin et al., 2013](#)). The effects of N
20 addition on sedge biomass increased through time, with the highest rate of N addition
21 (50 kg N/ha/yr) increasing sedge biomass by 360%. In this same treatment, grass biomass
22 increased by 14%, forb biomass was unchanged, and legume biomass decreased by 43%.
23 Unsurprisingly, these changes resulted in more sedge-dominated plant communities. Two
24 aspects of this community change are notable: (1) changes were largely complete after
25 4–5 years, and (2) the lowest rate of N addition (5 kg N/ha/yr) was sufficient to cause
26 significant changes ([Bassin et al., 2013](#)). This experiment also included an ozone
27 fumigation treatment, but there were no interactions between ozone and added N for
28 productivity or community composition ([Volk et al., 2014](#); [Bassin et al., 2013](#); [Bassin et](#)
29 [al., 2007](#)) and few N × ozone interactions for leaf physiological traits ([Bassin et al.,](#)
30 [2009](#)). Two related studies on alpine grasslands have also been conducted in the Swiss
31 Alps by members of the same research group. At 10 sites, ([Bassin et al., 2012](#)) found that
32 grassland aboveground productivity increased 30% with 2 years of NH₄NO₃ additions of
33 50 kg N/ha/yr. [Blanke et al. \(2012\)](#) planted seedlings of four local plant species into
34 intact grass/soil monoliths excavated from the same Swiss alpine grassland site as [Bassin](#)
35 [et al. \(2013\)](#), [Bassin et al. \(2009\)](#), and [Bassin et al. \(2007\)](#). Nitrogen addition
36 (50 kg N/ha/yr) treatments increased overall biomass of the unplanted vegetation in the
37 monoliths. Among the planted species, N additions increased biomass of the grass and
38 decreased biomass of the forb, but had no effect on the sedge or legume. Roots of the

1 grass, forb, and legume were colonized by arbuscular mycorrhizal fungi; N addition
2 increased mycorrhizal root colonization in the grass ([Blanke et al., 2012](#)).

3 As in other environments, the plant growth response to N additions in alpine and Arctic
4 ecosystems varies among taxonomic groups. For example, in the Swiss subalpine
5 grassland experiment, [Bassin et al. \(2013\)](#) noted that within plant communities, sedge
6 (Cyperaceae) species tended to show especially strong positive responses to N additions.
7 As discussed in [Appendix 5](#), [Bowman et al. \(2012\)](#) found N additions of 5, 10, and
8 30 kg N/ha/yr increased cover of the sedge *Carex rupestris* from 34 to 125% within a dry
9 meadow in Rocky Mountain National Park in Colorado. In the northern Caucasus
10 Mountains of Russia, [Onipchenko et al. \(2012\)](#) examined the response of four different
11 alpine plant communities to 90 kg N/ha/yr for 5 years. The N additions increased
12 vascular plant biomass in a lichen heath community, but not in grassland, meadow, or
13 snowbed communities. Within these communities, the response of individual plant
14 functional groups to N varied. The N additions increased sedge biomass in the lichen
15 heath, increased forbs and sedges in the meadow, increased grasses in the grassland, and
16 decreased legumes in the lichen heath and meadow. Shrubs were not significantly
17 affected by N additions. This variation among plant species was also observed in two
18 long-term N addition experiments in moist alpine meadows at the Niwot Ridge
19 Long-Term Ecological Research site in Colorado, wherein N additions (averaging either
20 229 or 288 kg N/ha/yr) for 7 or 11 years increased growth of the grass *Deschampsia*
21 *cespitosa*, but decreased growth of the perennial forb *Geum rossii* ([Farrer et al., 2015](#);
22 [Farrer et al., 2013](#)). The decrease in *Geum* abundance was not necessarily due to
23 competitive exclusion: *Geum* decreased even in study plots where *Deschampsia* had been
24 removed ([Farrer et al., 2013](#)). Instead, *Geum* showed effects of physiological stress with
25 N additions, with less C allocation to storage organs and lower concentrations of
26 nonstructural carbohydrates ([Farrer et al., 2013](#)). In wet, moist, and dry alpine meadows
27 at Niwot Ridge, two decades of N additions (averaging ~85 kg N/ha/yr) did not alter total
28 aboveground biomass, but significantly increased graminoid abundance in the moist and
29 wet meadows ([Yuan et al., 2016](#)). In a meta-analysis of 51 studies conducted within the
30 Tibetan Plateau, ([Fu and Shen, 2016](#)) found that N additions increased total plant
31 biomass, aboveground biomass, belowground biomass, plant height, and foliar N
32 concentrations. However, changes in aboveground biomass varied by plant functional
33 type, with graminoids and sedges responding positively to added N and forbs and
34 legumes responding negatively.

35 In addition to the research on alpine tundra in Colorado, there have been several other
36 recent publications on the effect of N additions on plant productivity in tundra
37 ecosystems in North America. Additions of 70 kg N/ha/yr for 3 years to plots in a central
38 Utah alpine meadow increased aboveground plant production by 10–20%, but did not

1 significantly impact soil respiration or soil C content ([Gill, 2014](#)). Given the large
2 contribution of root and mycorrhizal respiration to soil respiration, these results suggest a
3 change in C allocation toward aboveground growth. In shrub tundra in the Northwest
4 Territories of Canada, 8 years of N additions of 10 kg N/ha/yr had no effect on overall
5 aboveground plant biomass or the biomass of the dominant plant (*Betula*), but each of
6 these metrics was increased by N additions at a rate of 100 kg N/ha/yr ([Zamin et al.,
7 2014](#); [Zamin and Grogan, 2012](#)). Inflorescence production in *Betula* was unaffected at
8 both N addition rates. Elsewhere in the Northwest Territories, [Churchland et al. \(2010\)](#)
9 observed that a single year of N additions (100 kg N/ha/yr) increased foliar N
10 concentrations in shrub tundra plants. In an Alaskan tundra meadow, [Kelley and Epstein
11 \(2009\)](#) found that N additions (100 kg N/ha/yr for 3 years) increased foliar N
12 concentrations but had no effect on aboveground plant growth. Together, the results of
13 these studies in North America are consistent with the overall body N addition research in
14 tundra ecosystems ([Table 6-6](#)).

15 The influence of N additions on tundra plant biomass and productivity has also been
16 assessed in other areas of the world since 2008. In particular, numerous N addition
17 experiments have been conducted in alpine grasslands within the Tibetan Plateau region
18 of China ([Fu and Shen, 2016](#)). Although the effects of added N on plant growth clearly
19 vary by functional type ([Fu and Shen, 2016](#)), differences between functional groups are
20 not necessarily consistent between ecosystems. For instance, while ([Fu and Shen, 2016](#))
21 found that added N increased sedge biomass and decreased forb biomass in their
22 meta-analysis of Tibetan plateau studies, 4 years of NH₄NO₃ additions at rates of 10, 20,
23 40, and 80 kg N/ha/yr caused significant increases in aboveground plant biomass and
24 cover of grasses and forbs and either decreases or no change in sedges ([Zong et al.,
25 2016](#)). Species-specific changes in cover and foliar N concentration on the Tibetan
26 Plateau were observed even in studies using very high N addition rates (50, 150, or
27 300 kg N/ha/yr for 3 years) ([Xiong et al., 2016](#)). Also on the Tibetan Plateau,
28 100 kg N/ha/yr over 2 years increased leaf litter N concentrations in three herbaceous
29 species, but also changed the biochemical composition of leaf litter by increasing the
30 concentration of cellulose and decreasing the concentration of lignin in a forb (*Gentiana
31 straminea*) and decreasing the concentration of hemicellulose in a sedge (*Kobresia
32 humilis*) ([Zhu et al., 2016b](#)). While higher leaf litter concentrations of these structural
33 biochemicals were linked to slower decomposition overall within this experiment, N
34 additions did not significantly alter decomposition. As in other terrestrial ecosystems,
35 increases in plant biomass on the Tibetan Plateau appear to be more dependent on the
36 amount of N added (3.75 or 15 vs. 75 kg N/ha/yr) than the form of N added (NaNO₃,
37 [NH₄]₂SO₄, NH₄NO₃) ([Song and Yu, 2015](#)).

1 In an Arctic shrub ecosystem in Greenland, [Arens et al. \(2008\)](#) studied the effects of N
2 additions at 5, 10, and 50 kg N/ha/yr over 3 years on ecosystem C fluxes and community
3 composition. Net ecosystem productivity (NPP), gross primary production (GPP), and
4 ecosystem respiration (ER) all increased in response to N additions, but these responses
5 were saturated beyond 10 kg N/ha/yr. The smallest rate of N addition caused both GPP
6 and ER to nearly double. However, soil respiration was not significantly affected by the
7 N addition treatments. Dominant vascular plant cover was highest in the 10 kg N/ha/yr
8 treatment. Nitrogen additions increased the cover of subdominant vascular plants from
9 3% in control plots to 8% in the highest N treatment. There were also other changes in
10 the cover of plant functional groups, including a 41% increase in deciduous shrubs in the
11 lowest N addition plots, a doubling of graminoid biomass in the moderate N treatment
12 relative to control, and large increases in forb biomass in the moderate and high N
13 addition treatment.

14 As in forests, lichens are an important component of plant communities and a significant
15 contributor to ecosystem function in Arctic and alpine tundra ecosystems. Since 2008,
16 there have been numerous observations of how lichens respond to added N in these
17 systems ([Table 6-7](#)), and these responses are broadly similar to those observed in forests.
18 [Britton and Fisher \(2010\)](#) observed increased tissue N concentrations in three of four
19 lichen species from Scottish heathlands over the course of a growing season with N
20 additions of 2.5 to 22.5 kg N/ha/yr. [Hogan et al. \(2010b\)](#) collected lichens from
21 27 heathland sites in the U.K. along a wet N deposition gradient (2–33 kg N/ha/yr) and
22 observed increased thalli N concentrations, decreased thalli P concentrations, and
23 increased phosphomonoesterase activity, an enzyme important for P acquisition. [Hogan
24 et al. \(2010a\)](#) found similar results in an N addition study. [Armitage et al. \(2014\)](#)
25 observed a decline in lichen cover in alpine heathland sites across an N deposition
26 gradient of 0.6 to 39.6 kg N/ha/yr in the North Atlantic region of Europe. Similarly, there
27 were decreases in lichen biomass or lichen cover with additional N in studies in Scotland
28 ([Britton and Fisher, 2010](#)), Sweden ([Wardle et al., 2013](#)), Alaska ([Kelley and Epstein,
29 2009](#)), and Canada ([Zamin et al., 2014](#)).

Table 6-7 Alpine and Arctic tundra lichen growth and physiology responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Zamin et al. (2014)	Northwest Territories (Canada)	Shrub tundra (<i>Vaccinium vitisidaea</i> , <i>Rhododendron subarcticum</i> , <i>Andromeda polifolia</i>)	Addition	10, 100	8	Lichen biomass	<u>Low dose</u> : not significant <u>High dose</u> : decrease
Kelley and Epstein (2009)	Alaska	Tundra meadow (<i>Dryas integrifolia</i> , <i>Eriophorum vaginatum</i> , <i>Carex</i> spp.)	Addition	100	3	Lichen cover	Decrease
Wardle et al. (2013)	Sweden	Tundra meadow (<i>Deschampsia flexuosa</i> , <i>Empetrum hermaphroditum</i> , <i>Vaccinium</i> spp.)	Addition	50	21	Lichen cover	Decrease
Armitage et al. (2014)	Europe (North Atlantic)	Alpine heathlands	Ambient	0.6–39.6	n/a	Lichen cover	Decrease
Britton and Fisher (2010)	Scotland	Heathlands (<i>Calluna vulgaris</i>)	Addition	2.5, 7.5, 12.5, 22.5	0.25	Lichen thalli mass	<u>Three species</u> : not significant <u>Two species</u> : decrease
Hogan et al. (2010a)	U.K.	Heathland lichen (<i>Cladonia portentosa</i>)	Addition	8, 24, 56	4	Phosphomono-esterase activity	Increase
Hogan et al. (2010b)	U.K.	Heathland lichen (<i>Cladonia portentosa</i>)	Ambient	2.32–32.8	n/a	Phosphomono-esterase activity	Increase

Table 6 7 (Continued): Alpine and Arctic tundra lichen growth and physiology responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Britton and Fisher (2010)	Scotland	Heathlands (<i>Calluna vulgaris</i>)	Addition	2.5, 7.5, 12.5, 22.5	0.25	Thalli N %	<u>Three species:</u> increase <u>One species:</u> not significant

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; P = phosphorus; yr = year.

Notes: single studies are reported more than once if multiple endpoints or ecosystems were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 Because of the often sparse cover of vascular plants in tundra ecosystems, bryophytes are
2 often relatively larger components of plant communities than in other terrestrial systems.
3 As with lichens, bryophyte physiology and growth in tundra ecosystems can be impacted
4 by added N. [Armitage et al. \(2012\)](#) conducted an analysis of the tissue chemistry, growth,
5 and cover of the bryophyte *Racomitrium lanuginosum* in alpine heathlands at 36 sites in
6 Great Britain, Iceland, the Faroe Islands, and Norway. Estimated N deposition at these
7 sites ranged from ~1 kg N/ha/yr to nearly 40 kg N/ha/yr. Among environmental variables
8 that included temperature, precipitation, and grazing, N deposition was the largest
9 influence on tissue N and P concentrations. Notably, tissue N concentration increased
10 rapidly with N deposition rates up to 5 kg N/ha/yr, then increased at a slower rate with
11 higher levels of N deposition. Tissue N concentration was positively related to moss
12 shoot growth, but also positively related to shoot turnover and negatively related to moss
13 mat depth. These effects were nonlinear and especially pronounced at high tissue N
14 concentrations. Among other plant functional types at these sites, shrub growth decreased
15 with greater N deposition, graminoid growth increased, and forbs were not significantly
16 affected ([Armitage et al., 2014](#)). In related work using a subset of these sites, [Armitage et
17 al. \(2011\)](#) conducted a 2-year transplant experiment that moved *Racomitrium* between
18 10 sites receiving higher N deposition (8.2–32.9 kg N/ha/yr) and a lower N site
19 (7.2 kg N/ha/yr). When the authors transplanted *Racomitrium* from elevated N deposition
20 sites to low N deposition sites and vice versa, tissue N concentration remained higher in
21 the plants from higher N sites, whereas moss moved from lower N to higher N sites
22 increased tissue N to nearly match levels in the moss natural to the site. [Armitage et al.
23 \(2011\)](#) also observed that moss at high N sites had higher shoot growth, whereas moss
24 transplanted to lower N sites increased in biomass due to decreasing tissue C:N and
25 slowing decomposition ([Armitage et al., 2011](#)).

26 In high-latitude and high-elevation ecosystems, such as tundra, heathlands, and boreal
27 forests, plants in the Ericaceae family are often abundant. Notable members of the
28 Ericaceae family include blueberries and cranberries (both *Vaccinium*). Ericaceous plants
29 uniquely host ericoid mycorrhizae, which are distinct from ectomycorrhizae and
30 arbuscular mycorrhizae. Ericoid fungi are recognized for their ability to decompose large
31 organic molecules and absorb organic forms of soil N ([Read et al., 2004](#)). This
32 specialization in organic N uptake could make these mycorrhizae more sensitive to
33 increased inorganic N availability. However, only a relatively small number of N addition
34 studies have quantified changes in mycorrhizal growth or physiology in ecosystems
35 supporting plants that host ericoid mycorrhizae ([Table 6-8](#)). [Ishida and Nordin \(2010\)](#)
36 added 12.5 or 50 kg N/ha/yr for 4 or 12 years to boreal forests in Sweden and observed
37 no change in the percentage of *Vaccinium myrtillus* roots colonized by ericoid
38 mycorrhizae, the number of ericoid fungal species per root tip, or ericoid community
39 composition, and observed mixed effects on ericoid species richness. [Dean et al. \(2014\)](#)

1 studied the response of root-associated fungi in alpine tundra in Colorado to 8 years of N
2 additions (29 kg N/ha/yr). Ericoid fungi abundance decreased and the overall community
3 composition of root-associated fungi changed, including a reduction in diversity and
4 richness. Further research is needed to understand the response of ericoid mycorrhizae to
5 added N.

6 Although [Bouskill et al. \(2014\)](#) observed that N additions increased fungal biomass in a
7 meta-analysis of high-latitude N addition experiments, other studies of fungal biomass in
8 tundra ecosystems have found negative ([Xiong et al., 2016](#); [Farrer et al., 2013](#); [Wardle et
9 al., 2013](#)) or neutral responses ([Sundqvist et al., 2014](#)). [Bouskill et al. \(2014\)](#) did not find
10 a significant effect of added N on total microbial biomass in their meta-analysis, with
11 individual studies reporting a negative effect ([Farrer et al., 2015](#)), positive effect ([Xiong
12 et al., 2016](#); [Zong et al., 2016](#)) or no effect ([Zong et al., 2016](#); [Churchland et al., 2010](#)). In
13 a meta-analysis, [Treseder \(2008\)](#) found that N additions decreased bacterial biomass in
14 tundra ecosystems, but this analysis included only two studies. Of the four subsequent
15 studies of bacterial biomass, N additions had no effect in two, a positive effect in one,
16 and a negative effect in a fourth ([Table 6-9](#)). Notably, [Bouskill et al. \(2014\)](#) observed that
17 microbial biomass responses were positive under relatively low rates of N addition, but
18 became negative as N addition rates exceeded ~50 kg N/ha/yr. Belowground respiration
19 showed a similar response, but lower threshold (~25 kg N/ha/yr) at which the response
20 switched from positive to negative.

21 To examine the influence of added N on organisms at higher trophic levels, [Bishop et al.
22 \(2010\)](#) studied the effects of N additions (78 kg N/ha/yr for 5 years) on plant and
23 arthropod communities in alpine meadows that were primary successional ecosystems on
24 recently formed volcanic substrates on Mount St. Helens in Washington. The N additions
25 increased foliar N concentration in the dominant graminoid, but decreased foliar N
26 concentration in the dominant legume. The N additions also increased both plant species
27 diversity and plant cover, although in the final year of the experiment, increased
28 browsing by small mammals negated the effect of the N additions. There was no effect on
29 total arthropod abundance (individuals per m²), but the number of Orthoptera
30 approximately doubled. Overall, total arthropod abundance was strongly positively
31 related to both plant diversity and plant cover, with arthropod abundance among
32 individual orders both positively and negative related to plant diversity and plant cover

Table 6-8 Growth and biodiversity responses of ericoid mycorrhizal fungi to nitrogen added in experimental treatments.

6.2.5. Grasslands

1 The 2008 ISA contained limited information regarding the effects of N deposition on
2 productivity and related aspects of eutrophication in grasslands. That assessment included
3 the work of ([Neff et al., 2002](#)), who examined the long-term effects (+10 years) of N
4 deposition (10 kg N/ha/yr) in an alpine meadow, where N additions stimulated
5 aboveground NPP by 47%. Factors affecting productivity in grasslands are similar in
6 many ways to forests, with N availability limiting primary production. Grasslands
7 dominate largely in places where forests cannot grow because of low moisture
8 availability, high disturbance rates (such as from fire or grazing), and/or cold
9 temperatures and shorter growing seasons [such as at high latitudes and elevations;
10 ([Chapin et al., 2002](#); [Knapp et al., 1998](#))]. However, because of the commonality of N
11 limitation to primary production ([Vitousek and Howarth, 1991](#)), many of the processes
12 that occur when N is added to forests also occur when N is deposited onto grasslands.
13 These include increases in primary production and foliar N, increases in allocation to
14 aboveground biomass (increased shoot:root ratio), decreased levels of light reaching the
15 ground surface, elevated litter inputs, and changes in the soil biota ([Aerts and Chapin,
16 1999](#); [Knapp et al., 1998](#)), which are described further below.

17 Since the 2008 ISA, further advancements in our understanding of the effects of N
18 deposition on grasslands have occurred. A meta-analysis estimated that N additions
19 increased grassland aboveground NPP by 53% ([LeBauer and Treseder, 2008](#)). Increased
20 plant growth, NPP, or plant biomass in response to added N has been observed in prairies
21 in Wyoming, Kansas, and Minnesota ([Henry et al., 2015](#); [Farrior et al., 2013](#); [Isbell et al.,
22 2013a](#); [Hillerislambers et al., 2009](#); [Johnson et al., 2008](#)), in temperate grasslands in
23 Ontario ([Vankoughnett and Henry, 2014](#); [Hutchison and Henry, 2010](#)) and Michigan
24 ([Grman and Robinson, 2013](#)), in Mediterranean grasslands in California ([Tulloss and
25 Cadenasso, 2016](#); [Borer et al., 2014](#); [Vallano et al., 2012](#)), and steppe grasslands of China
26 ([Li et al., 2017a](#)). Although the response to N enrichment is variable among species in
27 many terrestrial ecosystems, the comparatively rapid turnover rate of plant biomass in
28 grasslands means that wide differences in the response of individual species to N
29 deposition are frequently observed even in short-term studies ([Tulloss and Cadenasso,
30 2016](#); [Hautier et al., 2014](#); [Vankoughnett and Henry, 2014](#); [Grman and Robinson, 2013](#);
31 [Isbell et al., 2013a](#); [Bradford et al., 2012](#); [Vallano et al., 2012](#); [Skogen et al., 2011](#)). Three
32 new syntheses of grassland responses to N additions or N deposition have been published
33 since the 2008 ISA. [Stevens et al. \(2015\)](#) used data from a network of 42 grassland sites
34 on four continents and found that estimated rates of atmospheric N deposition were the
35 strongest predictor of aboveground NPP in these ecosystems. On average, aboveground

1 NPP increased 3% for every 1 kg N/ha/yr increase in N deposition, and N deposition
2 explained 16% of the variance in productivity in these systems ([Stevens et al., 2015](#)),
3 implying that much of the variation in NPP was not understood. [Yue et al. \(2016\)](#)
4 conducted a meta-analysis of N addition studies and found a 50.4% stimulation of
5 grassland aboveground NPP, similar to the estimate of [LeBauer and Treseder \(2008\)](#).
6 Aboveground plant C was stimulated by an average of 30.5% in the [Yue et al. \(2016\)](#)
7 analysis.

8 The belowground productivity responses to N appear to be more mixed. [Yue et al. \(2016\)](#)
9 found a 28% increase in belowground plant C; whereas [Li et al. \(2015\)](#) did not observe a
10 significant change in grassland fine root biomass. Belowground net primary productivity
11 in an experimental grassland declined with N additions when summed over a 9-year
12 period, along with the ratio of belowground-to-aboveground net primary productivity ([Xu](#)
13 [et al., 2017b](#)). In a controlled pot experiment, [Wang et al. \(2017b\)](#) found that both fine
14 root production and turnover rates increased in a temperate grass species (*Bothriochloa*
15 *ischaemum*) with N additions. The net result was lower standing root biomass.

16 The differences in how individual plant species respond to added N may in part be due to
17 variation in functional traits, including the ability to change plant C allocation. In a
18 common garden experiment, [Johnson et al. \(2008\)](#) grew plants that were among the most
19 positively and negatively responsive to long-term N additions at the Cedar Creek and
20 Konza Prairie LTER sites. The plants that were most positively affected by N additions
21 allocated more biomass to shoots than roots and formed fewer associations with
22 mycorrhizal fungi. Likewise, [Grman and Robinson \(2013\)](#) also found that N additions
23 increased aboveground biomass and decreased the relative allocation of C to
24 mycorrhizae. Of the two grass species studied, the species that more strongly decreased
25 allocation to mycorrhizae as N availability increased also showed a greater aboveground
26 biomass response to added N. [Bradford et al. \(2012\)](#) documented a somewhat different
27 functional response, finding that increasing rates of N additions favored the species that
28 showed greater leaf trait plasticity in response to the N additions. Earlier studies
29 suggested leaf plasticity was an important determinant of plant growth responses to added
30 N, and that the ability of a species to upregulate production if nutrients were abundant
31 was an advantage ([Knops and Reinhart, 2000](#)). [Hillerislambers et al. \(2009\)](#) observed that
32 N amendments (40 kg N/ha/yr) had similar effects on grasses within the same functional
33 groups: C3 grasses tended to increase aboveground biomass and decrease seed
34 production, while C4 grasses increased seed production and decreased aboveground
35 biomass. In a survey of 44 species in 153 acidic grassland sites across northern and
36 western Europe, [Pannek et al. \(2015\)](#) found that species with high relative growth rates
37 tended to show beneficial responses to N deposition.

1 In multiyear studies, responses to N enrichment often varied through time. For instance,
2 over a 7-year period of N addition, [Henry et al. \(2015\)](#) found that the stimulation of
3 aboveground biomass ranged approximately 10 to nearly 100%. Working at a long-term
4 biodiversity and N deposition experiment at Cedar Creek in Minnesota that used seven
5 different N addition rates from 10 to 270 kg N/ha/yr, [Isbell et al. \(2013a\)](#) initially
6 observed that N additions increased grassland productivity, with higher rates of N
7 addition causing greater increases in productivity. Although N additions continued to
8 stimulate productivity, productivity decreased in plots that lost the most species over
9 time. In a large synthesis, [Hautier et al. \(2014\)](#) used data from studies of 41 experimental
10 grassland communities on 5 continents and found grassland communities had greater
11 annual variability in plant productivity (less stability) as the N input rate increased. Under
12 ambient conditions, annual variability in plant productivity is limited by asynchronous
13 productivity among different species, wherein slower growth by some species is balanced
14 by more rapid growth of neighboring species. In these unmanipulated systems, the
15 stability of plant productivity is positively associated with plant diversity ([Hautier et al.,](#)
16 [2014](#); [Tilman et al., 2001](#); [Tilman et al., 1997](#)). With added N, the increase in annual
17 variability in productivity could not be linked to a loss of species richness, but was
18 instead caused by a decrease in the asynchrony of productivity among individual plant
19 species. In a more recent experiment in China, [Zhang et al. \(2016a\)](#) observed that N
20 additions (10–500 kg N/ha/yr for 6 years) created a series of changes: decreased plant
21 species richness, decreased asynchrony among plant species, increased aboveground
22 productivity, and decreased stability (more annual variability) in aboveground
23 productivity.

24 Nitrogen enrichment can also cause variation in plant chemistry, particularly increases in
25 tissue N concentrations ([Lu et al., 2017](#); [Reich et al., 2003](#)). ([Bradford et al., 2012](#))
26 conducted a greenhouse experiment with several grass and forb species and observed
27 increases in shoot N concentrations, but root C:N and root mass N were not consistently
28 affected by N additions. In a greenhouse experiment conducted by ([Jamieson et al.,](#)
29 [2012](#)), N addition had no effect on the concentration of a defensive compound in shoots,
30 whereas concentrations decreased in flowers by ~35%. As in other terrestrial ecosystems,
31 these increases in shoot N concentrations can lead to an increase in leaf-level
32 photosynthesis if other resources are not limiting [e.g., ([Reich et al., 2003](#); [Lee et al.,](#)
33 [2001](#))]. However, such increases in photosynthesis vary among species and can vary
34 temporally ([Reich et al., 2003](#); [Lee et al., 2001](#)). Within a U.K. grassland exposed to N
35 additions of 35 or 140 kg N/ha/yr for 11 years, [Arróniz-Crespo et al. \(2008\)](#) observed
36 decreases in cover of two bryophyte species as well as a decrease in chlorophyll
37 fluorescence in both species (despite an increase in chlorophyll content in one species).
38 Both bryophyte species exhibited increased activity of an enzyme involved in P
39 acquisition (phosphomonoesterase) and decreased nitrate reductase enzyme activity, but

1 only one of the two bryophyte species exhibited increased tissue N concentrations and
2 N:P ratios.

3 Several experiments in Ontario, Canada have examined the response of old field
4 grasslands to the interaction between N additions and climate change in the form of
5 altered snowpack, soil freezing, or warming. [Vankoughnett and Henry \(2014\)](#) found that
6 N additions of 20 or 60 kg N/ha/yr increased aboveground production, but this increase
7 varied by species. In the first year of the experiment, plant production showed a stronger
8 response to N in plots where snow had been experimentally removed, but this interaction
9 did not occur in subsequent years. Although the extent of the effect varied by year, [Henry
10 et al. \(2015\)](#) found that 7 years of N additions at a rate of 60 kg N/ha/yr increased
11 aboveground biomass and showed no interaction with experimental warming.

12 Effects of water availability were also observed in grassland studies by [Friedrich et al.
13 \(2012\)](#), [Jamieson et al. \(2013\)](#), and [Farrior et al. \(2013\)](#). In a greenhouse experiment with
14 a grass native to German grasslands, [Friedrich et al. \(2012\)](#) found that N additions of
15 48 kg N/ha/yr increased aboveground biomass by 500%. However, plants receiving N
16 were more likely to suffer dieback when N additions were combined with drought.
17 Nitrogen enrichment in a Wyoming prairie increased the production of a defensive
18 chemical compound in an invasive plant by 37% under ambient conditions, but decreased
19 the production of this compound by 25% when water availability was reduced ([Jamieson
20 et al., 2013](#)). At Cedar Creek in Minnesota, [Farrior et al. \(2013\)](#) found complex responses
21 to changes in N and water availability: N enrichment increased shoot biomass regardless
22 of water availability, fine root biomass declined when availability of both water and N
23 was high, and higher water availability increased fine root biomass only at low rates of N
24 addition.

25 There has been less research on the effects on N enrichment on belowground C cycling in
26 grasslands than in forests ([Yue et al., 2016](#); [Li et al., 2015](#); [Liu and Greaver, 2010](#)). In a
27 meta-analysis, [Liu and Greaver \(2010\)](#) found that N additions to grasslands increased
28 aboveground litter inputs, but did not significantly affect soil respiration, microbial
29 respiration, or soil C. In part, the lack of an overall effect on these processes could be due
30 to the combination of high variability among grasslands and the small sample sizes for
31 the meta-analysis, as only approximately six studies were available for the [Liu and
32 Greaver \(2010\)](#) analysis. However, a more recent meta-analysis of N addition
33 experiments by [Yue et al. \(2016\)](#) that had larger sample sizes found somewhat similar
34 results: belowground plant C was stimulated by 24.2%, but there were no significant
35 effects on soil respiration, microbial respiration, litter decomposition rates, or soil organic
36 C. Meta-analyses of changes in microbial biomass have produced inconsistent results:
37 [Yue et al. \(2016\)](#) did not find a significant effect of added N, [Liu and Greaver \(2010\)](#)

1 found a negative effect, and [Geisseler et al. \(2016\)](#) observed a negative effect only with at
2 least 5 years of N additions.

3 The conflicting meta-analytic results for changes in grassland soil microbial biomass
4 could be caused by differences in analyses or data sets, or could reflect ecological
5 complexities that require more nuanced understanding, such as the influence of P
6 availability, varying responses among microbial taxa, or measurement techniques
7 ([Johnson et al., 2008](#)). For instance, at Jasper Ridge in the San Francisco Bay area, [Liang
8 et al. \(2015\)](#) did not find any significant changes in fungal lipid biomass caused by N
9 additions (70 kg N/ha/yr), yet did observe changes in the abundance of individual amino
10 sugars that indicated decreases in total microbial biomass and fungal biomass, and
11 increases in bacterial biomass. In measuring the abundance of nitrite-oxidizing bacteria at
12 Jasper Ridge, [Le Roux et al. \(2016\)](#) observed that N additions increased the abundance of
13 *Nitrobacter*, but did not affect *Nitrospira*. In the over 150-year Park Grass Experiment,
14 [Zhalnina et al. \(2015\)](#) observed that NaNO₃ additions had no effect on bacterial and
15 archaeal biomass as assessed by 16S ribosomal RNA abundance, but (NH₄)₂SO₄
16 additions decreased bacterial and archaeal biomass. [Li et al. \(2015\)](#) found no effect of N
17 additions on fine root biomass or mycorrhizal colonization of root tips in a meta-analysis
18 of grassland experiments, but sample sizes were small (four biomass studies, nine
19 mycorrhizal studies).

20 A number of studies have examined the effects of N additions on mycorrhizal abundance
21 in grasslands ([Table 6-3](#)). Grassland plants predominantly host arbuscular mycorrhizal
22 fungal associations. Like arbuscular mycorrhizal responses observed in forests [e.g., ([van
23 Diepen et al., 2010](#))], arbuscular mycorrhizal responses to added N in grasslands have
24 been inconsistent, with a similar number of studies showing no response ([Liang et al.,
25 2015](#); [Chen et al., 2014](#); [Mandyam and Jumpponen, 2008](#)) versus showing a negative
26 effect on colonization or growth [e.g., ([Chen et al., 2014](#); [Johnson et al., 2008](#); [Van Der
27 Heijden et al., 2008](#))].

28 Most studies of grassland soil microbial responses to N deposition ([Table 6-10](#)) have
29 focused on free-living soil heterotrophs or mycorrhizal fungi, but [Weese et al. \(2015\)](#)
30 examined the response of N fixing rhizobial bacteria in clover (*Trifolium*) as part of a
31 22-year chronic N addition (123 kg N/ha/yr as NH₄NO₃) experiment in a Michigan
32 grassland. Clover inoculated with rhizobial bacteria from soil or bacterial strains that
33 were collected from the long-term N addition experiment exhibited lower chlorophyll
34 content and decreased plant biomass, including fewer leaves and stolons. These patterns
35 were consistent across all three clover species used in the experiment. Notably, these
36 changes did not result from a shift in the community composition of the rhizobial
37 bacteria, but instead resulted from the evolution of new strains of the bacteria *Rhizobium*

1 *leguminosarum* that were less symbiotic and less cooperative in the exchange of C for N.
2 A similar change toward less mutualistic interactions in response to N additions have
3 been observed for mycorrhizae in grasslands ([Johnson, 1993](#)). It is unclear whether these
4 evolutionary changes are reversible, and if so, how long this reversion would take ([Weese
5 et al., 2015](#)).

6 [Zehnder and Hunter \(2008\)](#) performed a plant density manipulation experiment to
7 examine the effect of N deposition on the interaction between a host plant from the
8 southeastern U.S., *Asclepias tuberosa*, and its herbivore, *Aphis nerii*. Added N increased
9 aphid population growth, plant foliar N concentrations, and plant biomass. In southern
10 California coastal grasslands, [Borer et al. \(2014\)](#) observed that N additions (40 or
11 100 kg N/ha/yr as Ca[NO₃]₂) increased plant biomass, but only in the absence of
12 herbivores (pocket gophers, *Thomomys bottae*).

Table 6-10 Grassland microbial biomass responses to experimental nitrogen additions.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen

Liang et al. (2015)	California (northern)	Annual grassland (<i>Avena barbata</i> , <i>A. fatua</i>)	Addition	70	9	Saprotrophic fungal biomass	Not significant

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: single studies are reported more than once if multiple endpoints or ecosystems were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

6.2.6. Arid and Semiarid Ecosystems

1 Large portions of the western U.S. are covered by arid and semiarid ecosystems. While
2 many of these ecosystems receive little anthropogenic N deposition compared to the
3 eastern U.S., some areas downwind of agricultural and metropolitan centers receive high
4 levels of atmospheric N deposition ([Fenn et al., 2003b](#)). In addition, the unique nutrient
5 cycling processes in these systems can intensify the influence of N deposition on
6 ecosystem processes [([Homyak et al., 2014](#)); see [Appendix 4](#)].

7 The lack of moisture in arid and semiarid climates changes the nature of how N
8 deposition impacts biological communities in these ecosystems compared to more mesic
9 ecosystems such as tallgrass prairies and forests. First, the strong moisture constraint on
10 productivity limits the influence of increased N availability on plant communities
11 [e.g., ([Rao and Allen, 2010](#))], with shifts in community composition less likely to occur
12 without sufficient moisture [e.g., ([Concilio and Loik, 2013](#))]. Second, the lack of strong
13 biological demand for N during periods of moisture limitation, combined with infrequent
14 soil leaching and runoff events, leads to the accumulation of inorganic N in surface soils,
15 intensifying the effects of N deposition on soil N concentrations when moisture is
16 available [e.g., ([Homyak et al., 2014](#))]. Broadly, soil base saturation and pH increase as
17 the climate becomes more arid ([Schlesinger, 2005](#)), buffering dryland ecosystems from
18 the acidification-driven losses in biodiversity that are observed along N deposition
19 gradients [e.g., ([Simkin et al., 2016](#))]. Finally, the patchy vegetation that often develops
20 in deserts tends to create isolated islands of fertility, wherein nutrients (including N) are
21 concentrated beneath shrub canopies ([Titus et al., 2002](#); [Schlesinger and Pilmanis, 1998](#)).
22 Under these circumstances, anthropogenic N deposition can increase N availability in the
23 interspaces between shrubs, allowing the growth of annual grasses and forbs, which can
24 grow and reproduce during the brief seasonal periods with adequate moisture availability
25 ([Brooks, 2003](#)). In particular, there have been numerous observations from semiarid and
26 arid ecosystems that N deposition can increase the productivity and dominance of
27 invasive grasses [e.g., ([Brooks, 2003](#); [Fenn et al., 2003a](#); [Padgett and Allen, 1999](#))]. This
28 phenomenon provides a more continuous fuel bed for wildfires, increasing the potential
29 for fire ([Rao et al., 2010](#)) and shifting plant community composition away from species
30 that are not fire adapted ([Padgett and Allen, 1999](#); [Allen et al., 1998](#)).

31 There was already a large amount of information available on how N deposition impacted
32 arid and semiarid ecosystems at the time of the 2008 ISA, especially in areas around
33 southern California downwind of Los Angeles, where dry N deposition can be
34 >30 kg N/ha/yr ([Bytnerowicz and Fenn, 1996](#)). In particular, the 2008 ISA described
35 results from several N deposition studies in this region that showed increased biomass of

1 invasive species, high mortality of native shrubs in heavily polluted areas, and increased
2 fire risk ([Padgett and Allen, 1999](#); [Allen et al., 1998](#)). These experiments were primarily
3 conducted in coastal sage scrub (CSS) ecosystems or in the Mojave Desert.

4 The amount of land area covered by CSS in southern California has greatly declined in
5 the past 60 years due to changes in land use, grazing, and increased wildfire frequency
6 ([Allen et al., 1998](#)). In addition, native CSS vegetation has been replaced in many areas
7 by annual grasses from the Mediterranean region ([Padgett et al., 1999](#); [Padgett and Allen,
8 1999](#); [Allen et al., 1998](#)). In the mid-1990s, N deposition had been implicated as a
9 contributor to this ecosystem alteration because it decreased the growth of native shrubs
10 and increased the growth of invasive grasses, with the secondary effect of increasing fire
11 frequency ([Padgett et al., 1999](#); [Padgett and Allen, 1999](#); [Allen et al., 1998](#)). There was
12 also evidence that the N assisted conversion from CSS to invasive annual grasses had
13 altered the hydrology of these ecosystems ([Wood et al., 2006](#)). The loss of native
14 vegetation in the CSS and chaparral ecosystems in southern California is particularly
15 notable because these ecosystems are unique within the U.S., are limited in their spatial
16 extent, and are important global and national hotspots for biodiversity.

17 At the time of the 2008 ISA, similar effects of N deposition on plant communities had
18 also been observed farther east in the Mojave Desert. [Brooks \(2003\)](#) documented that
19 NH_4NO_3 additions (32 kg N/ha/yr) increased the biomass of invasive annual grasses and
20 forbs by more than 50%. The increased growth of the invasive plants suppressed the
21 growth of native annual plants. In particular, N additions stimulated the growth of
22 *Bromus madritensis* beneath the dominant native shrub *Larrea tridentata*, while the
23 invasive grasses in the genus *Schismus* and the invasive forb *Erodium cicutarium* had
24 enhanced growth in the interspaces between shrubs. This spatial nature of these effects is
25 important because as in the CSS, the spatially continuous fuel beds created by high grass
26 biomass have been associated with increased fire frequency in the Mojave Desert ([Brooks
27 et al., 2004](#); [Brooks and Esque, 2002](#); [Brooks, 1999](#)). This effect is stronger at higher
28 elevation, likely because the higher precipitation stimulates grass productivity. Fire was
29 relatively rare in the Mojave Desert until the 1980s ([Syphard et al., 2017](#)), but now fire
30 occurs frequently in areas that have experienced invasion of exotic grasses ([Brooks,
31 1999](#)). The comparatively unresponsive nature of native Mojave vegetation to N
32 deposition was also observed elsewhere. For instance, 3 years of N additions
33 [40 kg N/ha/yr as $\text{Ca}(\text{NO}_3)_2$] had almost no impact on leaf-level photosynthetic or
34 hydraulic performance in *Larrea tridentata* growing north of Las Vegas, NV ([Barker et
35 al., 2006](#)).

36 At the time of the 2008 ISA, N deposition effects on belowground processes in arid and
37 semiarid lands were not well understood. In a Chihuahuan Desert grassland in New

1 Mexico, 10 years of N additions (10 kg N/ha/yr) increased the activity of extracellular
2 glucosidase enzymes important in the breakdown of carbohydrates, but decreased the
3 activity of extracellular aminopeptidase enzymes important in the decomposition of
4 proteins and peptides ([Stursova et al., 2006](#)). In contrast, there were no differences in C
5 mineralization (decomposition) in soils collected at a similar southern California gradient
6 of CSS sites [4 to 23 kg N/ha/yr; ([Vourlitis and Zorba, 2007](#))]. Along a CSS N deposition
7 gradient in the Los Angeles area, arbuscular mycorrhizal fungi associated with the
8 dominant sagebrush shrub declined with increasing N pollution and also in response to N
9 additions (60 kg N/ha/yr; 4–5 years) at a relatively unpolluted site ([Sigüenza et al., 2006](#)).
10 Evidence is conflicting about whether these changes in mycorrhizal colonization
11 influenced the plant growth response to N deposition. An earlier study suggested that
12 differences in mycorrhizal colonization were not responsible for the effects of N
13 deposition on CSS plant growth in this region ([Yoshida and Allen, 2001](#)). [Sigüenza et al.](#)
14 [\(2006\)](#) found that sagebrush inoculated with arbuscular mycorrhizae from a high N
15 deposition site grew more slowly than those with inoculum from a low N deposition site.
16 Grasses in semiarid ecosystems in New Mexico and Colorado grew slower when
17 inoculated with mycorrhizae from sites that had received N additions than from sites
18 without N additions ([Corkidi et al., 2002](#)).

19 Research published since 2008 has continued to concentrate on CSS and Mojave Desert
20 ecosystems in the southern California, but new studies in southern California chaparral
21 ecosystems, the Sonoran Desert of Arizona, and elsewhere have also been published.
22 Most studies investigating the effects of N deposition in arid and semiarid environments
23 published since the 2008 ISA have further emphasized that the impacts of increased N are
24 heavily dependent on water availability ([Valliere and Allen, 2016a](#); [Rao et al., 2015](#);
25 [Homyak et al., 2014](#); [Newingham et al., 2012](#); [Ochoa-Hueso and Manrique, 2010](#); [Rao](#)
26 [and Allen, 2010](#)). The high dependence on precipitation is consistent with ecosystem
27 models for C cycling in desert systems ([Shen et al., 2008](#)).

28 For instance, [Rao and Allen \(2010\)](#) investigated how productivity in Joshua Tree
29 National Park annuals is altered by increasing N supply under a range of water
30 availabilities ([Table 6-11](#)). Using a 5-year field N addition experiment and N additions of
31 up to 30 kg N/ha/yr, the authors observed the greatest production of invasive grasses and
32 native forbs under the highest soil N and highest watering regime. Similarly, [Newingham](#)
33 [et al. \(2012\)](#) found that N additions of 10 or 40 kg N/ha/yr as Ca(NO₃)₂ in the Mojave
34 Desert increased branch production in creosote (*Larrea tridentata*) only during a wet
35 year, whereas the addition of water and N significantly increased the amount of rodent
36 herbivory.

Table 6-11 Arid and semiarid ecosystem plant productivity and physiology responses to nitrogen added in experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Rao and Allen (2010)	Garden (California, Mojave)	Invasive grass (<i>Bromus madritensis</i>), native forb (<i>Amsinckia tessellata</i>)	Addition	5, 30	1	Aboveground plant biomass	<u>Forb</u> : increase <u>Grass</u> : increase

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; NP = national park; P = phosphorus; yr = year.

Notes: single studies are reported more than once if multiple endpoints or ecosystems were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 A similar interaction between N and water was found in the Sonoran Desert. Herbaceous
2 annual biomass increased with added N (60 kg N/ha/yr) during above-normal rainfall
3 seasons, but not in low precipitation years ([Hall et al., 2011](#)). In contrast, no increases in
4 productivity were observed in the dominant shrub *Larrea tridentata*, even during
5 above-normal rainfall ([Hall et al., 2011](#)). Ecosystem modeling for this same study system,
6 however, conducted by [Shen et al. \(2008\)](#) suggested observed rates of N deposition in the
7 Phoenix region would increase *Larrea* productivity by more than an order of magnitude
8 in wet years. Mosses in this region also appear to be influenced by N deposition, with
9 lower moss abundance and higher tissue N concentrations at urban study sites that
10 receive higher N deposition ([Ball and Guevara, 2015](#)).

11 As in other terrestrial ecosystems (see [Appendix 6.2.2](#), [Appendix 6.2.3.1](#)), increases in
12 foliar N concentrations in ecosystems receiving chronic N additions are not necessarily
13 associated with changes in leaf physiological function in semiarid plants. With the
14 exception of the N fixing *Ceanothus*, shrubs in a chaparral ecosystem and a CSS
15 ecosystem in southern California increased foliar N concentrations in response to
16 long-term N additions (50 kg N/ha/yr for 10 years), but none of the four shrub species
17 (*Artemisia californica*, *Salvia mellifera*, *Adenostoma fasciculatum*, *Ceanothus greggii*)
18 increased leaf-level photosynthesis ([Pivovarov et al., 2016](#)). Several species in this study
19 had higher dry season predawn water potential, indicating relative improvements in water
20 availability. However, wet season water potential (predawn and midday) were
21 unresponsive to N additions and only *Artemisia* exhibited changes in plant hydraulic
22 function (increased stomatal conductance and sapwood conductivity and decreased wood
23 density) that would indicate the shrubs were benefitting from greater water availability.
24 In contrast, *Adenostoma* wood xylem became more prone to cavitation ([Pivovarov et al.,](#)
25 [2016](#)). The limited aboveground physiological responses of the dominant shrubs in these
26 ecosystems is consistent with the idea that other resources (e.g., water) are often more
27 limiting to plant productivity than N in arid and semiarid ecosystems.

28 Other studies document the overall effect of N deposition on vegetation communities,
29 including the occurrence of fire. At Joshua Tree National Park in the Mojave desert of
30 California, non-native grass biomass increased significantly at three of the four study
31 sites receiving 30 kg N/ha/yr for 2 years, but saw no change with 5 kg N/ha/yr of added
32 N ([Allen et al., 2009](#)). Native species showed no clear response to N addition, but these
33 plants made up a small fraction of community biomass. [Rao et al. \(2015\)](#) tried to model
34 the effects of N deposition on the biomass of invasive annual grasses and the occurrence
35 of wildfire in the Mojave Desert of California, but were unable to effectively disentangle
36 the effects of N deposition on fire from factors such as precipitation, distance from roads,
37 and firefighting resources. However, in an earlier modeling study of Mojave Desert
38 vegetation, [Rao et al. \(2010\)](#) did conclude that increases in precipitation and N deposition

1 raise fire risks by stimulating greater vegetation biomass, and thus fuel loads. In a study
2 covering California deserts stretching from the Mexican border into the Great Basin, the
3 stimulatory effect of N deposition on the growth of annual grasses was one of the largest
4 contributors to the occurrence of large fires (>20 ha) across four semiarid ecoregions,
5 including the Mojave Desert ([Syphard et al., 2017](#)). Additionally, [Wissinger et al. \(2014\)](#)
6 observed higher seed production in areas of the Mojave with higher atmospheric N
7 deposition (up to 16 kg N/ha/yr).

8 In arid ecosystems with low vascular plant cover, soil crusts with photoautotrophs such as
9 cyanobacteria, green algae, bryophytes, and lichens can be important ecosystem
10 components and large contributors to biogeochemical cycles. In the Mojave Desert, [Stark
11 et al. \(2011\)](#) investigated the effects of 10 or 40 kg N/ha/yr N addition on the dominant
12 biological soil-crust moss (*Syntrichia caninervis*) for a period of 5 years. Interestingly,
13 the lower rate of N application had negative effects on the amount dead chlorotic tissue in
14 shoots and crust regeneration, while higher rates of N addition only negatively impacted
15 apical meristem growth. In Spain, the abundance of most pigments associated with
16 cyanobacteria and green algae in soil crusts within Mediterranean ecosystems did not
17 significantly vary with N deposition along a gradient, but the cyanobacterial pigment
18 echinenone was negatively correlated with N deposition (4.3–7.3 kg N/ha/yr)([Ochoa-
19 Hueso et al., 2016](#)). In China, [Zhou et al. \(2016\)](#) observed that high N addition rates
20 (50 kg N/ha/yr for 4 years) decreased total chlorophyll and chlorophyll *b* content in soil
21 crusts dominated by cyanobacteria. Lower N addition rates (3–15 kg N/ha/yr), however,
22 did not affect cyanobacteria chlorophyll, and lichen chlorophyll was unaffected by the N
23 addition treatments. Cyanobacteria soluble sugar concentrations, an osmolyte produced
24 as a response to stress, increased at the second highest N dose, but other osmolytes
25 (proline, soluble protein) and lichens were unaffected ([Zhou et al., 2016](#)).

26 There are very few field studies of how N enrichment impacts belowground C cycling in
27 arid systems ([Liu and Greaver, 2010](#)). In a meta-analysis of these studies, [Liu and
28 Greaver \(2010\)](#) found no consistent effect of N enrichment on soil respiration. [Verburg et
29 al. \(2013\)](#) quantified the effects of increased summer precipitation and N deposition on
30 fine root dynamics in a Mojave Desert ecosystem during a 2-year field experiment.
31 Increased summer precipitation and 40 kg N/ha/yr N additions did not have an overall
32 significant effect on any of the measured root parameters. Within the Sonoran Desert near
33 Phoenix, [Marusenko et al. \(2015\)](#) observed that N additions (60 kg N/ha/yr for 8 years)
34 increased the abundance of the *amoA* gene, which is needed for ammonia oxidation, in
35 both archaea and bacteria. There was no increase in ammonia-oxidizing bacteria or
36 archaea along a narrow N deposition gradient (4.3–7.3 kg N/ha/yr) in Mediterranean
37 shrublands and grasslands in Spain, and overall bacterial abundance was negatively
38 related to N deposition ([Ochoa-Hueso et al., 2016](#)). [Sinsabaugh et al. \(2015\)](#) conducted a

1 meta-analysis of soil microbial responses to N additions (5 to 560 kg N/ha/yr; 0.3 to
2 10 years) in arid ecosystems and identified only 8 studies of various microbial biomass
3 responses and 10 studies of various microbial metabolic responses. Broadly, both metrics
4 increased with the addition of low amounts of N, but responses became negative once
5 threshold N addition rates (kg N/ha/yr: 88 for biomass, 70 for metabolism) or cumulative
6 loads (kg N/ha: 159 for biomass, 114 for metabolism) had been reached.

7 In a greenhouse study with California sagebrush (*Artemisia californica*) seedlings,
8 [Valliere and Allen \(2016a\)](#) observed that the effects of added N on root colonization by
9 arbuscular mycorrhizal fungi depended both on whether the soil inoculum came from a
10 high or low N deposition site and whether the seedlings were stressed by drought; root
11 colonization was generally lower with soil inoculum from the high N deposition site,
12 except when N was added under well-watered conditions. Notably, the same was also
13 true for root colonization by nonmycorrhizal fungi ([Valliere and Allen, 2016a](#)). A related
14 greenhouse study grew a non-native grass and two non-native forbs from CSS
15 ecosystems in two trials using either sterile soils or soil inoculated from plots receiving N
16 additions or control plots ([Valliere and Allen, 2016b](#)). This study found that N additions
17 (57 kg N/ha/yr) had no effect on arbuscular mycorrhizal root colonization in one forb
18 (*Hirschfeldia incana*), increased arbuscular mycorrhizal colonization in only the second
19 trial for the other forb (*Centaurea melitensis*), and increased arbuscular mycorrhizal
20 colonization in the second trial for the grass (*Bromus diandrus*) when it was inoculated
21 with soil from N addition plots ([Valliere and Allen, 2016b](#)). Although there were
22 differences in mycorrhizal colonization between the species and soil types, no direct link
23 was observed between colonization and the plant growth response to added N; while not
24 always significant, added N increased aboveground biomass in all plants and in all soil
25 types. The effect of added N was larger in the second trial and in inoculated soils, but
26 there was little difference in aboveground growth of the non-native plants between the N
27 addition inoculum and the control soil inoculum ([Valliere and Allen, 2016b](#)). However,
28 [Valliere and Allen \(2016a\)](#) only observed positive sagebrush seedling growth responses
29 to added N in soils with high N deposition site inoculum, whereas sterile and low N
30 deposition inoculum were unresponsive to added N. Thus, evidence is still mixed that soil
31 microbial communities at sites that have experienced N additions can themselves change
32 the growth response of plants to added N in arid and semiarid ecosystems.

33 [Vourlitis \(2012\)](#) measured the aboveground biomass and litter production of a post-fire
34 chaparral and a mature CSS stand in southern California over an 8-year period. Nitrogen
35 additions decreased NPP in the chaparral during the first 3 years of the study, but these
36 additions increased NPP during the last 3 years of the experiment. In the CSS, the effect
37 of added N positively correlated with precipitation and was only significant in the high
38 rainfall years. The authors suggested N enrichment (50 kg N/ha/yr) may increase the

1 productivity, but temporal patterns may take years to emerge and be dependent on water
2 availability. In contrast, shorter experiments conducted by [Vourlitis and Fernandez](#)
3 [\(2012\)](#) and [Vourlitis et al. \(2009\)](#) in chaparral and CSS ecosystems in southern California
4 found 4 years of dry season N addition at 50 kg N/ha/yr increased litter N and plant
5 tissue, but had no effect on ecosystem productivity or ecosystem N storage. Another
6 study using the same N deposition gradient in the CSS as [Padgett and Allen \(1999\)](#) found
7 lower soil C content at high deposition sites ([Liu and Crowley, 2009](#)). Further,
8 experimental N additions [50 kg N/ha/yr as Ca(NO₃)₂] decreased soil C content at the low
9 deposition site. However, there were no clear changes in microbial community
10 composition along the deposition gradient or as a result of the N additions.

11 A study by [Vourlitis and Pasquini \(2008\)](#) analyzed pre- and post-fire nutrient and soil
12 dynamics of three southern California chaparral stands exposed to varying levels of N
13 deposition and determined that periodic fire may not reduce N enrichment from decades
14 of N deposition. In a subsequent study, ([Pasquini and Vourlitis, 2010](#)) exposed chaparral
15 stands to different levels of N deposition over the first 3 years of post-fire succession.
16 High N deposition was associated with a lower relative abundance of *A. fasciculatum* and
17 a higher relative abundance of other shrub and herbaceous species. However, overall
18 aboveground net productivity was not related to N deposition.

19 Numerous studies were also conducted on dryland ecosystems outside of the U.S.,
20 including in China. Many of these Chinese N addition experiments have been conducted
21 in semiarid steppe ecosystems, particularly within the Inner Mongolia region. In these
22 experiments, N additions increased plant productivity ([Zeng et al., 2016](#); [Zhang et al.,](#)
23 [2015d](#); [Li et al., 2014](#); [Sun et al., 2014](#)), with a larger stimulation of aboveground growth
24 than belowground growth ([Wang et al., 2015b](#); [Zhang et al., 2015d](#); [Li et al., 2014](#)). In
25 one of these experiments, 4 years of N additions (50 kg N/ha/yr as urea) increased NEE
26 (+53.8%), ER (+47.6%), and GEP (+47.9%) in the last 3 years of the experiment ([Wang](#)
27 [et al., 2015b](#)). The N additions increased foliar N concentrations ([Zeng et al., 2016](#);
28 [Zhang et al., 2015a](#)), but [Zhang et al. \(2015a\)](#) also observed that the N additions
29 decreased the amount of N resorbed during leaf senescence in seven perennial grass,
30 sedge, and shrub species. Effects on microbial biomass in these Chinese N addition
31 experiments have been both positive ([Shi et al., 2016b](#); [Sun et al., 2014](#)) and negative ([Li](#)
32 [et al., 2016a](#)).

33 [Huang et al. \(2015\)](#) conducted a 3-year N × water experiment focused on soil microbial
34 community composition and function in a desert steppe ecosystem in northwestern China
35 that receives 25 kg N/ha/yr of ambient deposition. The N addition treatment
36 (50 kg N/ha/yr as NH₄NO₃) did not have consistent effects, increasing microbial
37 respiration in the spaces between shrubs in the first year, while decreasing microbial

1 respiration and microbial biomass C beneath the shrubs in the abnormally dry second
2 year. The N addition effects differed between inter-plant spaces and beneath shrub sites.
3 In the inter-plant spaces, N additions tended to increase overall microbial abundance,
4 with significant increases in bacteria and total microbial PLFA biomass in all 3 years and
5 an increase in actinobacteria in the last 2 years of the experiment. Beneath the shrubs, N
6 additions decreased bacterial biomass, fungal biomass, and total PLFA in 2 years and
7 decreased actinobacterial biomass in all 3 years ([Table 6-12](#)).

8 [Zhang et al. \(2015e\)](#) studied how N added (eight levels from 10 to 500 kg N/ha/yr as
9 NH₄NO₃) frequently (12 doses/yr) or infrequently (2 doses/yr) over 5 years influenced
10 plant productivity in a steppe grassland in the Inner Mongolia region of China. The
11 higher doses of N increased aboveground NPP regardless of how frequently the N was
12 added. However, the authors pointed to a group of similar studies that had shown small
13 frequent N doses caused more, less, or similar growth responses relative to large
14 infrequent N doses. As in other semiarid systems, the authors noted greater productivity
15 responses to N in years with higher precipitation. Although the N additions increased
16 ecosystem aboveground NPP, some individual species were less productive with added N
17 ([Zhang et al., 2015e](#)).

Table 6-12 Arid and semiarid microbial biomass responses to experimental nitrogen additions.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Treseder (2008)	Desert	Meta-analysis	Addition	50–500	0.4–2	Microbial biomass	Increase
Sinsabaugh et al. (2015)	Global	Arid lands meta-analysis	Addition	5–560	0.3–10	Microbial biomass	<u>Low dose:</u> increase <u>High dose:</u> decrease
Sinsabaugh et al. (2015)	Nevada (Mojave)	Creosote and bursage shrublands (<i>Larrea tridentata</i> , <i>Ambrosia dumosa</i>)	Addition	7, 15	1	Microbial biomass	Not significant
Sun et al. (2014)	China (north, Songnen)	Shrubland (<i>Leymus chinensis</i> , <i>Artemisia scoparia</i>)	Addition	23, 46, 69, 92	3	Microbial biomass C	<u>Highest dose:</u> increase <u>Other doses:</u> not significant
Huang et al. (2015)	China	Desert shrubs (<i>Haloxylon ammodendron</i>)	Addition	50	3	Microbial biomass C	Not significant
Sinsabaugh et al. (2015)	Global	Arid lands meta-analysis	Addition	5–560	0.3–10	Microbial metabolism	<u>Low dose:</u> increase <u>High dose:</u> decrease
Regus et al. (2017)	California	Desert, shrubland	Addition	1.8–8.7+	8 weeks	Nodule formation by rhizobia on native legume (<i>Acmispon strigosus</i>)	Decrease

C = carbon; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: single studies are reported more than once if multiple endpoints or ecosystems were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 In a greenhouse study of plants collected from a semiarid ecosystem in Spain, [Ochoa-](#)
2 [Hueso and Manrique \(2010\)](#) found that grass biomass was relatively unresponsive to N
3 enrichment of up to 50 kg N/ha, even when provided with increased water. However,
4 forb biomass and community biomass approximately tripled when both water and N were
5 enriched. In a related field experiment in central Spain, [Ochoa-Hueso and Stevens \(2015\)](#)
6 added N (10, 20, or 50 kg N/ha/yr as NH₄NO₃) to a semiarid shrubland ecosystem for
7 6 years. The effects on plant productivity varied by time. After 2.5 years, N additions
8 decreased the biomass of the dominant forb species. After 5.5 years, N additions
9 increased the biomass of plants in the Cruciferae family, but only in areas where
10 sufficient soil P was available. The authors noted that each of the biomass assessments
11 occurred in years with above-average precipitation. In Year 4 of the experiment, [Ochoa-](#)
12 [Hueso et al. \(2014\)](#) surveyed soil fauna (largely arthropods) and observed that the
13 moderate dose (20 kg N/ha/yr) significantly increased the total abundance of soil fauna
14 (organisms/g of soil), principally by increasing Collembola populations. This increase
15 was not significant at other doses and was attributed to soil acidification. At the highest
16 dose, soil Pauropoda increased ([Ochoa-Hueso et al., 2014](#)).

17 Elsewhere in Spain, [Taboada et al. \(2016\)](#) conducted a series of experiments to
18 understand how N deposition influenced herbivorous heather beetles (*Lochmaea suturalis*)
19 and their predators (beetles and Arachnids) in a semiarid *Calluna vulgaris* heathland. In
20 food-choice lab experiments, beetle larvae caused significantly greater shoot weight loss
21 in plants that had experienced high N addition rates (20, 50, or 56 kg N/ha/yr) than the
22 low N addition rate (10 kg N/ha/yr) or control, but N addition had no influence on shoot
23 consumption by adult beetles. [Taboada et al. \(2016\)](#) suggested that this was evidence that
24 the larvae could detect differences in tissue N and preferred to feed on high-N shoots.
25 The number of herbaceous heather beetle larvae was greater in plots that had received
26 long-term N additions (56 kg N/ha/yr for 10 years) than in the control or short-term
27 (2 year) N addition plots. In contrast, the number of predaceous Arachnids was
28 unaffected by N additions and the number of predatory beetles was greater in the control
29 plots, particularly in recently burned plots ([Taboada et al., 2016](#)).

6.3. Relationships between Nitrogen Deposition and Terrestrial Species Composition, Species Richness, and Biodiversity

6.3.1. Introduction

1 Given the role of N in biogeochemical cycling ([Appendix 4](#)), soil acidification
2 ([Appendix 5](#)), and the growth and physiology of terrestrial organisms ([Appendix 6.2](#)), it
3 is unsurprising that N availability can influence community composition and biodiversity.
4 In the 2008 ISA, the evidence was sufficient to infer a causal relationship between N
5 deposition on the alteration of terrestrial species composition, richness, and biodiversity.
6 In the 2008 ISA, the most sensitive terrestrial taxa were lichens. Empirical evidence
7 indicated that lichen composition and richness in the U.S. are adversely affected by
8 deposition levels as low as 3 kg N/ha/yr. Alpine ecosystems were also found to be
9 sensitive to N deposition. Changes in individual species were estimated to occur at
10 deposition levels near 4 kg N/ha/yr, and modeling indicated that deposition levels near
11 10 kg N/ha/yr alter plant community assemblages.

12 Since 2008, a large number of studies have examined the relationship between N and
13 terrestrial community composition and species richness. The effects of N deposition on
14 diversity have been observed in all major biomes ([Bobbink et al., 2010](#)), and these effects
15 have been particularly well studied in the temperate ecosystems prevalent across much of
16 the U.S. ([Murphy and Romanuk, 2016](#)). Changes in biological communities have been
17 found across a wide range of taxonomic and functional classifications, including trees,
18 shrubs, grasses, forbs, bryophytes, fungi (including mycorrhizae), bacteria, and
19 arthropods. Among these effects, N deposition has been identified as a threat to
20 12 terrestrial plant or animal species that are listed or candidates for protection under the
21 federal Endangered Species Act ([Hernández et al., 2016](#)).

22 A number of global, continental, and regional syntheses have compiled information about
23 changes in biodiversity as a result of N deposition. Some of these studies predate the
24 2008 ISA and served as part of the basis for the conclusions in that assessment
25 [e.g., ([Phoenix et al., 2006](#); [Pennings et al., 2005](#); [Suding et al., 2005](#); [Stevens et al.,](#)
26 [2004](#); [Bobbink et al., 2003](#); [Matson et al., 2002](#); [Gough et al., 2000](#); [Wallenda and](#)
27 [Kottke, 1998](#); [Vitousek et al., 1997](#))]. More recent assessments have reinforced the
28 conclusion that N deposition is a major cause of species loss in ecosystems around the
29 world [e.g., ([van Den Berg et al., 2016](#); [Phoenix et al., 2012](#); [De Schrijver et al., 2011](#);
30 [Pardo et al., 2011a](#); [Bobbink et al., 2010](#))]. Further, these new assessments have provided
31 a more detailed understanding of both sensitive and heavily impacted species,
32 ecosystems, and biomes and have created a more precise understanding of the

1 mechanisms linking species loss to N deposition. This new research, combined with
2 information from the 2008 ISA, creates a body of evidence sufficient to infer a causal
3 relationship between N deposition and the alteration of species richness, community
4 composition, and biodiversity in terrestrial ecosystems.

6.3.2. Mechanisms Operating across Terrestrial Ecosystems

5 Given the complexities of N effects, it is difficult to develop mechanistic models that can
6 accurately predict shifts in the composition of ecological communities as a result of N
7 deposition. Consequently, assessments of how N deposition alters species diversity,
8 species richness, and changes in community composition predominately rely on
9 experimental manipulations and empirical relationships developed across large spatial
10 and temporal scales [e.g., ([Simkin et al., 2016](#); [Verheyen et al., 2012](#); [Clark et al., 2007](#);
11 [Suding et al., 2005](#))].

12 Much of the ecological theory regarding the loss of species richness with N enrichment
13 has been developed from observations of changes in plant species abundance in
14 grasslands and other nonforest ecosystems [e.g., ([Farrer and Suding, 2016](#); [Pennings et
15 al., 2005](#); [Suding et al., 2005](#); [Gough et al., 2000](#))]. Many investigators have found a
16 unimodal relationship between plant species richness and aboveground primary
17 productivity, such that there is a negative relationship between productivity and
18 local-scale plant species richness in terrestrial ecosystems that takes effect once an initial
19 threshold for minimum productivity has been reached ([Suding et al., 2005](#); [Gough et al.,
20 2000](#); [Gross et al., 2000](#); [Grime, 1973](#)). In a synthesis of long-term (>4 years) N addition
21 experiments (90–130 kg N/ha/yr) in open-canopy ecosystems (grasslands, tundra, etc.),
22 [Gough et al. \(2000\)](#) found that as the relative stimulation of aboveground primary
23 productivity by N additions increased, there was a greater relative loss of species
24 richness. Thus, there was a direct linkage between the stimulation of productivity by
25 added N and the loss of plant species richness.

26 Variation among plants in the magnitude of growth responses to added N can have
27 critical and asymmetric effects on community composition because small differences in
28 plant height can cause substantial differences in the amount of light absorbed by plant
29 foliage ([Farrer and Suding, 2016](#)). There are a number of potential causes for the
30 variation in plant response to added N within communities. Two meta-analyses published
31 in 2005 synthesized data from nonforested N addition experiments across North America
32 to understand the role of plant functional traits versus random effects in determining
33 changes in community diversity ([Pennings et al., 2005](#); [Suding et al., 2005](#)). The
34 random-loss hypothesis of biodiversity decline suggests that rare species are most likely

1 to disappear as increased competition for resources such as light eliminates less
2 successful individuals, whereas the functional trait hypothesis predicts that organisms
3 will become more or less successful when N is added depending upon particular traits.
4 These mechanisms could operate simultaneously ([Suding et al., 2005](#)). In this synthesis,
5 N additions increased primary production and decreased species richness in all terrestrial
6 ecosystems ([Suding et al., 2005](#)). There was also support for random loss of species: the
7 rarest species had a >60% chance of disappearance, while the chance of disappearance
8 for the most abundant species was 10%. This suggests ecosystems with many rare species
9 that experience increases in competition after N additions are especially sensitive to
10 species loss.

11 There was also support for the functional trait hypothesis: N fixing forbs, species shorter
12 in stature, and perennial plants were more likely to be lost, although there was variation
13 among the sites in which traits made species the most sensitive to N additions. [Pennings
14 et al. \(2005\)](#) took a somewhat different approach by following the fate of 20 individual
15 species across experiments. They noted consistent responses in 10 of the 20 species, but
16 for all but two species, these responses were dependent on the combination of site
17 productivity, species richness, functional traits, and initial abundance ([Pennings et al.,
18 2005](#)). In a related synthesis of these data to understand the environmental and
19 experimental factors associated with the loss of species richness, [Clark et al. \(2007\)](#)
20 observed that several individual factors were almost equally correlated to the loss of
21 species richness, including aboveground plant production ($r = -0.50$), lower soil cation
22 exchange capacity ($r = 0.48$), and length of the experiment ($r = -0.57$). Overall, a full
23 multifactor structural equation model indicated that increased risk of species loss among
24 the study sites was tied to lower average annual minimum temperature, low soil cation
25 exchange capacity, and larger productivity responses to N additions ([Clark et al., 2007](#)).
26 This suggests that high latitude or high elevation ecosystems, those with low cation
27 exchange capacity (often associated with traits such as sandy soils, low pH, low organic
28 matter content, and highly weathered soils), and productivity that is strongly limited to N,
29 would be the most sensitive to plant species loss—traits common in alpine and Arctic
30 tundra, among other ecosystems.

31 More recently, [De Schrijver et al. \(2011\)](#) conducted a meta-analysis of plant species
32 richness responses in N addition experiments conducted in forests (understory plants
33 only), heathlands, grasslands, tundra, and wetlands. Additions of N increased graminoid
34 biomass, decreased bryophyte biomass, and decreased the biomass of understory plants in
35 forests. The addition of N decreased species richness when analyzed across experiments;
36 within individual ecosystems the effect was only significant in grasslands and heathlands,
37 while other ecosystems had negative effects but small sample sizes. The loss of species
38 richness increased with higher cumulative N loads.

1 The alteration of species interaction by added N occurs via several mechanisms. In
2 addition to altered interactions between species within the same trophic level
3 (e.g., competition between plant species), an increased supply of N can change
4 interactions across trophic levels. These trophic shifts can include changes in the
5 plant-fungal symbioses that occur in mycorrhizae ([Appendix 6.2.3.2](#) and
6 [Appendix 6.3.3.3](#)), the photobiont-mycobiont relationships in lichens ([Appendix 6.2.3.3](#)
7 and [Appendix 6.3.7](#)), and more complex changes in foodwebs that can occur as a
8 consequence of decreases in plant C allocation to belowground processes
9 ([Appendix 6.2.3.2](#)) and chemical changes in the plant tissues and litter that are consumed
10 by herbivores and detritivores ([Appendix 6.2.3.1](#), [Appendix 6.3.3.4](#)). Changes at higher
11 trophic levels can feed back to affect the productivity and diversity of primary producers.
12 For instance, in a greenhouse experiment conducted by [Farrer and Suding \(2016\)](#) using
13 plants and soils from three long-term N addition experiments (prairie, alpine tundra, arid
14 grassland), mesocosms inoculated with microorganisms collected from soils that had
15 received the long-term N additions were significantly more productive and less diverse
16 than mesocosms inoculated by microorganisms from soils that had not received added N;
17 these effects occurred regardless of whether the mesocosms received N additions.
18 [Valliere and Allen \(2016a\)](#) conducted a similar experiment with California sagebrush
19 (*Artemisia californica*) and observed that plant productivity was greater under low N
20 deposition conditions when plants were grown with inoculum from low deposition sites
21 and greater under high N deposition conditions with inoculum from high deposition sites.
22 These types of interactions complicate predictions of species loss from N deposition.

23 A new analysis by [Simkin et al. \(2016\)](#) has dramatically increased our understanding of
24 how N deposition is altering plant biodiversity in the continental U.S. They gathered data
25 on herbaceous species richness from more than 15,000 study plots in a variety of habitats.
26 N deposition had a strong effect on species richness, but this effect differed between
27 closed canopy and open ecosystems (i.e., forests and nonforest). In nonforested
28 ecosystems (grasslands, deserts, shrublands, subalpine ecosystems), there was a positive
29 relationship between N deposition and herbaceous species richness at low rates of N
30 deposition, then a decrease in species richness with higher rates of N deposition over a
31 threshold of 8.7 kg N/ha/yr. The effect was notably stronger at low pH. In forests, the
32 relationship between N deposition and herbaceous species richness was similar, but more
33 complex. In acidic soils, the relationship was similar to open canopy systems. In neutral
34 or basic soils, the relationship between N deposition and species richness was
35 consistently positive. Overall, these national-scale results are consistent with the
36 relationship between productivity and species richness suggested by ecological theory
37 [e.g., ([Clark et al., 2007](#); [Suding et al., 2005](#))] and provide evidence that vegetation on
38 acidic soils is more susceptible to species loss under elevated N.

1 There are few direct analyses comparing the impacts of oxidized and reduced forms of N
2 deposition on biodiversity. Because NO_3^- tends to be more readily lost to both leaching
3 and denitrification than NH_4^+ ([Brady and Weil, 1999](#)), it is possible that this form of N is
4 less likely to accumulate in the soil and cause fewer changes in plant and microbial
5 communities. The meta-analyses literature referenced previously ([Table 6-1](#)) tended to
6 find no difference in the effects of individual forms of N on ecological and
7 biogeochemical endpoints, such as plant productivity or microbial biomass. This is
8 suggestive that plant diversity is also not affected, yet a number of individual studies
9 have observed differential effects on diversity of NH_4^+ versus NO_3^- additions [e.g., ([Dias](#)
10 [et al., 2014](#); [Kleijn et al., 2008](#))]. For example, in a nutrient-poor, Mediterranean site, an
11 NH_4^+ addition (40 kg N/ha/yr) increased plant richness, while the addition of a half NH_4^+
12 and half NO_3^- mixture (for a total of 40 kg N/ha/yr also) did not. In the U.K., [van Den](#)
13 [Berg et al. \(2016\)](#) observed that once an overall negative effect of N deposition on plant
14 species richness had been accounted for, the $\text{NH}_x:\text{NO}_y$ ratio decreased species richness in
15 grasslands, but increased species richness in woodlands. By contrast, [Jovan et al. \(2012\)](#)
16 observed that lichen communities in the Los Angeles basin were best predicted by total N
17 deposition (as throughfall) than the deposition or gaseous concentrations of any particular
18 form of N. The national-scale analysis of herbaceous species richness completed by
19 [Simkin et al. \(2016\)](#) only evaluated total N deposition, not individual forms of deposition.

20 Future effects of N deposition on biodiversity will depend in part on not only N
21 emissions, but also on the rate at which populations and communities respond to
22 increases or decreases in emission rates and the pace at which total cumulative N
23 deposition increases. Compared to the number of N addition studies, there have been
24 relatively few studies of recovery following the cessation of N additions or decreases in
25 N deposition, and nearly all of these have been in Europe ([Stevens, 2016](#)). In a review of
26 these recovery studies, [Stevens \(2016\)](#) found that soil nitrate and ammonium
27 concentrations recovered to levels observed in untreated controls within 1 to 3 years, but
28 that soil processes such as N mineralization and litter decomposition were slower to
29 recover. For instance, differences in decomposition and soil N_2O emissions persisted 4
30 and 7 years, respectively, after installation of a roof system to decrease atmospheric
31 deposition to European forests ([Borken and Beese, 2002](#); [Boxman et al., 1998b](#)).
32 Although there were observations that plant physiological processes recovered in less
33 than 2 years, grassland plant communities were slower to recover and still differed from
34 controls 11 to 20 years after the cessation of N additions ([Isbell et al., 2013b](#); [Stevens et](#)
35 [al., 2012](#)). [Stevens \(2016\)](#) observed a wide range of recovery times for mycorrhizal
36 community composition and abundance, with some recovery observed in as few as
37 4 years ([Emmett et al., 1998](#)) and differences persisting for as long as 28 or 48 years
38 ([Strengbom et al., 2001](#)). Based on the slow pace at which plant community composition
39 recovered following observed or experimental decreases in deposition elsewhere in

1 Europe, [Stevens et al. \(2016\)](#) predicted that despite future decreases in reactive N
2 emissions, habitat suitability would decline in 2020 and 2030 for a majority of plant
3 species within grasslands, heathlands and bogs, and deciduous forests in Great Britain
4 due to the cumulative effects of N deposition. Plant communities in these ecosystems
5 were predicted to become more eutrophic: favoring grasses, decreasing the abundance of
6 forbs and lichens, and having mixed species-specific effects on bryophytes and other
7 plant groups ([Stevens et al., 2016](#)).

6.3.3. Forests

6.3.3.1. Overstory Trees

8 The 2008 ISA reported that there was very little information on the effect of N deposition
9 on the biodiversity of overstory trees in the U.S. However, the altered growth rates
10 caused by N enrichment have the potential to affect forest structure and biodiversity. The
11 life span of many trees is 100 years or more; therefore, it is difficult to observe how
12 changes in growth or mortality affect biodiversity within established forests. The 2008
13 ISA cited evidence for boreal forest encroachment into grasslands under increased N
14 deposition ([Köchy and Wilson, 2001](#)). Since the 2008 ISA, little new direct information
15 is available on the effect of N deposition on the biodiversity of overstory trees in the U.S.
16 or Europe. In subtropical forests in China along a rural to urban N deposition gradient of
17 30 to 43 kg N/ha/yr across four sites, [Huang et al. \(2012\)](#) found a decrease in tree
18 diversity with increasing N deposition, but there were also differences in management
19 regimes, elevation, and dominant vegetation among the study sites. There is widespread
20 evidence of species-specific effects of N deposition on tree growth and mortality in the
21 U.S. [e.g., ([Dietze and Moorcroft, 2011](#); [Thomas et al., 2010](#))], but this information has
22 not yet been transformed into a quantitative assessment of changes in tree community
23 composition. A broad-scale analysis of changes in overstory community composition as a
24 result of N deposition remains a research need.

6.3.3.2. Understory Plants

25 Compared to overstory trees, there was more information available in the 2008 ISA
26 regarding the effects of N deposition on understory plants. A major influence on the 2008
27 ISA was a review by [Gilliam \(2006\)](#), who identified nine studies on N deposition effects
28 on forest understory plant communities, all within the U.S. and Europe. All of the North
29 American studies cited by [Gilliam \(2006\)](#) were N addition experiments within temperate

1 forests in the northeastern U.S.; two of these studies found no significant changes in
2 community composition ([Gilliam et al., 2006](#); [Gilliam et al., 1994](#)). Notably, research by
3 [Gilliam et al. \(2016b\)](#) has subsequently reported decreases in understory species richness,
4 community evenness, and diversity, and changes in community composition at one of the
5 northeastern temperate forest sites where understory community composition had earlier
6 been unaffected by chronic N additions ([Gilliam et al., 2006](#); [Gilliam et al., 1994](#)). In
7 particular, the change in understory community composition caused by N additions
8 included a large increase in the cover of blackberry (*Rubus* spp.) shrubs ([Gilliam et al.,](#)
9 [2016b](#); [Walter et al., 2016](#)), but more broadly included an increase in nitrophilous species
10 and a loss of more N efficient (oligotrophic) species ([Gilliam et al., 2016b](#)). In Sweden,
11 shifts in understory plant community composition were documented along two forest N
12 deposition gradients that ranged from 6 to 20 kg N/ha/yr ([Brunet et al., 1998](#)) and from 3
13 to 12 kg N/ha/yr ([Strengbom et al., 2001](#)).

14 Many of the mechanisms through which N additions alter plant community composition
15 and species richness in other terrestrial ecosystems also function in forest understory
16 environments, including shifts in mycorrhizal communities, competitive exclusion,
17 increases in herbivory, and species-specific growth responses to increased N availability
18 ([Gilliam, 2006](#)). However, resource heterogeneity in forests can be especially high, and
19 limited light availability can constrain the effects of competitive exclusion ([Simkin et al.,](#)
20 [2016](#)). Since the 2008 ISA, a number of new studies of N addition and ambient
21 deposition effects on understory plant diversity have been conducted in temperate and
22 boreal forests in the U.S. and Europe, as well as in subtropical forests in China
23 ([Table 6-13](#)). In a national-scale analysis of herbaceous species richness, [Simkin et al.](#)
24 [\(2016\)](#) found that the effect of N deposition on forest understory species richness was
25 highly dependent on soil pH. At all soil pH values, low rates of N deposition
26 (~5 kg N/ha/yr) had neutral or positive effects on species richness. At a low pH (4.5),
27 species richness declined at N deposition rates >11.6 kg N/ha/yr, but among neutral and
28 basic soils there was no point in the data set at which N deposition had a negative effect
29 on species richness (the analysis included deposition values up to ~20 kg N/ha/yr). In a
30 study that synthesized data from >1,200 forest understory vegetation plots in northern
31 and central Europe, [Verheyen et al. \(2012\)](#) did not find a significant effect of increasing
32 N deposition (8.3 to 35.7 kg N/ha/yr) on species richness. Although understory plant
33 species richness did not change, community composition shifted significantly away from
34 light-demanding species and toward nutrient-demanding species. [van Dobben and de](#)
35 [Vries \(2010\)](#) found a similar result in 366 plots in managed forests throughout western
36 and northern Europe and in a smaller network of 197 plots within the Netherlands: N
37 deposition was not a significant influence on plant species richness or diversity and only
38 a minor influence on community composition via a shift toward more nitrophyllic
39 species. Soil, elevation, climate, and overstory tree composition were much more

1 important determinants of community composition at this scale ([van Dobben and de](#)
2 [Vries, 2010](#)). In a study of forest understory vegetation plots at 28 sites across Europe,
3 [Dirnböck et al. \(2014\)](#) also found that although understory plant species richness was not
4 affected by N deposition, plant communities became more strongly dominated by both
5 more nutrient-demanding species and more shade-tolerant species as N deposition rates
6 increased beyond identified critical loads.

7 There is also evidence for shifts in plant communities across local and regional N
8 deposition gradients. In a survey of 260 sessile oak (*Quercus petraea*) forests in Ireland,
9 [Wilkins and Aherne \(2016\)](#) observed that N deposition was negatively correlated with
10 plant species richness and had a significant influence on community composition.
11 Community composition and species richness were also significantly influenced by soil
12 pH (positive effect on species richness) and atmospheric NH₃ concentrations (negative
13 effect). Ten species were positively associated with total N deposition and atmospheric
14 NH₃, while 10 other species had negative associations with these N variables; each group
15 included shrubs, trees, ferns, and bryophytes ([Wilkins and Aherne, 2016](#)). The authors
16 suggested that focusing on a single forest type allowed them to better isolate the effect of
17 N deposition relative to studies of broader forest communities in Europe ([Wilkins and](#)
18 [Aherne, 2016](#)). In a survey of woodlands across the U.K., [van Den Berg et al. \(2016\)](#)
19 observed a negative effect of N deposition on plant species richness. [Huang et al. \(2012\)](#)
20 observed that understory plant species richness was negatively correlated with N
21 deposition along a rural to urban gradient (30 to 40 kg N/ha/yr) of four subtropical forests
22 in China. At a network of 40 sugar maple forest monitoring sites in Ontario, [McDonough](#)
23 [and Watmough \(2015\)](#) observed that most of the variability in understory plant
24 community composition could be explained by climate and soil factors, but that N
25 deposition (8 to 12.9 kg N/ha/yr) explained a statistically significant portion of the
26 variability. However, there was no effect on understory species richness over this
27 relatively narrow range of N deposition.

Table 6-13 Forest plant diversity responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Huang et al. (2012)	China (southern tropical)	Moist subtropical evergreen broadleaf forests	Ambient	30.1–43.1	n/a	Overstory species richness	Decrease

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 Understory plant species richness was also not affected in several N addition studies in
2 temperate forests in the U.S. ([Chapman et al., 2016](#); [Talhelm et al., 2013](#); [Jones and](#)
3 [Chapman, 2011](#)). In an oak forest in the Philadelphia, PA area, [Jones and Chapman](#)
4 [\(2011\)](#) found that native understory plant diversity and richness were negatively
5 correlated with soil inorganic N, but not significantly impacted by N additions
6 (13 kg N/ha/yr). In a follow up at the same site, [Chapman et al. \(2016\)](#) used higher rates
7 of N additions (100 or 200 kg N/ha/yr as NH₄NO₃ for 4 years). Changes in total, native,
8 or invasive species cover were not detected, but N additions increased invasive species
9 richness in some years. In Michigan, [Talhelm et al. \(2013\)](#) found that although N
10 additions did not alter understory plant species richness, community composition was
11 altered. Tree sapling communities were apparently more resistant, as neither species
12 richness nor community composition changed in response to N additions ([Talhelm et al.,](#)
13 [2013](#)).

14 The effects of N additions on forest understory plant communities can be long lasting.
15 [Strengbom and Nordin \(2008\)](#) found significant differences in understory plant
16 communities in recently harvested regenerating Swedish forests as a result of two single
17 additions of 150 kg N/ha 22 and 30 years earlier. The forests that received N decades
18 earlier had denser understory vegetation, much less shrub cover, and much more herb and
19 graminoid cover. The abundance of individual species, including ground-dwelling
20 bryophytes and lichens, differed by as much as 20 times due to the N additions
21 ([Strengbom and Nordin, 2008](#)). In a related study, [Hedwall et al. \(2013\)](#) found that the
22 amount of change in understory plant community composition in regenerating forests
23 caused by N additions was negatively correlated with the rate of N deposition along a
24 Swedish deposition gradient of 4.4 to 16.1 kg N/ha/yr. [Wardle et al. \(2016\)](#) observed that
25 6 years of N additions (100 kg N/ha/yr) decreased species richness and altered
26 community composition in boreal forest understory communities dominated by Ericaceous
27 shrubs and bryophytes.

6.3.3.3. Microbial Diversity

28 There is an ongoing debate about how to define a microbial species, so taxonomists often
29 use measures of similarity in genetic material to classify microbial diversity ([Fraser et al.,](#)
30 [2009](#)). This can lead to discussion of biodiversity changes in terms of taxonomic
31 community shifts or taxonomic richness. For instance, [Turlapati et al. \(2013\)](#) measured
32 microbial diversity in surface soils at Harvard Forest by clustering operational taxonomic
33 units (OTUs) based on 97% sequence similarity from 16S rRNA pyrosequencing.

1 Soils contain a high amount of microbial diversity ([Lynch et al., 2012](#)), but this diversity
2 is not evenly distributed among phylogenetic groups. In the Harvard Forest study,
3 [Turlapati et al. \(2013\)](#) observed that 2% of the OTUs contained >50% of the total
4 sequences, while 80% of the OTUs were infrequently observed and contained only about
5 10% of total sequences. This suggests that many individual soil microbes are either from
6 the same or closely related taxonomic groups, while concomitantly there are a large
7 number of relatively rare taxonomic groups. Reanalyzing these data with a more detailed
8 oligotype sequence clustering approach, [Turlapati et al. \(2015\)](#) found a more even
9 distribution of taxonomic groups, but 2% of oligotypes still represented ~38% of the total
10 number of sequences. In an oligotype analysis of soil fungal communities at the same
11 site, [Morrison et al. \(2016\)](#) observed a similar distribution of fungal populations: the
12 Basidiomycota phylum comprised 63–71% of all sequences, while the Ascomycota
13 phylum averaged 26%, and the ectomycorrhizal genus *Russula* made up 40–50% of all
14 sequences across plots. A shotgun metagenomics assessment of microbial communities in
15 four northern hardwood forests in Michigan documented that taxonomic classification of
16 the metagenomics hits via the RDP databased within MG-RAST were heavily dominated
17 by bacteria (98% of reads), with much smaller contributions of fungi (1%) and archaea
18 (0.03%) ([Freedman et al., 2016](#)). However, annotation databases are biased toward
19 culturable bacteria and there is transcriptomic evidence that metagenomic approaches
20 greatly underrepresent the fungal contribution to soil metabolic function ([Freedman et al.,
21 2016](#)).

22 Much of the available information about changes in microbial community composition
23 published since 2008 has been about changes in fungal communities, including
24 mycorrhizal species. Of the studies identified for this assessment that quantified the
25 compositional response of forest fungal communities to N additions, one study had
26 site-specific results, but N additions changed community composition in five of the
27 remaining seven studies ([Table 6-14](#)). Among studies of ectomycorrhizal fungi
28 community composition, N caused changes in six out of seven studies, including in four
29 studies along ambient N deposition gradients ([Table 6-15](#)). As with lichens and plants,
30 the sensitivity of ectomycorrhizal fungi appears to vary taxonomically, with these
31 taxonomic differences apparently related to differences in functional traits such as
32 organic N acquisition ([Lilleskov et al., 2011](#)). At Harvard Forest, [Morrison et al. \(2016\)](#)
33 observed that N additions (50 or 150 kg N/ha/yr) decreased the relative abundance of the
34 ectomycorrhizal genus *Cenococcum* and increased the ectomycorrhizal genera
35 *Scleroderma* and *Rhizoscyphus*. *Scleroderma* is thought to be important in organic P
36 acquisition, and *Rhizoscyphus* has proteolytic, cellulytic, and partial lignin degradation
37 capabilities, but less is known about *Cenococcum*. The overall abundance of the genus
38 *Russula* did not change as a result of N additions, but the *Russula* species (*R. vinacea*)

1 that was the single most abundant OTU in the data set increased from 10% relative
2 abundance to 28–37% in the N addition plots, while the other *Russula* decreased.

3 Shifts in ectomycorrhizal composition have also been observed along N depositional
4 gradients. [Kjøller et al. \(2012\)](#) observed changes in the ectomycorrhizal community
5 composition and a loss of ectomycorrhizal species richness across an N deposition
6 gradient in Denmark from 27 to 43 kg N/ha/yr at the edge of a spruce forest. In Scotland,
7 [Jarvis et al. \(2013\)](#) analyzed ectomycorrhizal fungal communities from 15 seminatural
8 Scots pine forests and found changes in abundance of *Cortinarius* spp. at higher N
9 deposition (9.8 kg N/ha/yr). In red spruce-dominated forests in the northeastern U.S.,
10 [Lilleskov et al. \(2008\)](#) observed changes in ectomycorrhizal communities over a much
11 lower N deposition gradient, ranging from 2.8 to 7.9 kg N/ha/yr of wet deposition.
12 Nitrogen deposition was positively related to fine root N concentrations, and those root N
13 concentrations had positive relationships with the abundance of three of the
14 ectomycorrhizal fungal morphotypes, negative relationships with three morphotypes, and
15 ambiguous relationships with three other morphotypes. In Scots pine (*Pinus sylvestris*)
16 forests in Germany and the U.K. arrayed along an N deposition gradient ranging from 4.6
17 to 28.6 kg N/ha/yr, [Cox et al. \(2010\)](#) used DNA extracted from fine roots and group
18 sequences at 97% similarity to assess changes in ectomycorrhizal community
19 composition. Similar to the results in the [Lilleskov et al. \(2008\)](#) study, N deposition was
20 positively correlated to foliar N concentrations and foliar N was linked to shifts in
21 mycorrhizal community structure. In particular, foliar N concentrations were significantly
22 negatively correlated with ectomycorrhizal richness. Of the 35 taxa that occurred widely
23 across the gradient, 11 showed significant responses to increased N availability: 6 taxa
24 increased and 5 taxa decreased with greater N availability ([Cox et al., 2010](#)). Thus, the
25 effects of N deposition on ectomycorrhizal community composition observed by
26 [Lilleskov et al. \(2008\)](#) and [Cox et al. \(2010\)](#) were indirect.

1 Although shifts in fungal community composition are widely reported, these shifts are
2 not necessarily consistent, even in similar ecosystems. [Allison et al. \(2010\)](#) conducted an
3 N addition experiment in a recently burned boreal forest in Alaska. In that site, the forest
4 microbial community was dominated by fungi in the Ascomycota, and N additions
5 increased their abundance. In contrast, [Allison et al. \(2008\)](#) conducted a similar
6 experiment in a mature boreal forest in Alaska and observed that the microbial
7 community was dominated by Basidiomycota, and N additions did not change the overall
8 abundance of fungi in this phylum. However, in both ecosystems, N additions greatly
9 changed the relative abundance of individual taxa (orders and families) within these
10 phyla ([Allison et al., 2010](#); [Allison et al., 2008](#)). Individual components of microbial
11 communities also appear to react to N additions at different speeds. In a long-term forest
12 N addition in Switzerland, [Gillet et al. \(2010\)](#) observed that both ectomycorrhizal and
13 saprotrophic fungal communities responded to an increase in soil N input, but the
14 ectomycorrhizal community rapidly decreased in species richness, whereas the
15 saprotrophic community was less affected. The response was highly species specific,
16 especially for the saprotrophic community. At Harvard Forest, [Frey et al. \(2004\)](#) found
17 fungal biomass was reduced in fertilized versus control plots, and this was accompanied
18 by a decrease in phenol oxidase activity, an enzyme produced by saprophytic, white-rot
19 fungi to decompose lignin. Among fungal saprotrophs at Harvard Forest, [Morrison et al.](#)
20 [\(2016\)](#) found that high rates of N addition (150 kg N/ha/yr for 25 years) decreased the
21 abundance of the saprotrophic basidiomycete genus *Agaricus*, which has lignolytic
22 abilities, and increased the abundance of two saprophytic ascomycete genera (*Hypocrea*,
23 *Phialophora*) that are cellulolytic. These changes in the fungal community at Harvard
24 Forest are consistent with observations elsewhere ([Freedman et al., 2016](#); [Edwards et al.,](#)
25 [2011](#)) that N additions can stimulate cellulose decomposition and inhibit fungal
26 decomposition of lignin (see [Appendix 4](#)).

27 Decreases in taxonomic richness among fungi appear to be less common than changes in
28 community composition. Taxonomic richness is often used as a measure of biodiversity
29 for microbial communities since it can be difficult to define species as noted previously.
30 Only three studies of taxonomic richness in overall fungal communities were identified
31 for this assessment ([Table 6-14](#)). One study saw changes at two of four study sites
32 ([Eisenlord et al., 2013](#)); there was no effect in another study ([Krumins et al., 2009](#)); and
33 [Morrison et al. \(2016\)](#) observed a shift in composition under a very high dose
34 (150 kg N/ha/yr), but not a more moderate dose (50 kg N/ha/yr). Of the 11 identified
35 ectomycorrhizal richness studies, decreases were observed in 6 studies ([Table 6-15](#)).

36 Compared to ectomycorrhizal fungi, there is also less information about how N additions
37 alter arbuscular mycorrhizal and bacterial community composition ([Table 6-14](#),
38 [Table 6-16](#)). Two studies on arbuscular mycorrhizae were identified, one in Ecuador

1 ([Camenzind et al., 2014](#)) that observed no effect of added N (50 kg N/ha/yr for 3 years)
2 on community composition and another in northern hardwood forests in Michigan where
3 the effect of added N (30 kg N/ha/yr for +12 years) on community composition was
4 dependent on the measurement technique ([van Diepen et al., 2013](#); [van Diepen et al.,
5 2011](#)). At the Harvard Forest long-term N addition study in Massachusetts (50 and
6 150 kg N/ha/yr), ([Turlapati et al., 2015](#); [Turlapati et al., 2013](#)) used molecular techniques
7 to assess changes in bacterial community composition. Using a 97% sequence identity
8 approach to clustering OTUs, ([Turlapati et al., 2013](#)) found the chronic N additions
9 caused major changes in the bacterial phyla of Acidobacteria, Proteobacteria, and
10 Verrucomicrobia. Using the more detailed oligotype sequence clustering approach,
11 [Turlapati et al. \(2015\)](#) observed five genera that exclusively appeared in N treated soils
12 (*Aquabacterium*, *Nitrosospira*, *Yersinia*, *Legionella*, and *Niabella*) and eight genera that
13 were present only in the control plots (*Comamonas*, *Microbacterium*, *Mycetocola*,
14 *Brochothrix*, *Flavobacterium*, *Pedobacter*, *Sphingobacterium*, and *Terrimonas*).
15 However, the N addition treatments also caused shifts in community structure within
16 most genera. As with [Fierer et al. \(2012\)](#), microbial communities in the mineral soil were
17 less affected by the N additions than communities in the organic soil.

Table 6-16 Arbuscular mycorrhizal responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
van Diepen et al. (2011)	Michigan (four sites)	Sugar maple (<i>Acer saccharum</i>)	Addition	30	13	Community composition	Change
van Diepen et al. (2013)	Michigan (four sites)	Sugar maple (<i>Acer saccharum</i>)	Addition	30	14	Community composition	Not significant

Chen et al. (2014)	China	Steppe grassland	Addition	100	6	Soil microbial phylotype diversity	Not significant
Chen et al. (2014)	China	Steppe grassland	Addition	100	6	Soil microbial phylotype richness	Decrease
van Diepen et al. (2011)	Michigan (four sites)	Sugar maple (<i>Acer saccharum</i>)	Addition	30	13	Taxonomic diversity	<u>Three sites</u> : not significant <u>One site</u> : decrease

Table 6 16 (Continued): Arbuscular mycorrhizal responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
van Diepen et al. (2013)	Michigan (four sites)	Sugar maple (<i>Acer saccharum</i>)	Addition	30	14	Taxonomic richness	Decrease
Camenzind et al. (2014)	Ecuador	Evergreen tropical forest	Addition	50	3	Taxonomic richness	Decrease

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 Shifts in microbial community composition can alter ecosystem processes and plant
2 community diversity, in addition to affecting plant productivity as noted previously
3 ([Appendix 6.2.3](#)). Lower microbial diversity has been linked to slower decomposition of
4 plant litter and can affect, for example, ecosystem C and nutrient cycling ([Bardgett and](#)
5 [van Der Putten, 2014](#); [Handa et al., 2014](#)). In a global scale study, [Delgado-Baquerizo et](#)
6 [al. \(2016\)](#) found a positive correlation between microbial diversity and a broad suite of
7 ecosystem services and functions. Mycorrhizal diversity has been shown experimentally
8 to affect plant diversity. For instance, [Van Der Heijden et al. \(1998\)](#) concluded that plant
9 species composition fluctuated greatly under low arbuscular mycorrhizal diversity,
10 whereas it increased and exhibited greater stability alongside higher mycorrhizal
11 diversity. Specifically on N effects, [Van Der Heijden et al. \(2008\)](#) observed smaller
12 impacts on plant community composition from N additions (100 kg N/ha/yr) when plant
13 mesocosms were inoculated with arbuscular mycorrhizal fungi than in those without
14 fungal inoculum. Plant communities in the inoculated mesocosms had greater evenness
15 among functional groups. Altogether, these studies suggest microbial, including
16 mycorrhizal, diversity have a positive effect on ecosystem processes and plant
17 community diversity. This implies that N induced decreases in microbial diversity may in
18 turn negatively affect these endpoints.

6.3.3.4. Arthropod and Other Invertebrate Diversity

19 Arthropods can be key components of forest productivity and nutrient cycling because
20 they can feed on living plant tissues, plant litter, or on litter-degrading fungi, and
21 arthropod communities can be directly or indirectly altered by changes in plant
22 productivity and chemistry ([Gan et al., 2014](#); [Throop and Lerdau, 2004](#)). Consequently,
23 recent research has quantified the response of arthropods to added N ([Table 6-17](#)). Both
24 before and after the 2008 ISA, Jones and colleagues published a series of studies on how
25 N air pollution altered plant-associated insect communities in mixed conifer forests
26 outside Los Angeles, CA ([Jones et al., 2011](#); [Jones et al., 2008](#); [Jones and Paine, 2006](#);
27 [Jones et al., 2004](#)). [Jones et al. \(2004\)](#) observed significantly higher tree mortality and
28 bark beetle activity at a high versus a low N pollution site. Moreover, experimental N
29 additions at the low pollution site increased mortality and bark beetle activity relative to
30 unfertilized control plots. In contrast, the opposite occurred at the high pollution site, with
31 the control plots exhibiting higher tree mortality and beetle activity. The authors
32 suggested this could be because N deposition already exceeded biological demand at the
33 high pollution site, with additional N no longer increasing tree mortality. [Jones et al.](#)
34 [\(2008\)](#) found that insect herbivore communities on California black oak (*Quercus*
35 *kelloggii*) trees did not change in response to several years of N additions

1 (150 kg N/ha/yr) at a relatively unpolluted and dry site, but were altered by N additions at
2 a wetter site that received more ambient N deposition. [Jones et al. \(2011\)](#) found a similar
3 response for insect herbivore communities associated with bracken fern plants at these
4 sites, with no change in insect taxonomic richness at the dry and low-deposition site and
5 increased richness at the wetter, higher deposition site. Notably, as with plant
6 productivity responses in grassland and arid environments, the effects of added N on
7 insect abundance and diversity appeared to be strongly dependent on climate ([Jones et al.,
8 2011](#)).

9 [Gan et al. \(2013\)](#) and [Gan et al. \(2014\)](#) quantified changes in the abundance and
10 community composition of soil microarthropods and trophic position of soil-dwelling
11 oribatid mites at the same four northern hardwoods forests in which [Talhelm et al. \(2013\)](#)
12 quantified changes in understory plant composition. The overall abundance of
13 microarthropods declined by approximately 45% in response to N additions, a change
14 that was attributed to changes in soil food webs as a consequence of previously
15 documented decreases in litter decomposition ([Zak et al., 2008](#)), decreases in mycorrhizal
16 productivity ([van Diepen et al., 2010](#)), and shifts in the microbial community
17 composition ([van Diepen et al., 2013](#); [Edwards et al., 2011](#); [van Diepen et al., 2011](#)).
18 More specifically, [Gan et al. \(2013\)](#) observed decreases in two orders of detritivores
19 (Oribatida, Collembola) and one order of predaceous mites (Mesostigmata), with the
20 largest decline in the oribatid mites. The decrease in oribatid mites did not affect species
21 richness or their trophic position, but did cause a shift in the community composition
22 ([Gan et al., 2014, 2013](#)).

23 Lastly, in addition to arthropods, other soil invertebrates, such as earthworms or
24 nematodes, can be affected by N additions ([Table 6-17](#)). [Romanowicz and Zak \(2017\)](#),
25 for example, observed that the abundance of middens created by the non-native
26 earthworm species *Lumbricus terrestris* was 363% higher in plots receiving N additions
27 at one of the four sites in the study. Many northern temperate forests in the U.S. have no
28 native earthworms and the spread of these non-native worms can cause decreases in soil
29 C storage, a redistribution of soil C and N as earthworms consume the soil organic
30 horizon, shifts in soil foodwebs, and changes in understory plant communities ([Bohlen et
31 al., 2004](#)).

Table 6-17 Arthropod and other invertebrate responses to experimental nitrogen additions.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

6.3.4. Alpine and Arctic Tundra

1 There was consistent and coherent evidence in the 2008 ISA indicating that alpine plant
2 communities are among the terrestrial communities most sensitive to atmospheric N
3 deposition. The previous assessment identified a number of factors that made these
4 ecosystems sensitive to N deposition, including low rates of primary production, short
5 growing seasons, low temperature, and low rates of N mineralization ([Bowman and Fisk,
6 2001](#); [Bowman and Steltzer, 1998](#); [Fisk et al., 1998](#); [Bowman, 1994](#); [Bowman et al.,
7 1993](#)). Alpine plants are broadly N limited, and increased N inputs have been observed to
8 cause changes in alpine growth and species composition ([Bowman et al., 2006](#); [Bowman
9 and Steltzer, 1998](#); [Vitousek et al., 1997](#)). Alpine plant communities have also developed
10 under conditions of low nutrient supply, in part because soil-forming processes are poorly
11 developed, and this was also thought to contribute to their N sensitivity.

12 Many of the alpine tundra ecosystems in the U.S. are found in the western U.S.,
13 particularly in the Rocky Mountains, Cascade Mountains, and the Sierra Nevada.
14 Atmospheric deposition tends to be low in the western U.S., but alpine sites can be
15 affected by relatively low or moderate levels of N deposition because of their high
16 sensitivity. In several studies, the capacity of Colorado Rocky Mountain alpine
17 catchments to sequester N was exceeded at input levels of 10 kg N/ha/yr or less
18 [e.g., ([Baron et al., 1994](#))]. Similarly, relatively low N addition rates can cause shifts in
19 alpine plant communities. [Bowman et al. \(2006\)](#) estimated that changes in the abundance
20 of *Carex rupestris* occurred at deposition rates of 4 kg N/ha/yr and changes in alpine
21 tundra community composition occurred at deposition rates of approximately
22 10 kg N/ha/yr. In Europe, critical loads for alpine plant communities were estimated to be
23 between 5 and 15 kg N/ha/yr ([Bobbink et al., 2003](#)).

24 Since 2008, there was further research in the U.S. on the effects of added N on plant
25 communities in Colorado at the Niwot Ridge Long-Term Ecological Research Site and in
26 Rocky Mountain National Park (RMNP), as well as on Mount St. Helens in Washington
27 ([Table 6-18](#)). In RMNP, [Bowman et al. \(2012\)](#) conducted a 4-year study in a dry alpine
28 meadow ecosystem where N was added at rates of 5, 10, and 30 kg N/ha/yr, while
29 ambient N deposition was 4 kg N/ha/yr. No shifts in species richness or diversity were
30 observed in response to the N additions; however, *Carex rupestris* increased in cover
31 from 34 to 125% in response to the treatments([Bowman et al., 2014](#)). More broadly, as
32 noted in [Appendix 5](#), [McDonnell et al. \(2014a\)](#) used the ForSAFE-VEG model to assess
33 changes in vegetation cover in subalpine ecosystems in RMNP since 1900 and forecast
34 the changes through the end of the 21st century as a result of N deposition and climate
35 change scenarios. Based on the model output, plant community composition changed by

1 10% over the past 100 years as a result of increases in N deposition, with increases in
2 graminoid species and decreases in forb species. Over the next 100 years, forecasted
3 changes in N deposition and climate factors are predicted to increase tree cover. At Niwot
4 Ridge, two decades of N additions (averaging ~75 kg N/ha/yr) generally decreased plant
5 species richness across a wet-to-dry gradient of alpine meadows, with a significant
6 decrease in the moist meadow type ([Yuan et al., 2016](#)). Plant diversity increased with N
7 additions (78 kg N/ha/yr for 5 years) on Mount St. Helens, but this plant community was
8 growing on very N poor soils formed following the volcanic eruption there in 1980
9 ([Bishop et al., 2010](#)).

10 Internationally, plant diversity research has been conducted in Arctic ecosystems in
11 Scandinavia and North Atlantic Europe (Greenland, Iceland, northern Great Britain, etc.)
12 and in alpine ecosystems in Switzerland and China. In a subalpine grassland in the Swiss
13 Alps, [Bassin et al. \(2013\)](#) observed that 7 years of N additions of 5 to 50 kg N/ha/yr
14 decreased plant diversity and changed plant community composition. [Arens et al. \(2008\)](#)
15 found no effects of N additions (5, 10, or 50 kg N/ha/yr) on plant community
16 composition over 3 years in dwarf shrub/herb tundra ecosystems in Greenland. In
17 Sweden, [Sundqvist et al. \(2014\)](#) did not observe any change in plant species diversity or
18 plant species richness as a result of 3 years of N additions (100 kg N/ha/yr) to a tundra
19 heath and a tundra meadow. Elsewhere in Sweden, [Wardle et al. \(2013\)](#) found that two
20 decades of N additions (50 kg N/ha/yr) to a tundra meadow decreased both plant species
21 richness and plant community diversity.

Table 6-18 Alpine and Arctic tundra plant diversity responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Arens et al. (2008)	Greenland	Dwarf-shrub/herb tundra (Salix arctica, Carex rupestris, Dryas integrifolia)	Addition	5, 10, 50	3	Plant community composition	Not significant

Wardle et al. (2013)	Sweden	Tundra meadow (<i>Deschampsia flexuosa</i> , <i>Empetrum hermaphroditum</i> , <i>Vaccinium</i> spp.)	Addition	50	21	Plant species richness (vascular)	Decrease

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 Because of the similarities in soil and plant community properties, heathlands are
2 discussed in this alpine and arctic tundra section. [Southon et al. \(2013\)](#) quantified plant
3 species richness at heathland sites in the U.K. along an N deposition gradient
4 (5.9–32.4 kg N/ha/yr) and observed declines in both vascular plant species richness and
5 bryophyte species richness. Similarly, [Armitage et al. \(2014\)](#) observed changes in plant
6 community composition and decreases in plant species richness in alpine heathlands
7 along an N deposition gradient of 0.6 to 39.6 kg N/ha/yr across the northern U.K.,
8 Iceland, Norway, and the Faroe Islands. Three studies quantified changes in lichen
9 species richness in alpine tundra ecosystems along atmospheric N deposition gradients in
10 northern Europe; two observed significant declines with increases in N deposition. At 15
11 of the U.K. alpine tundra sites surveyed by [Armitage et al. \(2014\)](#), [Mitchell et al. \(2016\)](#)
12 sampled soil microarthropods (oribatid, prostigmatid, and mesostigmatid mites, and
13 collembola). Across the gradient of sites, there was no direct influence of N deposition on
14 microarthropod community structure or the species richness, community composition, or
15 density for Collembola or any of the three groups of mites. However, N deposition
16 indirectly affected microarthropod communities by altering variables such as graminoid
17 cover, moss depth, moss cover, and plant biomass C:N ratio, all of which significantly
18 influenced microarthropod communities ([Mitchell et al., 2016](#)).

19 There has been a considerable amount of new research on the effects on added N plant
20 diversity in alpine meadows within the Tibetan Plateau region of China. In a
21 meta-analysis of N addition studies in this region, [Fu and Shen \(2016\)](#) found that N
22 additions decreased both plant species richness and plant diversity. [Song and Yu \(2015\)](#)
23 examined how different rates (3.75, 15, or 75 kg N/ha/yr) and chemical forms of N
24 ($[\text{NH}_4]_2\text{SO}_4$, NaNO_3 , or NH_4NO_3) additions over 8 years influenced plant diversity and
25 the stability of plant communities in alpine plant communities on the Tibetan Plateau in
26 China. Throughout the experiment, there were no effects of N form. The highest rate of N
27 addition decreased community stability (mean biomass/mean temporal standard
28 deviation), species richness, and the dominance of community composition by individual
29 species; other rates of N did not affect these metrics. Broadly, added N also increased the
30 temporal synchrony of species cover, meaning that there were stronger correlations
31 among species and functional groups in year-to-year variation in cover. This suggests that
32 N additions can decrease compensatory effects within plant communities, wherein one
33 species or functional group increases in cover during periods when others are exhibiting
34 decreased growth. Instead, the high N treatment increased the abundance of both of the
35 two dominant grass species. [Song and Yu \(2015\)](#) suggested that the reduction in
36 compensatory growth could result from decreased competition for N. As expected, there
37 was a strong correlation between log-transformed species variance in abundance and
38 log-transformed mean abundance, meaning that more abundant species were also more
39 variable in their abundance; this relationship was not affected by N additions. Notably,

1 there was no relationship between community stability and species richness. Although
2 this is unusual among studies of community stability and richness [e.g., ([Loreau and de](#)
3 [Mazancourt, 2013](#); [Tilman et al., 2006](#); [Steiner et al., 2005](#); [Tilman, 1996](#))], the high rate
4 of N addition caused the loss of only 2 of 20 species within these communities; neither
5 was a dominant species in the community. In comparison, 4 years of N additions
6 (100 kg N/ha/yr as NH₄NO₃) had no effect on plant species richness or diversity in a less
7 diverse (10–14 species) alpine meadow community on the Tibetan Plateau ([Zong et al.,](#)
8 [2016](#)).

9 Among studies of microbial diversity ([Table 6-19](#)), three studies ([Yuan et al., 2016](#);
10 [Farrer et al., 2013](#); [Nemergut et al., 2008](#)) investigated the effect of N additions in the
11 Rocky Mountains. [Farrer et al. \(2013\)](#) asked whether soil microbial changes were related
12 to the demonstrated decline in the abundance of the plant *Geum rossii* under increased N
13 deposition. Microbial community composition changed, but the influence of this change
14 on *G. rossii* was unclear. However, there was evidence that N additions imposed a
15 stronger physiological C limitation on *G. rossii*. [Nemergut et al. \(2008\)](#) also found shifts
16 in fungal and bacterial soil communities with chronic N additions (10 to 25 kg N/ha/yr
17 for >10 years). The fungal community shifted in response to N amendments, with a
18 decrease in the relative abundance of basidiomycetes. Bacterial community composition
19 also shifted in the N amended soil, with increases in the relative abundance of sequences
20 related to the Bacteroidetes and Gemmatimonadetes, and decreases in the relative
21 abundance of the Verrucomicrobia. [Yuan et al. \(2016\)](#) observed changes in bacterial
22 community composition after 20 years of N additions, with N additions increasing the
23 abundance of the phyla Chloroflexi and Bacteroidetes and N additions decreasing
24 Acidobacteria and Verrucomicrobia. Notably, forb biomass (but not grass biomass) was
25 positively correlated with bacterial diversity and bacterial richness covaried with plant
26 richness. Structural equation modeling revealed that the effects of N additions on
27 bacterial community composition were primarily indirect effects occurring via changes in
28 soil pH and forb biomass rather than direct effects of N availability ([Yuan et al., 2016](#)).

Table 6-19 Alpine and Arctic tundra microbial diversity responses to nitrogen added via experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Payne et al. (2012)	U.K.	Heathland (<i>Calluna vulgaris</i>)	Addition	10, 20, 40, 80, 120	11, 21	Amoeba community composition	Change

6.3.5. Grasslands

1 In the 2008 ISA, there was consistent and coherent evidence suggesting that N additions
2 reduced plant biodiversity in grasslands in the U.S. and Europe. In the U.S., [Clark and](#)
3 [Tilman \(2008\)](#) evaluated the effects of chronic N addition over 23 years in Minnesota
4 prairie grasslands and found species numbers declined at the lowest addition level
5 (10 kg N/ha/yr added to 6 kg N/ha/yr of ambient deposition). In the San Francisco Bay
6 area of California, exotic nitrophilous grasses displaced native grass species, likely due to
7 greater N availability from deposition—at the time approximately 10 to
8 15 kg N/ha/yr—and from the cessation of grazing, which previously exported N out of
9 the ecosystem ([Fenn et al., 2003b](#); [Weiss, 1999](#)).

10 In Europe, there were observations of N deposition-related declines in grassland plant
11 diversity in a variety of environments, including calcareous, neutral, and acidic soils,
12 species-rich heaths, and montane-subalpine grasslands ([Stevens et al., 2004](#); [Bobbink et](#)
13 [al., 1998](#); [Bobbink et al., 1992](#)). In a transect of 68 acidic grasslands across Great Britain
14 that covered a broad range of ambient N deposition (5 to 35 kg N/ha/yr), chronic N
15 deposition significantly decreased plant species richness ([Stevens et al., 2004](#)). Species
16 richness declined as a linear function of the rate of inorganic N deposition, with a
17 reduction of one species per 4-m² quadrant for every 2.5 kg N/ha/yr of chronic N
18 deposition ([Stevens et al., 2004](#)).

19 Although only a few studies had examined low levels of N inputs to grasslands in the
20 U.S. as of 2008, there were many that added higher levels of N ([Clark et al., 2007](#);
21 [Bradley et al., 2006](#); [Suding et al., 2005](#); [Gough et al., 2000](#)) and examined how N
22 enrichment interacted with other factors such as fire, elevated atmospheric CO₂, species
23 diversity, and climate change ([Zavaleta et al., 2003](#); [Reich et al., 2001](#); [Collins et al.,](#)
24 [1998](#)). These studies were not necessarily designed to simulate N deposition, rather their
25 focus was on nutrient limitation and what happened following the alleviation of this
26 limitation. Recent gradient studies and studies using low level N addition rates verify that
27 the direction of effect between low and high N input rates are similar. This suggests that
28 although the magnitude of effect depends on the level of input, the direction of effect
29 does not, and that nutrient enrichment in grasslands follows a general response. This
30 response includes increases in aboveground production, decreases in light availability at
31 the soil surface, changes in soil fauna, and increases in litter buildup, all of which can
32 lead to competitive displacement of slower growing and shorter plant species from either
33 shading and/or reduced recruitment and regrowth ([Hautier et al., 2009](#); [Bobbink et al.,](#)
34 [1998](#); [Tilman, 1993, 1987](#)).

1 In total, before 2008, large-scale biodiversity assessments across gradients of atmospheric
2 N deposition were restricted to Europe ([Stevens et al., 2004](#)). Although there was wide
3 evidence in the U.S. linking the composition of plant and microbial communities to N
4 availability, most of these experiments had been conducted using N addition rates
5 considerably exceeding observed atmospheric N deposition rates in the U.S.
6 [e.g., ([Bradley et al., 2006](#); [Suding et al., 2005](#))]. Experiments demonstrating the
7 sensitivity of grassland community composition to lower rates of N deposition were more
8 limited, with evidence for Mediterranean grasslands ([Weiss, 1999](#)) and a northern prairie
9 ecosystem ([Clark and Tilman, 2008](#)).

10 Since the 2008 ISA, research on the effects of anthropogenic N on biodiversity in
11 grassland ecosystems has expanded to include a wider range of organisms and
12 ecosystems and a further understanding of how added N (particularly at more realistic N
13 input rates) alters biodiversity, including the species and functional groups most
14 susceptible to increased N availability. Much of this new research has been conducted in
15 the U.S. (particularly at Cedar Creek in Minnesota) and in western Europe, but China has
16 also emerged as a center for research on the effects of excess N on grasslands.

17 As noted earlier, [Simkin et al. \(2016\)](#) quantified the effect of N deposition on species
18 richness in the continental U.S. using data from over 15,000 plots, including grassland
19 ecosystems. While Europe has several large-scale continental studies on the effects from
20 N deposition ([Stevens et al., 2010a](#); [Stevens et al., 2004](#)), this is the first study of its size
21 in the U.S. and provides a unique insight on the impacts from N deposition on U.S.
22 grassland ecosystems. In their analysis, [Simkin et al. \(2016\)](#) observed that at very low
23 rates of N deposition, increases in N deposition were associated with higher plant species
24 richness in open canopy ecosystems (e.g., grasslands, shrublands, and woodlands), but
25 species richness declined at N deposition rates above 8.7 kg N/ha/yr (5th–95th percentile:
26 6.4–11.3 kg N/ha/yr). Levels causing a decline in species richness are common across
27 much of the eastern and central U.S. and also occur near urban and intensive agricultural
28 areas in the West. Evidence of increases at low N input rates had not been observed
29 across N deposition gradients in Europe, likely due to higher historical deposition rates.
30 [Simkin et al. \(2016\)](#) also reported that the loss of species was strongly contingent on soil
31 pH, with more losses occurring in more acidic soils. Notably, the authors reported that
32 approximately 40% of grassland plots used for the study received N deposition at rates
33 above the threshold for declines in species richness.

34 A number of studies in Europe have built upon the work of [Stevens et al. \(2004\)](#) in
35 documenting N deposition impacts on grassland plant communities over long time
36 periods and/or large geographic areas, with these studies consistently indicating changes
37 in plant community composition and decreases in diversity as a result of N deposition

(see also [Appendix 5](#) for discussion). Changes in grassland plant diversity in the U.K. from N deposition have been particularly well documented. [Stevens et al. \(2010b\)](#) and [Maskell et al. \(2010\)](#) built on the work of [Stevens et al. \(2004\)](#) in the U.K., trying to identify whether changes in plant community composition caused by N deposition were the result of acidification or eutrophication. [Stevens et al. \(2010b\)](#) worked from the same 68 acidic grasslands in Great Britain as [Stevens et al. \(2004\)](#), but included more detailed information about soil pH and the sensitivity of individual plant species to pH and N availability. Based on these data, [Stevens et al. \(2010b\)](#) observed that N deposition mostly caused a shift toward more acid-tolerant species rather than nitrophilic species, suggesting that acidification is the primary impact of N deposition on acidic grassland plant communities. A broader analysis by [Maskell et al. \(2010\)](#), which expanded the work of [Stevens et al. \(2004\)](#) and [Stevens et al. \(2010b\)](#) beyond acidic grasslands to also include calcareous grasslands, heathlands, and mesotrophic grasslands—and also included direct soil measurements at a subset of these sites—also found that the primary link between N deposition and species loss was acidification in acidic grasslands and heathlands. However, eutrophication was the primary link between species loss and N deposition in calcareous grasslands ([Maskell et al., 2010](#)). Notably, species losses along the deposition gradient were smaller in calcareous ecosystems than in acidic ecosystems. In a similar assessment, [van Den Berg et al. \(2016\)](#) observed negative effects of N deposition on plant species richness in ecosystems across the U.K. (woodlands, heaths, bogs, and grasslands), with the exception of a positive effect of deposition on species richness in calcareous grasslands. [Henry et al. \(2011\)](#) used data from two national observation networks over Great Britain and found clear negative trends in plant species prevalence to increasing N in all acidic grassland habitats. [Field et al. \(2014\)](#) also expanded on the work of [Stevens et al. \(2004\)](#) by surveying a broader range of ecosystem types across the U.K.: acidic grasslands, bogs, upland and lowland heaths, and sand dunes. Higher N deposition was associated with decreases in species richness and changes in community composition across all ecosystem types. Among functional groups, N deposition decreased the diversity of mosses, lichens, forbs, and graminoids, but generally increased the cover of graminoids ([Field et al., 2014](#)). [van Den Berg et al. \(2016\)](#) found that N deposition increased the ratio of grass-to-forb species in some U.K. ecosystems (heathlands, bogs, acidic grasslands), but had the opposite effect in calcareous grasslands.

Similar results were observed at broader scales in Europe. Several studies surveyed 153 acidic grassland sites across northern and western Europe ([Pannek et al., 2015](#); [Stevens et al., 2011a](#); [Stevens et al., 2011b, 2010a](#)). These sites spanned a deposition gradient of 2 to 44 kg N/ha/yr, but the decreases in plant species richness were not linear and the highest rate of species loss occurred at deposition rates <20 kg N/ha/yr ([Stevens et al., 2010a](#)). Across the gradient, most of the decline in species richness was caused by

1 a loss of forb species, but grass and bryophyte species also declined ([Stevens et al.,](#)
2 [2010a](#)). As a fraction of total species richness, grass species richness increased and forb
3 species richness declined with increasing N deposition ([Stevens et al., 2011b](#)). Notably,
4 these changes occurred without consistent effects of N deposition on soil NO_3^- , soil
5 NH_4^+ , or tissue N concentrations in broadly sampled forb (*Galium saxatile*) and grass
6 (*Agrostis capillaris*) species, but both soil C:N and the foliar N concentration of a
7 bryophyte (*Rhytidiadelphus squarrosus*) were positively correlated with N deposition
8 ([Stevens et al., 2011b](#)). [Stevens et al. \(2011b\)](#) were able to explain 24% of the total
9 variation in plant species composition using climate, soil, and atmospheric deposition
10 metrics. Among this 24% of the total variation, soil variables (pH, aluminum
11 concentrations, C and N content) explained 38% of the variation and deposition
12 represented about 10% of this variation ([Stevens et al., 2011a](#)). This influence of
13 deposition on community composition was notably weaker than the relationship to
14 changes in species richness. A survey of 44 species in these grasslands found that the
15 presence of 16 species responded to N deposition, with 12 of these 16 species responding
16 negatively ([Pannek et al., 2015](#)). In the Atlantic region of France, [Gaudnik et al. \(2011\)](#)
17 observed that N deposition was one of the primary determinants of community
18 composition in acidic grasslands, even though the observed range of N deposition was
19 much smaller than in [Stevens et al. \(2004\)](#). [Dupre et al. \(2010\)](#) examined plant
20 community composition change in acidic grasslands in north-central Europe and the U.K.
21 over 70 years, dating back to 1939. Vegetation communities were differentiated
22 predominately according to soil pH, soil N availability, cumulative N deposition and S
23 deposition, and sampling date. Plot species richness declined through time for both
24 vascular plants and bryophytes, with cumulative N deposition identified as the primary
25 determinant of species loss.

26 While these N deposition gradient studies have provided strong documentation that
27 anthropogenic N pollution is altering biodiversity in grasslands in North America and in
28 Europe, experimental N addition studies have provided new information about the
29 mechanisms linking N deposition to shifts in community composition. For instance, using
30 grassland mesocosms in Switzerland receiving 150 to 200 kg N/ha/yr, [Hautier et al.](#)
31 [\(2009\)](#) conducted a unique experiment to understand the role of light competition in the
32 loss of species under conditions of high N availability. The addition of N increased
33 aboveground productivity and decreased both light availability near the ground surface
34 and species richness. An experimental increase in light availability caused by the use of
35 plant growth lights beneath the grassland canopy further increased productivity, but also
36 prevented the loss of plant species richness. Similarly, light competition was a
37 mechanism behind the negative effects of N deposition on species richness in grassland
38 sites in Israel ([Demalach et al., 2017](#)).

1 At Cedar Creek in Minnesota, [Reich \(2009\)](#) conducted a 10-year experiment where
2 grassland assemblages of 16 perennial species were grown under factorial combinations
3 of ambient and elevated CO₂ and ambient and elevated N. Increased N (40 kg N/ha/yr)
4 reduced species at both ambient and elevated CO₂, by 16 and 8%, respectively. The
5 reduced losses of biodiversity at higher CO₂ levels remains an active area of research but
6 is thought to be caused by greater soil water availability at higher CO₂ levels (from
7 reduced stomatal conductance) that reduced the competitive displacement with N
8 addition. An even longer experiment, 25 years, conducted at Cedar Creek and analyzed
9 by [Isbell et al. \(2013a\)](#) also demonstrated that N enrichment decreased the number of
10 plant species, and that over time, this effect became increasingly negative at all rates of N
11 addition. Moreover, species losses were nonrandom, with initially dominant native
12 perennial grasses becoming less dominant and then lost, and non-native perennial C3
13 grasses becoming increasingly dominant. Plot composition changed from a
14 high-diversity, native-dominated state (C4 grasses) to a low-diversity, non-native
15 dominated state (C3 grasses). Several earlier studies at this site also reported this general
16 effect ([Clark and Tilman, 2008](#); [Tilman, 1987](#)). Nine native species were particularly
17 susceptible to becoming locally extinct under chronic nutrient enrichment, including
18 initially dominant and initially rare species. All of the findings from this seminal
19 experiment in Cedar Creek, MN, are representative of terrestrial eutrophication, as
20 opposed to acidification, because these soils were limed to maintain a constant pH
21 ([Tilman, 1987](#)). However, there were no lime additions in the experiment conducted at
22 this site by [Reich \(2009\)](#), indicating that both terrestrial eutrophication and acidification
23 could be occurring in that experiment.

24 [Lan et al. \(2015\)](#) examined how N deposition altered spatial patterns in biodiversity and
25 species-area relationships by measuring plant species loss and species richness in a
26 grassland in Inner Mongolia in 14 different plot sizes ranging from 1 to 25 m². The
27 experiment included five levels of N addition between 17.5 and 280 kg N/ha/yr
28 (NH₄NO₃) for 10 years. Except for the 17.5 kg N/ha/yr treatment, N additions decreased
29 species richness. The absolute number of species lost versus the control group increased
30 rapidly as plot size increased from 1 to 8 m², but then stayed the same (high N doses) or
31 decreased (low N doses). However, the proportional loss of species decreased as plot size
32 increased, which allowed for predictions of critical loads for species loss at different plots
33 sizes: 11.4 kg N/ha/yr at 5 m² and 17.4 kg N/ha/yr at 25 m². A previous study at these
34 sites using 0.5-m² plots found a critical load of 8.5 kg N/ha/yr, indicating that species loss
35 as a consequence of N additions is sensitive to survey design.

36 Ecological theory suggests that plant diversity can be maintained by several factors,
37 including disturbance [e.g., ([Davis et al., 2000](#); [Mack et al., 2000](#); [Hobbs and Huenneke,](#)
38 [1996](#))]. Among grasslands, the managed reintroduction of some disturbances has been

1 proposed as a way of maintaining plant diversity in eutrophic ecosystems. In a California
2 serpentine grassland, ([Pasari et al., 2014](#)) examined the interactive effects of grazing and
3 simulated N deposition (80 kg N/ha total over 4 years) on native and exotic species
4 dynamics. With N additions, grazing helped maintain native species richness. High
5 grazing intensity decreased exotic plant cover, but only under ambient conditions ([Pasari
6 et al., 2014](#)). In a southern California coastal grassland, [Borer et al. \(2014\)](#) conducted
7 several nutrient enrichment experiments, two of which involved the addition of N (40 and
8 100 kg N/ha/yr). At the higher N level, species richness (forbs primarily) was reduced by
9 one species per 0.5 m² after 2 years. However, unlike in the work of [Pasari et al. \(2014\)](#),
10 this change in diversity was not affected by the presence of pocket gophers (*Thomomys
11 bottae*), a keystone herbivore that eliminated the effect of N on plant productivity. In an
12 annually burned Kansas tallgrass prairie, [McLaughlan et al. \(2014\)](#) analyzed a 27-year
13 record of plant community composition and N cycling. Despite rates of N deposition
14 (average 7 kg N/ha/yr) persistently within the range of critical loads for temperate
15 grasslands in the region, there was no evidence for increases in plant N concentrations,
16 decreases in forb diversity, or shifts in the relative abundance of dominant grass species.
17 The authors suggested that losses of N through frequent burning or grazing are sufficient
18 to prevent grassland eutrophication at low rates of N deposition.

19 There is also new evidence that N additions can alter flowering, seed production, and
20 seed abundance in grasslands. In Minnesota, [Hillerislambers et al. \(2009\)](#) developed a
21 statistical model to determine the effects of multiple global change factors, including N
22 deposition, on inflorescence mass. The effects of N deposition on seed production were
23 similar within functional groups and negatively correlated with aboveground
24 productivity: C3 grasses increased aboveground biomass and decreased seed production,
25 while C4 grasses decreased aboveground biomass and increased seed production. In a
26 greenhouse study of California oak savannah annual grasses, N additions (28 kg N/ha/yr
27 for 1 year) increased seed production (g/plant) by an invasive grass ([Tulloss and
28 Cadenasso, 2016](#)). In addition to seed production, the abundance of seed in soil seed
29 banks is important because seed banks help in revegetation following disturbances and
30 help maintain plant diversity, especially in small and isolated ecosystems ([Piessens et al.,
31 2004](#)). However, N impacts on grassland seed banks are not necessarily directly related to
32 changes in plant cover or flowering. [Basto et al. \(2015a\)](#) found that 13 years of simulated
33 N deposition at rates of 35 or 140 kg N/ha/yr decreased cover and flowering in only one
34 species (*Potentilla erecta*) in an acidic grassland in England, but total seed bank
35 abundance declined by 34 and 61% in the low and high N treatments, respectively.
36 Further, seed bank species richness declined by 29 and 41% in these treatments. Among
37 taxa, there were decreases of >50% in the seed bank abundance of forbs, sedges, and
38 grasses with the high N dose, but only a significant decrease (34%) in grass seed bank
39 abundance at the lower N dose. Seed banks were quantified again 4 years after the

1 cessation of N additions, but did not significantly recover in any metric of abundance,
2 richness, or composition.

3 The Park Grass Experiment in England is the longest ecological experiment in the world
4 and has examined the effect of various soil amendments, including N (96 kg N/ha/yr) as
5 $(\text{NH}_4)_2\text{SO}_4$ or NaNO_3 , on grassland productivity and composition since 1856. [Zhalnina et](#)
6 [al. \(2015\)](#) conducted 16S ribosomal RNA sequencing of soil samples from this
7 experiment to assess bacterial and archaeal community composition ([Table 6-20](#)). Soil
8 nitrate concentrations were positively correlated with the abundance of Thaumarchaeota
9 and Nitrospirae DNA, whereas total soil N was negatively correlated with Firmicutes,
10 Verrucomicrobia, and Chloroflexi. Multivariate analyses of community composition
11 found that the primary determinants of microbial community composition were soil pH
12 and C:N. Soil C:N was negatively correlated with Thaumarchaeota, Nitrospirae, and
13 Gemmatimonadetes, but positively correlated with Acidobacteria and Chlamydiae.
14 Changes in soil pH were a much larger control on microbial abundance, with significant
15 correlations with 17 of the 37 most abundant soil microbial genera. The two different
16 forms of N had different effects on pH, and unsurprisingly, different effects on microbial
17 community composition. Amendments of $(\text{NH}_4)_2\text{SO}_4$ decreased the phyla
18 Verrucomicrobia and Chloroflexi and the genera *Bradyrhizobium*, *Paenibacillus*, and
19 *Geobacter*, while NaNO_3 increased the abundance of the phyla Thaumarchaeota and
20 Nitrospirae and the genera *Geobacter*, *Candidatus*, *Nitrososphaera*, *Nitrospira*, and
21 *Methylibium*. In comparison, 27 years of N additions at Cedar Creek in Minnesota
22 changed bacterial composition ([Fierer et al., 2012](#); [Ramirez et al., 2010b](#)) but had no
23 effect on bacterial diversity [([Fierer et al., 2012](#)); [Table 6-20](#)].

Table 6-20 Grassland microbial diversity responses to nitrogen added via experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Ramirez et al. (2010b)	Minnesota (Cedar Creek)	Temperate grassland	Addition	30, 60, 100, 160, 280, 500, 800	27	Bacterial community composition	Change
Fierer et al. (2012)	Minnesota (Cedar Creek)	Temperate grassland	Addition	34, 272	27	Bacterial community composition	<u>Low dose</u> : not significant <u>High dose</u> : change
Fierer et al. (2012)	Minnesota (Cedar Creek)	Temperate grassland	Addition	34, 272	27	Bacterial diversity	Not significant
Wang et al. (2017d)	China (Inner Mongolia)	Steppe grassland	Addition	50, 100, 150	8+	Ratio of fungal to bacterial abundances	Declined
Zhalnina et al. (2015)	U.K.	Temperate grassland	Addition	96	153	Microbial community composition	Change
Daebeler et al. (2017)	Iceland	Subarctic grassland	Addition	100	5	Microbial community composition (archaeal ammonia-oxidizing communities)	Not significant

Table 6 20 (Continued): Grassland microbial diversity responses to nitrogen added via experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Wang et al. (2017d)	China (Inner Mongolia)	Steppe grassland	Addition	50, 100, 150	8+	Microbial composition (relative abundance of different microbial groups)	Change; Actinomycetes, Gram-negative bacteria, and arbuscular mycorrhizae declined; Gram-positive bacteria increased; no significant change in saprophytic fungi

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 Relative to forests, there is comparably little information on how N additions shift the
2 composition of mycorrhizal communities in grasslands ([Table 6-16](#)). In a steppe
3 grassland in China, [Chen et al. \(2014\)](#) observed that 6 years of N additions
4 (100 kg N/ha/yr) decreased the richness of arbuscular mycorrhizal phylotypes found in
5 the soil, but did not affect the diversity of soil phylotypes or alter the richness or diversity
6 of phylotypes observed in plant roots.

7 As with that of forests, some information is also available regarding the effects of N
8 additions on grassland soil fauna ([Table 6-17](#)). In particular, several studies have been
9 conducted on soil fauna and their role in soil food webs at Cedar Creek in Minnesota
10 ([Cesarz et al., 2015](#); [Eisenhauer et al., 2013](#); [Eisenhauer et al., 2012](#)). ([Eisenhauer et al.,](#)
11 [2012](#)) observed that the N deposition treatment at Cedar Creek (40 kg N/ha/yr)
12 significantly altered the abundance of 5 of 14 groups of soil biota. Simulated N
13 deposition decreased predaceous nematode abundance by 62%, but increased fungal
14 feeding nematodes by 206%. Nematode taxon richness and microarthropod taxon
15 richness declined by 7 and 15% under added N ([Eisenhauer et al., 2012](#)). A more detailed
16 analysis by [Cesarz et al. \(2015\)](#) found that N enrichment increased the density of the
17 plant-feeding Longidoridae nematode family by 148% and increased the density of a
18 rapidly growing guild of fungal-feeding nematodes, while a slower-growing guild of
19 predaceous nematodes declined ([Cesarz et al., 2015](#)). Overall, N additions increased
20 nematode community composition toward nematode guilds favored by decomposition
21 pathways dominated by fungi and away from bacterial-dominated decomposition
22 pathways ([Cesarz et al., 2015](#); [Eisenhauer et al., 2012](#)). However, while simulated N
23 deposition had significant effects on soil food webs, these influences were weaker than
24 the direct effects caused by differences in plant diversity ([Eisenhauer et al., 2013](#)).

6.3.6. Arid and Semiarid Ecosystems

25 As of the 2008 ISA, there was consistent and coherent evidence of altered plant
26 communities in N addition experiments in arid and semiarid ecosystems, particularly
27 within CSS and chaparral ecosystems along the southern California coast and in portions
28 of the Mojave Desert near large population centers. There was further additional evidence
29 about shifts in plant and microbial community composition from N addition experiments
30 in the Mojave, Chihuahuan, Sonoran, and Great Basin Deserts. Although many of these
31 ecosystems are relatively remote and lightly impacted by anthropogenic N deposition, the
32 2008 ISA noted that deposition to some arid and semiarid ecosystems can be high
33 downwind of major urban and agricultural areas, reaching more than 30 kg N/ha/yr in
34 areas of southern California ([Fenn et al., 2003b](#)). Like other terrestrial ecosystems, there
35 was widespread evidence that N additions altered plant communities by causing a

1 differential stimulation of growth among plant species ([Báez et al., 2007](#); [Inouye, 2006](#)),
2 such as by favoring rapidly growing nitrophilous species ([Fenn et al., 2003b](#)). In addition
3 to these effects on plant communities, [Egerton-Warburton and Allen \(2000\)](#) found a shift
4 in arbuscular mycorrhizal community composition with decreased species richness and
5 diversity along an N deposition gradient among CSS ecosystems in southern California (2
6 to 57 $\mu\text{g N/g}$ as soil NO_3^-). These shifts in mycorrhizal fungal communities may facilitate
7 replacement of native plant communities by exotic annual grasslands.

8 There are two ecological interactions that are particularly important controlling how N
9 deposition influences plant community composition in arid and semiarid ecosystems:
10 (1) the strong dependence of biological responses on an adequate water supply and
11 (2) the ability of N deposition to promote the growth of exotic plants [particularly annual
12 grasses; ([Brooks, 2003](#))], which can dramatically alter the fire cycle by providing a more
13 spatially continuous fuel supply ([Brooks et al., 2004](#)). The fire cycle impacts of increased
14 invasive grass biomass were particularly apparent in southern California in CSS
15 ecosystems near the coast and in Mojave Desert ecosystems inland ([Brooks et al., 2004](#);
16 [Brooks and Esque, 2002](#); [Cione et al., 2002](#); [Yoshida and Allen, 2001](#); [Brooks, 1999](#);
17 [Eliason and Allen, 1997](#)). Fire was relatively rare in the Mojave Desert until the past two
18 decades, but fire now occurs frequently in areas that have experienced invasion of exotic
19 grasses ([Brooks, 1999](#)). These interactions are apparent in an NH_4NO_3 addition
20 (32 kg N/ha/yr) study in the Mojave Desert of southern California conducted by [Brooks](#)
21 ([2003](#)). In the second and wetter year of the experiment, N additions decreased species
22 richness among native annual plants ([Brooks, 2003](#)). Overall, N additions increased the
23 growth of the invasive grass compact brome (*Bromus madritensis*) beneath the dominant
24 native shrub creosote bush (*Larrea tridentata*) and increased the growth of invasive
25 grasses in the genus *Schismus* and the invasive forb *Erodium cicutarium* in the
26 interspaces between *Larrea* shrubs, creating a more continuous fuel bed.

27 Since the 2008 ISA, a number of new N addition experiments and ambient N deposition
28 gradient studies on shifts in plant community composition and diversity have been
29 conducted, primarily in California and in arid portions of China ([Table 6-21](#)). Broadly,
30 while some of these studies found decreases in plant species richness [e.g., ([Sun et al.,](#)
31 [2014](#); [Allen et al., 2009](#))], there were more frequent observations of changes in plant
32 community composition. This disparity may be a function of both the relative brevity of
33 these experiments (mostly 2 to 4 years) and the strong moisture limitation that constrains
34 biological responses to added N in these ecosystems.

Table 6-21 Arid and semiarid ecosystem plant diversity responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Rao et al. (2009)	California (Joshua Tree NP)	Creosote bush (<i>Larrea tridentata</i>) or pinyon-juniper woodland (<i>Pinus monophylla</i> , <i>Juniperus californica</i>)	Ambient	2.7–14.4	n/a	Invasive annual grass cover	Increase
Allen et al. (2009)	California (Joshua Tree NP; four sites)	Creosote Bush (<i>Larrea tridentata</i>) scrub; pinyon-juniper woodland (<i>Pinus monophylla</i> , <i>Juniperus californica</i>)	Addition	5, 30	2	Native plant species richness	<u>Low dose</u> : not significant <u>High dose</u> : not significant at two sites, increase at one site, decrease at one site
Vourlitis (2017)	California (southern, coastal)	Coastal sage scrub (<i>Artemisia californica</i> , <i>Salvia mellifera</i>)	Addition	50	13	Native and exotic plant species cover	Increase in the native shrub <i>Artemesia californica</i> in the 4th and 5–9th yr of the 13-yr experiment; decrease in the native shrub <i>Salvia mellifera</i> in the 4th and 11–13th yr; increase in the exotic plant <i>Brassica nigra</i> in the 11–13th yr
Vourlitis and Pasquini (2009)	California (southern coastal)	Coastal sage scrub (<i>Artemisia californica</i> , <i>Salvia mellifera</i>)	Addition	50	5	Plant community composition	Change
Vourlitis and Pasquini (2009)	California (southern coastal)	Chaparral (<i>Adenostoma fasciculatum</i> , <i>Ceanothus greggii</i>)	Addition	50	5	Plant community composition	Not significant

Table 6 21 (Continued): Arid and semiarid ecosystem plant diversity responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Pasquini and Vourlitis (2010)	California (southern; three sites)	Chaparral (<i>Adenostoma fasciculatum</i> , <i>Ceanothus</i> spp.)	Ambient	8.1, 11.9, 18.4	n/a	Plant community composition	Change
Concilio and Loik (2013)	California (Great Basin)	Cheatgrass (<i>Bromus tectorum</i>) in sagebrush (<i>Artemisia tridentata</i>) steppe	Addition	50	4	Plant community composition	Not significant
Cox et al. (2014)	California (southern coastal)	Coastal sage scrub	Ambient	5.7–23.8	n/a	Plant community composition	More invasive grasses when N deposition >11 kg N/ha/yr
Ochoa-Hueso and Stevens (2015)	Spain	Shrubland (<i>Quercus coccifera</i> , <i>Rosmarinus officinalis</i> , <i>Lithodora fruticosa</i>)	Addition	10, 20, 50	3	Plant community composition	Change
Zhang et al. (2015b)	China (north, Songnen)	Alkaline grassland (<i>Leymus chinensis</i> , <i>Kalimeris integrifolia</i>)	Addition	100	4	Plant community composition	Change
Collins et al. (2017)	New Mexico	Grassland (<i>Bouteloua eriopoda</i> , <i>Bouteloua gracilis</i>)	Addition	20	1 to 7	Plant community composition	Change in 3 of the 4 yr following fire; not significant in 2 yr preceding fire and last year of the experiment
McHugh et al. (2017)	Utah	Semiarid grassland	Addition	2, 5, 8	2	Plant community composition	Not significant
Zhang et al. (2015b)	China (north, Songnen)	Alkaline grassland (<i>Leymus chinensis</i> , <i>Kalimeris integrifolia</i>)	Addition	100	4	Plant community evenness	Not significant
Zhang et al. (2014)	China (north, Inner Mongolia)	Alkaline grassland (<i>Leymus chinensis</i> , <i>Stipa grandis</i>)	Addition (2 or 12 additions/yr)	10, 20, 30, 50, 100, 150, 200, 500	5	Plant species diversity	Decrease (stronger decrease with two additions/yr)

Collins et al. (2017)	New Mexico	Grassland (<i>Bouteloua eriopoda</i> , <i>Bouteloua gracilis</i>)	Addition	20	1 to 7	Plant species richness for grasses and forbs	Not significant

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; NP = national park; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 Within southern California, there was a continued research focus on how N deposition
2 alters the abundance of invasive annual plants (particularly grasses) in CSS, chaparral,
3 and Mojave Desert ecosystems ([Cox et al., 2014](#); [Pasquini and Vourlitis, 2010](#); [Allen et
4 al., 2009](#); [Rao et al., 2009](#); [Vourlitis and Pasquini, 2009](#); [Talluto and Suding, 2008](#)).
5 Among inland ecosystems, [Allen et al. \(2009\)](#) added N (5 and 30 kg N/ha/yr for 2 years)
6 to four sites at Joshua Tree National Park (JOTR) in California and found that the effects
7 of added N on native plant diversity depended on the abundance of invasive grasses. At
8 one site where invasive grass biomass (primarily *Bromus madritensis*) was high and
9 responded positively to added N, N additions decreased native forb species richness; at a
10 site where invasive grasses were a small component of the plant community, N additions
11 increased native forb cover and species richness. Given that [Rao et al. \(2009\)](#) found
12 greater invasive annual grass cover at sites with higher N deposition across a 16-site N
13 deposition gradient in the JOTR area, the results of [Allen et al. \(2009\)](#) imply that N
14 deposition may be decreasing native forb richness across broad areas in the JOTR area.

15 Near the southern California coast, [Vourlitis and Pasquini \(2009\)](#) investigated the effects
16 of dry-season N addition in chaparral (dominated by the shrubs *Adenostoma fasciculatum*
17 and *Ceanothus greggii*) and CSS (dominated by the shrubs *Artemisia californica* and
18 *Salvia mellifera*) stands over a 5-year period. The additional N (50 kg N/ha/yr)
19 significantly altered the community composition of CSS, but not chaparral. The
20 differences in CSS community composition were due to changes in the relative
21 abundance of dominant shrubs, not herbaceous plant species. This is not necessarily
22 consistent with previous research, including observations that although both native shrubs
23 and invasive annual plants can exhibit faster growth rates with added N, high N
24 availability can cause mortality in native shrubs ([Allen et al., 1998](#)). [Talluto and Suding
25 \(2008\)](#) revisited 232 plots in southern California that had been dominated by CSS
26 vegetation during a 1930s vegetation survey and found that CSS cover had declined by
27 49%, and only 15% of the 1930s CSS plots lacked invasive annual grasses. At a
28 landscape scale, the conversion of CSS to invasive-dominated land was positively related
29 to N deposition rates and fire frequency, which itself has been linked to N deposition. In
30 another landscape-level analysis of vegetation change since the 1930s, [Cox et al. \(2014\)](#)
31 observed that CSS converted to non-native grasslands when N deposition was greater
32 than 11 kg N/ha/yr, more consistent with the previous results. Also in southern
33 California, [Pasquini and Vourlitis \(2010\)](#) found evidence that N deposition caused
34 changes in chaparral plant community composition in recently burned ecosystems, but
35 the influence of N deposition in this study was confounded by changes in other
36 environmental factors across the three-site N deposition gradient (8.1 to 18.4 kg N/ha/yr)
37 used for this research.

1 Elsewhere in California, [Concilio and Loik \(2013\)](#) studied the effects of added N
2 (50 kg N/ha/yr for 4 years) on sagebrush steppe ecosystems in the eastern Sierra Nevada
3 where the invasive annual grass *Bromus tectorum* was beginning to establish. Although N
4 addition treatments increased plant available N and total N, no changes were observed in
5 cover, community composition, or richness of native or invasive species. *Bromus*
6 *tectorum* cover was inversely related to native forb species richness, but increased N
7 deposition did not affect plant diversity. However, [Concilio and Loik \(2013\)](#) cautioned
8 that precipitation was below average during the study and N additions may have different
9 effects when moisture availability is greater.

10 Several notable N addition studies have been conducted in the arid steppe grassland and
11 shrubland ecosystems in northern and western China. [Zhang et al. \(2014\)](#) studied whether
12 the frequency of additions (12 doses/year vs. 2 doses/year) altered the effect of added N
13 on plant diversity in a steppe grassland in the Inner Mongolia region of China (eight
14 levels from 10 to 500 kg N/ha/yr as NH_4NO_3 for 5 years). Species richness declined by
15 about 50% as N addition rates increased; plant diversity also decreased more with higher
16 N addition rates. [Zhang et al. \(2014\)](#) noted that the declines in diversity and richness were
17 smaller with the smaller frequent N doses than with the large infrequent doses, and
18 suggested that this implied that some N addition studies may be overestimating the
19 negative effects on plant biodiversity. However, at the lower N addition rates (10, 20, and
20 30 kg N/ha/yr) that are more relevant to N deposition levels in the U.S., the effects of
21 dose frequency were not consistently observed; species richness was sometimes
22 (nonsignificantly) higher with the large infrequent doses at these N addition rates. The
23 frequency of N additions did not impact the rate of species loss in perennial forbs, but did
24 affect the rate of species loss in grasses and annual and biennial forbs. Notably, N
25 additions were associated with significant decreases in soil temperature, soil moisture,
26 and soil pH and increases in NH_4^+ and NO_3^- . All of these soil changes were correlated
27 with each other and the proportional changes in each of these variables were correlated
28 with the proportional loss in species richness. Among these soil traits, higher N addition
29 frequency increased NH_4^+ , but had no other significant effects. In subsequent research at
30 these sites, [Zhang et al. \(2016b\)](#) observed that the lower plant species richness in the low
31 frequency N addition plots relative to the high frequency plots was not caused by
32 differences in the rate of species loss, but instead resulted from slower colonization by
33 new species in the plots that received large infrequent N additions. In another experiment
34 in semiarid Chinese steppe grasslands, [Li et al. \(2016a\)](#) observed that N additions (50,
35 100, 150 kg N/ha/yr for 8 years) decreased species richness, decreased diversity, and
36 altered community composition for both plant and bacterial communities and that
37 changes in plant and microbial communities were significantly correlated. [Li et al.](#)
38 [\(2016a\)](#) also observed that N additions decreased both plant and microbial species

1 richness and altered microbial community composition in a semiarid Chinese steppe
2 grassland.

3 A recent study by [Tian et al. \(2016b\)](#) examined how N addition at several rates affected
4 grassland structure and function in the temperate steppe of China (20, 40, 80, 160,
5 320 kg N/ha/yr). They found that N addition led to increases in aboveground biomass and
6 to shifts in relative abundance from forbs to grasses even at the lowest input rate, as
7 reported in other studies. However, they reported a novel mechanism related to
8 manganese (Mn) toxicity to explain reductions in forb diversity that had not been
9 demonstrated before, but had been reported in forestry literature ([St.Clair et al., 2008](#);
10 [St.Clair and Lynch, 2005](#)). They reported that forbs were much more prone to Mn
11 toxicity than grasses following N addition because of physiological differences in root
12 enzymes associated with metal uptake. Manganese accumulated more in forbs than
13 grasses, leading to decreased forb photosynthetic rates and shifts in relative abundances
14 towards grasses. It is unknown whether this mechanism is operating in other grassland
15 systems.

16 In an arid steppe grassland in northeastern China, [Sun et al. \(2014\)](#) observed that N
17 additions of 23, 46, 69, and 92 kg N/ha/yr (3 years, as urea) caused proportional
18 decreases in forb species richness, but found added N caused soil bacterial communities
19 to become more diverse except at the highest N dose ([Table 6-22](#)). [Huang et al. \(2015\)](#)
20 conducted a 3-year N × water experiment focused on soil microbial community
21 composition in a desert steppe ecosystem in northwestern China that receives
22 25 kg N/ha/yr of ambient deposition. The N addition treatment (50 kg N/ha/yr as
23 NH₄NO₃) effects on microbial composition differed between inter-plant and beneath
24 shrub sites. In the interspaces, N additions increased the portion of bacteria in total
25 microbial biomass in all 3 years and increased actinobacteria in the last 2 years of the
26 experiment. Beneath the shrubs, N additions broadly suppressed microorganisms in all
27 domains. In the Sonoran Desert near Phoenix, [Marusenko et al. \(2015\)](#) found that
28 although N additions (60 kg N/ha/yr for 8 years) increased the abundance of the *amoA*
29 gene (needed for ammonia oxidation) in both archaea and bacteria, the community
30 composition of ammonia-oxidizing microorganisms was unaffected.

31 In Mediterranean shrublands in Spain, N additions (10, 20, and 50 kg N/ha/yr for 4 years)
32 increased the abundance of Collembola, which were a dominant component (44%) of the
33 soil fauna. The N additions did not significantly affect soil fauna richness or diversity, but
34 there was a significant negative relationship between richness and soil C:N ratio and a
35 positive relationship between diversity and soil pH ([Ochoa-Hueso et al., 2014](#)).

Table 6-22 Arid and semiarid ecosystem microbial diversity responses to nitrogen added via experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Marusenko et al. (2015)	Phoenix, AZ	Creosote and bursage shrublands (<i>Larrea tridentata</i> , <i>Ambrosia</i> spp.)	Addition	60	8	Archaeal and bacterial <i>amoA</i> (NH ₃ mono-oxygenase) community composition	Not significant

6.3.7. Lichens

1 In the 2008 ISA, there was consistent and coherent evidence indicating that lichen
2 communities were affected by current levels of N deposition. Lichen community
3 composition is highly sensitive to atmospheric pollution from N and S ([Jovan, 2008](#)).
4 Based on the widely recognized sensitivity of lichen species to air pollution, [Geiser and](#)
5 [Neitlich \(2007\)](#) developed a model to assess local air quality in Pacific Northwest forests
6 based on lichen community composition. In addition to being good subjects for
7 biomonitoring, lichens constitute important components of the forest ecosystem by
8 contributing to biodiversity, regulating nutrient and hydrological cycles, and providing
9 habitat elements for wildlife ([McCune and Geiser, 1997](#)). The composition of the lichen
10 community is important because individual species have different physical and
11 physiological traits, and thus make particular contributions to the provisioning of
12 ecosystem services.

13 Lichens containing a cyanobacterial photobiont appear to be more sensitive to adverse
14 effects from atmospheric N deposition than most other lichens ([Hallingbäck and Kellner,](#)
15 [1992](#); [Hallingbäck, 1991](#)). In central Europe, [Hauck and Wirth \(2010\)](#) analyzed
16 514 lichen species and found that shade-adapted lichen species are nearly universally
17 intolerant of high rates of N deposition. Nearly all of these shade-tolerant and
18 pollution-sensitive species are crustose lichens ([Hauck and Wirth, 2010](#)). The decline of
19 lichens containing cyanobacteria in parts of northern Europe has been associated with N
20 deposition in the range of 5 to 10 kg N/ha/yr ([Bobbink et al., 1998](#)). In Sweden, the
21 probability of occurrence for three genera of hair lichens (*Alectoria*, *Bryoria*, *Usnea*) on
22 Norway spruce (*Picea abies*) in forest inventory plots peaked at 3–6 kg N/ha/yr of
23 deposition and then rapidly declined; N deposition was the strongest or second-strongest
24 environmental predictor of lichen occurrence ([Esseen et al., 2016](#)). In the U.S., lichen
25 species are negatively affected by N inputs as low as 3 to 8 kg N/ha/yr ([Fenn et al.,](#)
26 [2003a](#)).

27 In the San Bernardino Mountains, CA, up to 50% of lichen species that occurred in the
28 region in the early 1900s have disappeared ([Fenn et al., 2003a](#); [Nash and Sigal, 1999](#)). In
29 mixed conifer forests in California, the critical load for lichen communities has been
30 estimated at 3.1 kg N/ha/yr ([Fenn et al., 2008](#)). Compared to California, air pollution has
31 historically been less problematic in the Pacific Northwest and this region still has large
32 populations of pollution-sensitive lichens ([Jovan, 2008](#); [Fenn et al., 2003a](#)). [Jovan \(2008\)](#)
33 reported that hotspots for lichen diversity in the U.S. include Klamath-Siskiyou region
34 along the Oregon-California border, the Okanogan highlands region in northeastern
35 Washington, and the Blue Mountains in eastern Oregon—all areas that are relatively
36 distant from large human population centers and industrial centers. However, lichen

1 communities in the Pacific Northwest are beginning to show evidence of changes in
 2 response to increased N pollution, including decreased distribution of sensitive lichen
 3 taxa and their replacement with nitrophilous species ([Geiser and Neitlich, 2007](#)).

4 Research on lichens since 2008 continues to indicate that lichen communities change in
 5 response to increased atmospheric N, in both U.S. and Europe. Unlike most other N
 6 deposition biodiversity studies, lichen research has been dominated by studies using
 7 measurements along ambient N deposition gradients rather than using experimental N
 8 additions ([Table 6-23](#)). Within the U.S., there are numerous examples of shifts in lichen
 9 community composition along gradients of atmospheric N deposition. Lichen community
 10 composition has been quantified in many parts of the U.S. as part of the U.S. Department
 11 of Agriculture Forest Service’s Forest Inventory and Analysis (FIA) program. [Jovan](#)
 12 [\(2008\)](#) reported the results from surveys of almost 800 plots conducted from 1998 to
 13 2003 in California, Washington, and Oregon, documenting clear shifts in lichen
 14 community composition in forests in and around areas of intensive agricultural and
 15 industrial production in the Central Valley of California, the Willamette Valley in
 16 Oregon, and the Puget Trough (Seattle/Tacoma/Olympia) in Washington. In the
 17 northeastern U.S., [Will-Wolf et al. \(2015\)](#) analyzed approximately 600 plots of survey
 18 data collected in the 1990s and 2000s as part of the FIA program and from other sources.
 19 These data showed strong relationships between total N deposition and decreased lichen
 20 abundance, reduced species richness, and altered community composition, but the high
 21 overlap between N deposition and acidifying deposition in this region made it difficult to
 22 discern the primary influence on lichen biodiversity.

Table 6-23 Lichen biodiversity responses to nitrogen added via atmospheric deposition or experimental treatments.

Reference	Study Location	Vegetation	Ambient Deposition or Addition	Nitrogen Addition Rate (kg N/ha/yr or as Otherwise Noted)	Duration (yr)	Endpoint	Effect of Additional Nitrogen
Jovan (2008)	California, Oregon, Washington	Forest	Ambient	0.5–21	n/a	Community composition	Change
Rogers et al. (2009)	Utah and Idaho	Aspen forests (<i>Populus tremuloides</i>)	Ambient (NH ₃ gas)	7.3–92.2 μm/m ³	n/a	Community composition	Change
Geiser et al. (2010)	Oregon and Washington	Conifer forests	Ambient	0.8–8	n/a	Community composition	Change

Will-Wolf et al. (2015)	North-eastern U.S.	Forests	Ambient	Not stated	n/a	Species richness	Decrease

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; NH₃ = ammonia; NO₂ = nitrogen dioxide; ppb = parts per billion; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

1 Other surveys of lichen community composition in the U.S. also documented changes
 2 even at relatively low rates of N deposition. For instance, lichen community composition
 3 in southeastern Alaska shifted toward more eutrophic species along an N deposition
 4 gradient of 0.05 to 1.05 kg N/ha/yr ([Schirokauer et al., 2014b](#)). In the northern Rockies,
 5 [McMurray et al. \(2015\)](#) observed a shift in lichen community composition at deposition
 6 rates greater than 4.0 kg N/ha/yr. In montane aspen forests in the Utah-Idaho border
 7 region, [Rogers et al. \(2009\)](#) observed a shift in lichen community composition away from
 8 nitrophilous species along a NH₃ concentration gradient away from urban and
 9 agricultural sources. In the Los Angeles Basin area of California, [Jovan et al. \(2012\)](#)
 10 documented increases in the abundance of eutrophic lichen species along a gradient of N
 11 deposition. In coniferous forests in the Pacific Northwest, shifts in lichen community
 12 composition and declines in oligotrophic lichen species were observed as N deposition
 13 increased to levels from 3 to 9 kg N/ha/yr range ([Geiser et al., 2010](#); [Glavich and Geiser,
 14 2008](#)).

15 Outside of the U.S., changes in lichen community composition have been observed in
 16 Canada and in Europe. In the U.K., [Southon et al. \(2013\)](#) and [Field et al. \(2014\)](#) observed
 17 decreased lichen species richness in over 50 heathland survey locations along an N
 18 deposition gradient of 5.4 to 32.4 kg N/ha/yr. However, [Armitage et al. \(2014\)](#) did not
 19 find a significant change in lichen species richness along an N deposition gradient of 0.6
 20 to 39.4 kg N/ha/yr in alpine heathlands in the North Atlantic region of Europe. In
 21 Sweden, [Johansson et al. \(2012\)](#) found additions of 6 kg N/ha/yr, applied directly onto
 22 trees in a liquid spray, in old growth boreal spruce forests changed the species
 23 composition of epiphytic lichen communities and reduced species richness. [Gibson et al.
 24 \(2013\)](#) also noted that in Cape Breton Highlands National Park in Nova Scotia, the
 25 number of pollutant-intolerant lichen species decreased from 10 to 5 when summer and
 26 winter atmospheric NO₂ concentrations increased to 0.46 and 0.15 ppb, respectively.
 27 [McDonough and Watmough \(2015\)](#) were unable to detect an influence of N deposition

1 on epiphytic foliose lichen species richness across a network of 40 sugar maple forest
2 monitoring plots across Ontario, Canada. However, study sites in areas with a history of
3 intense industrial activity tended to have very low epiphytic foliose lichen species
4 richness.

6.3.8. Most Sensitive Ecosystems

5 The 2008 ISA reported that the most responsive ecosystems to N enrichment from
6 atmospheric N deposition were those that receive high levels of N loading, are N limited,
7 or contain species that have evolved in nutrient-poor environments. Species adapted to
8 low N supply are readily outcompeted by species that have higher N demand when the
9 availability of N is increased ([Krupa, 2003](#); [Tilman and Wedin, 1991](#); [Aerts et al., 1990](#)).
10 As a consequence, some native species can be eliminated by N deposition ([Stevens et al.,](#)
11 [2004](#); [Falkengren-Grerup, 1989, 1986](#); [Roelofs, 1986](#); [Ellenberg, 1985](#)).

12 Unlike the case of acidifying deposition where ecosystem sensitivity is tied principally to
13 underlying geology, most terrestrial ecosystems are N limited and, therefore, sensitive to
14 perturbation caused by N additions ([LeBauer and Treseder, 2008](#)). Consequently, little
15 was known in the 2008 ISA about the full extent and distribution of the terrestrial
16 ecosystems in the U.S. most sensitive to adverse impacts caused by atmospheric N
17 deposition. Effects were most likely to occur where areas of relatively high atmospheric
18 N deposition intersect with N limited plant communities. The factors governing the
19 sensitivity of terrestrial ecosystems to nutrient enrichment from N deposition include the
20 degree of N limitation, rates of N deposition, elevation, species composition, length of
21 growing season, and soil N retention capacity. Thus, ecosystems such as alpine tundra,
22 which are typically strongly N limited, contain vegetation adapted to low N availability,
23 often have thin soils with limited N retention capacity, and have short growing seasons,
24 can be particularly sensitive to N deposition. Similarly, the ability of atmospheric N
25 deposition to override the natural spatial heterogeneity in N availability in arid
26 ecosystems, such as the Mojave Desert and CSS ecosystems in southern California,
27 makes these ecosystems more prone to wildfires and sensitive to N deposition.

28 In the 2008 ISA, effects on individual plant species had not been well studied in the U.S.
29 More was known about the sensitivity of particular plant communities, based largely on
30 results obtained in more extensive studies conducted in Europe, which included
31 hardwood forests, alpine meadows, arid and semiarid lands, and grassland ecosystems.
32 Among communities sensitive to N deposition, lichens and ectomycorrhizal fungi have
33 particularly low thresholds for effects (see [Appendix 6.5.1](#) and [Appendix 6.5.2](#)). Thus,
34 the ecosystems containing a large number and/or diversity of these organisms, such as

1 temperate and boreal forests and alpine tundras, could be considered particularly sensitive
2 to N deposition. More broadly, there has been substantial work on critical loads for N in
3 U.S. ecoregions since the 2008 ISA (see [Appendix 6.5](#)), creating an improved
4 understanding of which processes, taxa, and regions are sensitive to N deposition
5 impacts.

6.4. Climate Modification of Ecosystem Nitrogen Response

6 Biotic responses to N deposition can be modified by climatic shifts in temperature and
7 precipitation. [Appendix 13](#) provides an overview of this topic, whereas this section
8 describes in brief some of the climate modifications specific to the N response of
9 terrestrial ecosystems, particularly plant productivity and diversity. Shifts in temperature
10 and precipitation can alter the effects of N deposition on these two endpoints, as well as
11 the N response of microbial communities.

12 Temperature and precipitation can interact with N to affect plant productivity. As noted
13 in [Appendix 6.2](#), [Xia and Wan \(2008\)](#) identified almost 1,600 observations of plant
14 biomass growth in response to N additions, excluding agricultural and horticultural
15 species ([Figure 6-1A](#)). They found that biomass responses to N increased linearly with
16 mean annual precipitation (MAP). [LeBauer and Treseder \(2008\)](#) had a considerably
17 smaller data set ($n = 126$) than [Xia and Wan \(2008\)](#) and did not find that MAP, mean
18 annual temperature (MAT), or latitude had significant overall influences on
19 responsiveness of NPP to added N. However, within individual biomes, forest and tundra
20 NPP responses to N increased with MAT, and forests also became more responsive with
21 greater MAP. In general, as precipitation increases, water limitation to plant productivity
22 is relieved, allowing vegetation to be more responsive to changes in N.

23 As also described in [Appendix 6.2](#), [Tian et al. \(2016a\)](#) developed a “N response
24 efficiency” metric ($100\% \times (\text{ANPP}_{\text{treatment}} - \text{ANPP}_{\text{control}}) / \text{ANPP}_{\text{control}} / \text{N addition rate}$) in
25 order to examine how plant growth responses per unit N changed with increasing levels
26 of N. They found N response efficiency significantly changed with environmental
27 factors. Response efficiency decreased with soil pH and total soil N concentration, and
28 increased with soil C:N ratios and with precipitation until annual precipitation reached
29 800 mm/year. The N response efficiency also peaked with moderate annual temperatures
30 ($\sim 8^\circ\text{C}$) and declined under cooler or warmer conditions ([Tian et al., 2016a](#)).

31 Not surprisingly, climate modification of plant productivity responses can be particularly
32 pronounced in drier ecosystems. In the Sonoran Desert near Phoenix, [Hall et al. \(2011\)](#)
33 added 60 kg N/ha/yr and found little or no increase in production among herbaceous
34 annuals in low precipitation years, moderate N responses with average rainfall, and

1 strong increases in biomass with added N during above-normal rainfall seasons. [Vourlitis](#)
2 [\(2012\)](#) measured aboveground biomass and litter production in a mature CSS stand in
3 southern California over an 8-year period. The effect of added N positively correlated
4 with precipitation and was only significant in the high rainfall years. Similarly, [Zhang et](#)
5 [al. \(2015e\)](#) observed greater plant productivity responses to N in years with higher
6 precipitation in a steppe grassland in Inner Mongolia.

7 In addition to shifts in plant productivity, plant diversity can also be affected by the
8 interactions of temperature, precipitation, and N ([Porter et al., 2013](#)). In their
9 national-scale analysis of herbaceous species richness, [Simkin et al. \(2016\)](#) found that
10 temperature and precipitation could moderate N effects in some instances. They did not
11 observe a significant interaction between N and temperature or precipitation on plant
12 species richness for closed canopy systems (deciduous, evergreen, and mixed forests), but
13 did in open canopy systems (grasslands, shrublands, and woodlands). In these open
14 canopy ecosystems, they found that N had a more negative effect on species richness at
15 lower temperatures. This finding is consistent with [Clark et al. \(2007\)](#) who also found a
16 small increase in the risk of species loss with lower annual minimum temperatures,
17 among other factors. Even though the overall effects within closed systems were not
18 significant, [Simkin et al. \(2016\)](#) also analyzed smaller regional forest gradients
19 dominated by maple-birch (*Acer-Betula*), white oak (*Quercus alba*), or Douglas-fir
20 (*Pseudotsuga menziesii*) trees. At this scale, the threshold for negative deposition effects
21 tended to be lower (7.5–9.5 kg N/ha/yr), and the negative effects of N deposition on
22 species richness were greatest when temperature and precipitation were high.

23 Some studies have explored these interactive effects under future climatic and N
24 scenarios. In ForSAFE-VEG model projections of plant community composition in three
25 French forests, two N reduction scenarios—the maximum feasible N emission reductions
26 scenario and the current European legislation scenario for reactive N emissions
27 rates—resulted in gradual shifts over the next 90 years back toward the plant community
28 composition observed at the beginning of the 20th century ([Rizzetto et al., 2016](#)).
29 Notably, the recovery of these plant communities occurred only if climatic factors were
30 held constant at current levels. In another modeling study, [Phelan et al. \(2016\)](#) made a
31 similar observation for understory plant community composition in northern hardwood
32 forests at Bear Brook Watershed in Maine and Hubbard Brook in New Hampshire: the
33 simulated plant community composition returned toward preindustrial conditions over the
34 next century only in a scenario in which N deposition rates returned to background and
35 climate was kept stable.

36 Finally, in addition to plant responses, climatic factors also can modify the N response of
37 microbial communities and other soil biota. For instance, N deposition has been shown to

1 alter the soil microbial community responsible for a step in nitrification, particularly at
2 ambient temperature and precipitation ([Horz et al., 2004](#)). The N effect was then reduced
3 when temperature and precipitation were increased ([Horz et al., 2004](#)). Similarly, N
4 additions and lower precipitation interacted to shift microbial community composition in
5 forests soils in northeastern China ([Wang et al., 2014c](#)) and in grassland soils in Inner
6 Mongolia ([Li et al., 2016a](#)). [Jarvis et al. \(2013\)](#) found that both changes in precipitation
7 and nitrogen were associated with shifts in ectomycorrhizal species composition in
8 European Scots pine (*Pinus sylvestris*) stands, although their observational study did not
9 allow them to test the interactive effects. In a Minnesota grassland, [Eisenhauer et al.](#)
10 [\(2012\)](#) observed a decline in several categories of biota within a soil food web (numbers
11 of nematode predators, microarthropod herbivores, and taxa richness of nematodes and
12 microarthropods) under increased N, and a decrease in ciliate protists under high N and
13 drought. The authors suggested the impact of drought may have been limited by the soil
14 food web's prior adaption to dry conditions because the study was conducted on a sandy
15 outwash soil, which dries out quickly in the summer. These studies on disparate biota and
16 ecosystems suggest climatic factors, namely temperature and precipitation, can interact
17 with N to affect soil biotic communities. In general, the functional implications to
18 terrestrial ecosystems of these combined climate-and-N induced shifts in soil biota
19 remain unclear, although there are notable exceptions [e.g., nitrification; ([Horz et al.,](#)
20 [2004](#))].

21 Overall, studies investigating the interactive effects of climatic factors and N have been
22 limited to date ([Porter et al., 2013](#)). Despite this, evidence suggests climatic shifts in
23 temperature and/or precipitation can alter the effects of N on plant productivity and
24 diversity, and soil microbial communities and other soil biota.

6.5. Critical Loads

25 As discussed elsewhere in this ISA (e.g., [Appendix 1](#), [Appendix 4](#), [Appendix 5](#)), critical
26 loads (CLs) are a determination of how much atmospheric deposition can be tolerated by
27 an environmental system before a significant change occurs. Most commonly, this
28 approach defines a level of deposition associated with an adverse geochemical or
29 biological response within an ecoregion. As of the 2008 ISA, most of the CLs developed
30 for North American ecosystems were for aquatic ecosystems (lakes and streams) in
31 Canada and the northeastern U.S. Among terrestrial ecosystems in North America, the
32 2008 ISA identified efforts to develop empirical CLs for western ecosystems in the U.S.,
33 particularly alpine and arid ecosystems. The reported effect levels ranged from 4 to
34 5 kg N/ha/yr for changes in the abundance of individual sensitive alpine plant species, to
35 20 kg N/ha/yr for community level changes in alpine plant communities. [Clark and](#)

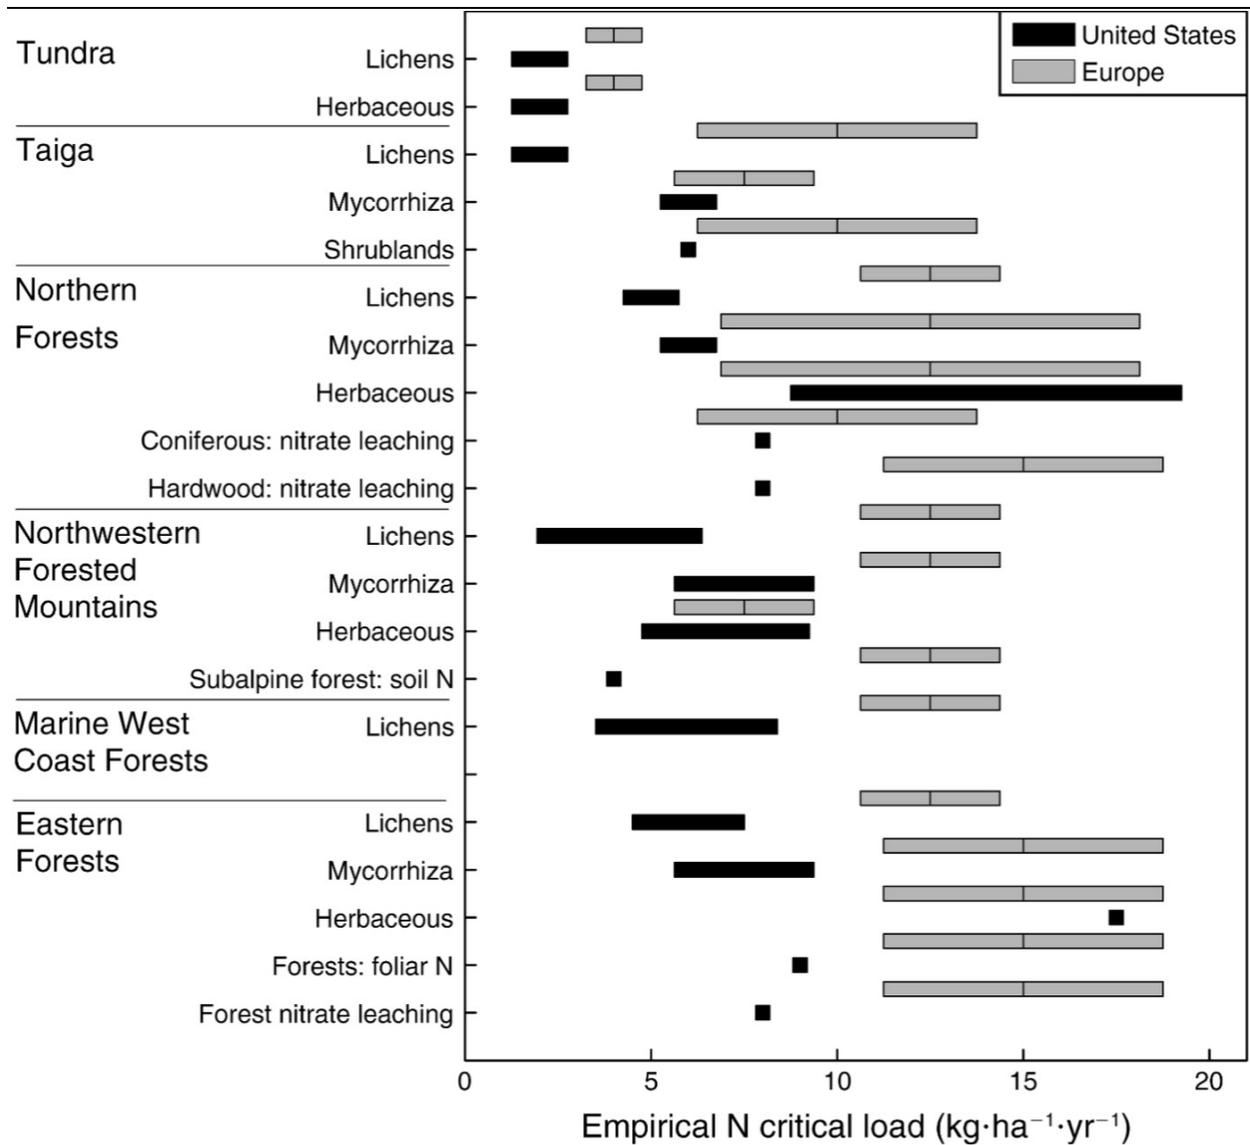

1 [Tilman \(2008\)](#) calculated the CL for the onset of reduced relative species numbers in
2 grasslands to be 5.3 kg N/ha/yr with a 95% inverse prediction interval of
3 1.3–9.8 kg N/ha/yr. A CL of 3.1 kg N/ha/yr was considered protective of lichen
4 communities in the western U.S. ([Fenn et al., 2008](#)). However, as of 2008, there was no
5 published CL assessment that spanned the U.S.

6 A large body of work has been published on CLs for N since the 2008 ISA. Most notably,
7 the U.S. Department of Agriculture (USDA)-Forest Service (FS) created a detailed
8 national assessment of empirically developed CLs for the U.S. ([Pardo et al., 2011c](#)),
9 which has also been summarized into a refereed manuscript ([Pardo et al., 2011a](#)). This
10 national CL document, *Assessment of Nitrogen Deposition Effects and Empirical Critical*
11 *Loads* ([Pardo et al., 2011c](#)), reports CLs for various biological and biogeochemical
12 endpoints in 15 terrestrial ecoregions. Additionally, in some cases, more recent CLs have
13 been published, often falling into the range of CLs identified by the USDA-FS
14 assessment ([Pardo et al., 2011c](#)) (summarized in [Appendix 6.6.3](#)).

15 As with many published CL estimates, most of the CLs reported in the USDA-FS
16 assessment were empirically derived, based on ecological changes observed along
17 atmospheric N deposition gradients or in response to experimental N additions at rates
18 near ambient deposition. Consequently, the links between N deposition and the measured
19 response variable are direct for empirically derived CLs, and full process-level
20 knowledge is not required. There can be a few potential sources of uncertainty with
21 empirically derived CLs, however. The lack of a full process-based understanding can
22 make it difficult to extrapolate observed results across space and time. Spatially, variation
23 in biological and biogeochemical processes imposed by climate, geology, biota, and other
24 environmental factors may alter the observed deposition-response relationship. This is
25 particularly problematic in areas where N deposition has received sparse research
26 attention. [Pardo et al. \(2011c\)](#) reported that for some ecoregions, a single study or very
27 few studies were available. If the variability of ecosystem response to N deposition across
28 an ecoregion is not available, the estimated CL for N may be relevant for only a single
29 ecosystem type or a single subregion within the ecoregion. Whereas atmospheric
30 deposition responds dynamically to shifts in emissions and weather patterns, ecological
31 processes react to environmental stress at a variety of timescales. Because ecological
32 changes can be dependent on a series of underlying processes, there can be a time lag
33 between deposition and ecological responses. Finally, reference plots at the low end of
34 the deposition gradient may already have been altered from a “pristine” condition, which
35 can bias CL estimates upwards. This shift from a background state can be particularly
36 problematic for highly sensitive indicators, as well as in regions such as the northeastern
37 U.S. that have long and geographically extensive histories of elevated N deposition. In

1 the USDA-FS assessment, [Pardo et al. \(2011c\)](#) reported CLs that tended to be higher in
2 regions experiencing greater rates of N deposition.

3 Because environmental factors are large influences on both biogeochemical cycling and
4 biological processes ([Pardo et al., 2011c](#)), the discussion of terrestrial biological CLs in
5 this ISA focuses largely on research conducted in North America. Notably, [Pardo et al.](#)
6 [\(2011c\)](#) reported that CLs developed for Europe and China both tended to be higher than
7 those reported in the U.S., likely because of the higher rates of N deposition in these
8 regions ([Figure 6-4](#)). Further, because a large portion of the variation in CLs is a function
9 of particular ecological receptors ([Pardo et al., 2011c](#)), the analysis of CL research
10 presented here compares observations for key receptors (e.g., mycorrhizal fungi, lichens,
11 herbaceous plants) across ecoregions, focusing on the estimates created by [Pardo et al.](#)
12 [\(2011c\)](#) and other CL research published since 2008.

Source: [Pardo et al. \(2011a\)](#).

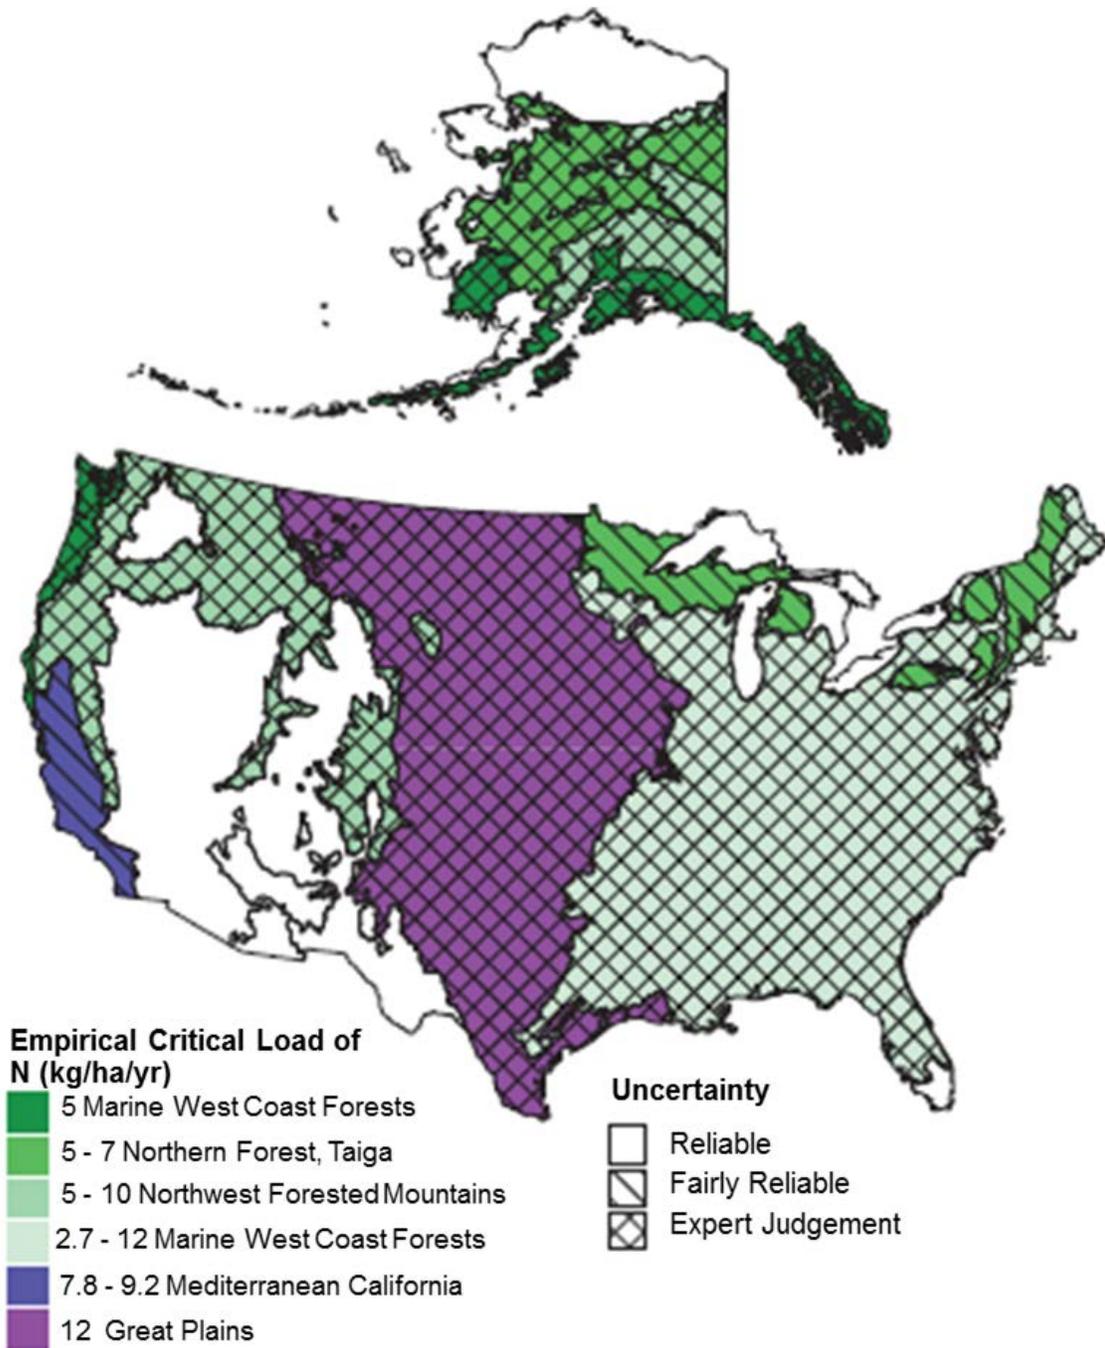

Figure 6-4 Comparison of European and U.S. empirical critical loads for nitrogen from [Pardo et al. \(2011a\)](#).

6.5.1. Mycorrhizal Fungi

1 Mycorrhizal fungi are symbiotic organisms hosted on the roots of many plant species,
 2 with important roles in plant nutrient acquisition, belowground C cycling, and as food
 3 sources for other organisms. As noted in [Appendix 6.2](#) and [Appendix 6.3](#), mycorrhizal
 4 fungi can be sensitive to added N, responding through changes in physiology and growth

1 ([Table 6-2](#), [Table 6-3](#), and [Table 6-8](#)), as well as shifts in species richness and community
2 composition ([Table 6-15](#) and [Table 6-16](#)).

3 Nitrogen CLs for mycorrhizal fungi range between 5 and 12 kg N/ha/yr in the U.S.
4 ([Figure 6-5](#); [Table 6-24](#)) according to studies assessed in [Pardo et al. \(2011c\)](#) and one
5 additional study conducted in a southern California CSS ecosystem ([Allen et al., 2016](#)).
6 [Pardo et al. \(2011c\)](#) documented that N deposition in the range of 5 to 10 kg N/ha/yr can
7 significantly alter ectomycorrhizal fungi community composition and decrease species
8 richness in N limited conifer forests. Similarly, N deposition levels of 7.8 to
9 12 kg N/ha/yr can lead to arbuscular mycorrhizal community changes in CSS ecosystems
10 in California and grasslands in the Midwest (see Mediterranean California and Great
11 Plains ecoregions in [Figure 6-5](#)), due to declines in spore abundance and root
12 colonization, and changes in community function. Based on additional analysis, ([Pardo et
13 al., 2011c](#)) suggested the threshold for N effects on mycorrhizae are even lower because
14 high background deposition precludes consideration of sites receiving deposition at or
15 near preindustrial levels. The provisional expert judgment was that CLs for mycorrhizal
16 diversity for sensitive ecosystem types are 5 to 10 kg N/ha/yr ([Table 6-24](#)). [Pardo et al.
17 \(2011c\)](#) indicated there is high uncertainty in this estimate because few studies had been
18 conducted at low rates of N deposition. Since the publication of the USDA-FS
19 assessment, there has been one additional study on CLs for mycorrhizae in the U.S. In
20 that study, [Allen et al. \(2016\)](#) estimated an N deposition CL of 10–12 kg N/ha/yr for
21 mycorrhizal biodiversity in southern California CSS ecosystems.

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: the range of CLs reported for mycorrhizal fungi is shown for each ecoregion. The hatch marks indicate increasing level of uncertainty: no hatch marks for the most certain "reliable" category, single hatching for the "fairly reliable" category, and double hatching for the "expert judgment" category. The color sequence moves from green toward blue and violet as the CL increases. As the range of the CL gets broader, the saturation of the color decreases. White areas lack data for CL determination for mycorrhizal fungi.

Source: [Pardo et al. \(2011c\)](#).

Figure 6-5 Map of critical loads for mycorrhizal fungi by ecoregion in the U.S.

Table 6-24 Mycorrhizal critical loads.

Type of Ecosystem	Critical Load (kg N/ha/yr)	Biological and Chemical Effects	Study Species	Reference
California coastal sage scrub	10–11	Rapid decline in mycorrhizal biodiversity	Arbuscular mycorrhizal fungi	Allen et al. (2016)
Sensitive ecosystem types in the U.S.	5–10	Diversity	Mycorrhizal	Pardo et al. (2011c)
Scots pine forest in Scotland	5–10	Community composition	Ectomycorrhizal fungi	Jarvis et al. (2013)

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

6.5.2. Lichens and Bryophytes

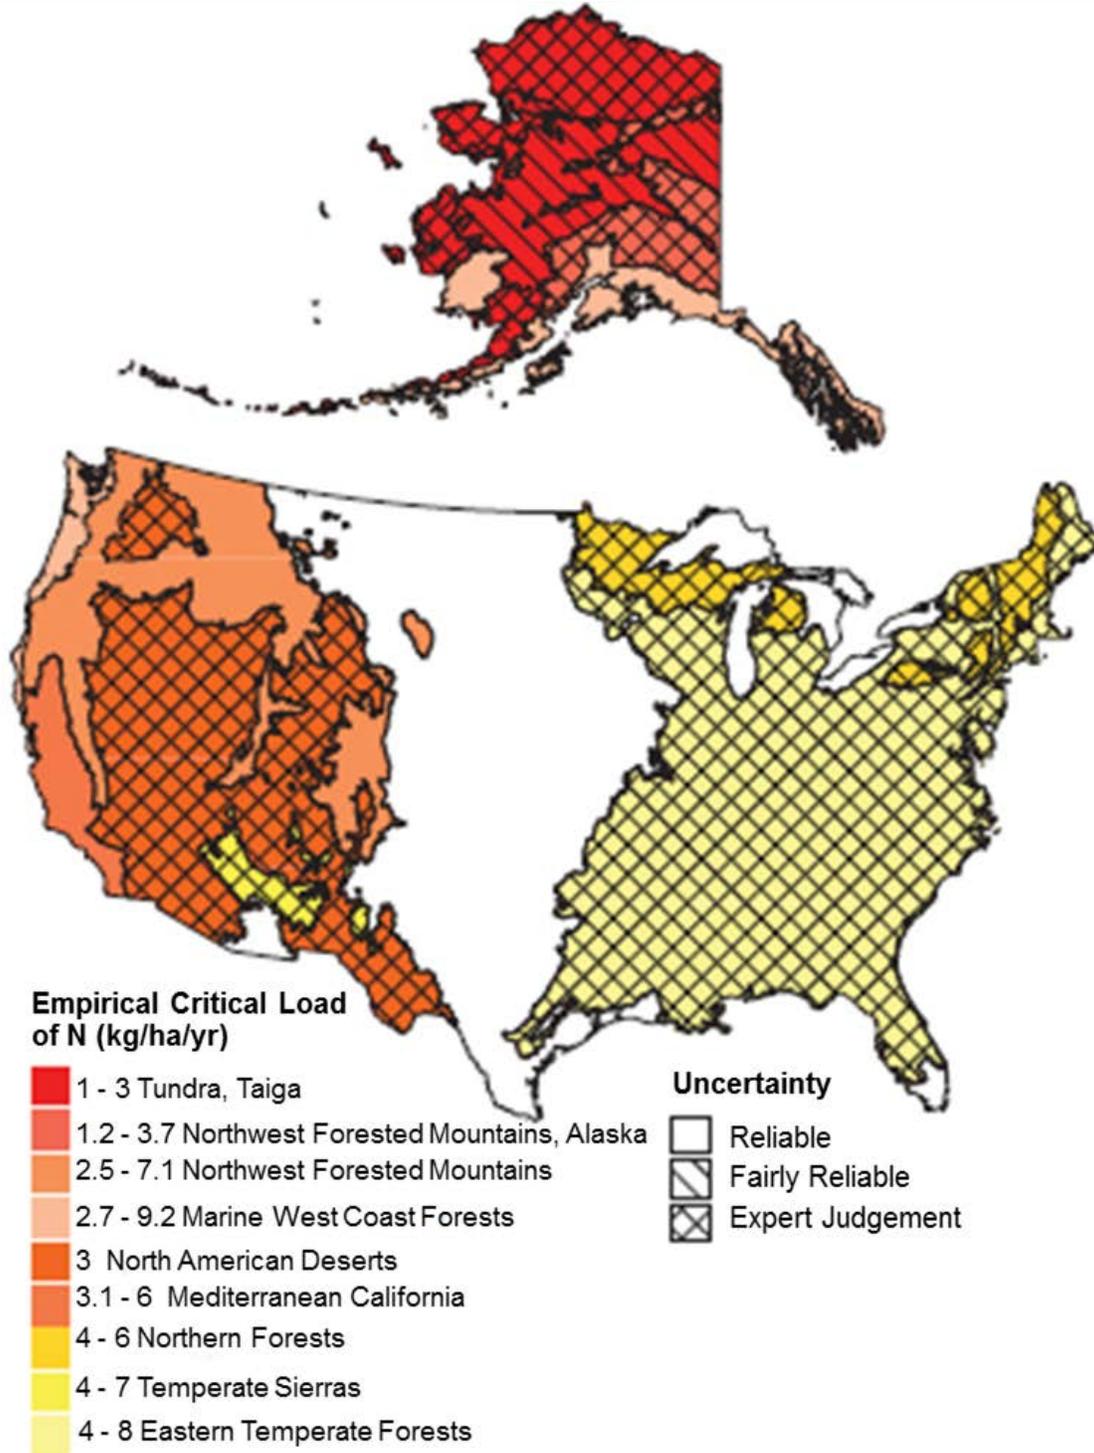

1 Lichens are symbioses between fungi and algae or cyanobacteria and are important
2 components of plant communities in forests, tundra, and some arid ecosystems. Lichens
3 contribute to ecosystem function by providing food and habitat for wildlife and affecting
4 nutrient and hydrologic cycling. Like mycorrhizae, the growth, physiology, and
5 community composition of lichens is sensitive to atmospheric N deposition ([Table 6-5](#),
6 [Table 6-7](#), and [Table 6-23](#)). The 2008 ISA documented observations that N deposition
7 altered lichen community composition at deposition rates of 3 to 8 kg N/ha/yr ([Fenn et](#)
8 [al., 2003a](#)). In the San Bernardino Mountains in southern California, up to 50% of lichen
9 species that occurred in the region in the early 1900s had disappeared by the 1990s ([Fenn](#)
10 [et al., 2003a](#); [Nash and Sigal, 1999](#)). The CL has been calculated for lichen communities
11 in mixed conifer forests in California at 3.1 kg N/ha/yr ([Fenn et al., 2008](#)). In the Pacific
12 Northwest, lichen communities have shown evidence of changes in response to increased
13 N pollution, including decreases in the distribution of sensitive lichen taxa and the
14 replacement of these taxa with nitrophilous species ([Geiser and Neitlich, 2007](#)).

15 Since the 2008 ISA, it has become clear that although simple N deposition CL estimates
16 for changes in lichen community composition can be constructed [([McMurray et al.,](#)
17 [2013](#); [Fenn et al., 2008](#)), accounting for the effects of climate and other environmental
18 factors can improve lichen CL estimates ([Blett et al., 2014](#); [Pardo et al., 2011c](#); [Geiser et](#)
19 [al., 2010](#)), providing more refined estimates of CL variability and exceedance. As noted
20 in [Appendix 6.2.3.3](#), changes in lichen growth are best correlated with integrated

1 measures of total N deposition, rather than with the deposition of a single chemical
2 species such as HNO₃ or NH₄⁺. Lichen responses to N deposition such as increases in
3 thalli N concentration and shifts in community composition have been most tightly
4 correlated with colocated canopy throughfall measurements of N-NO₃⁻ + N-NH₄⁺
5 ([McMurray et al., 2013](#); [Root et al., 2013](#); [Jovan et al., 2012](#); [Fenn et al., 2007](#)) and
6 ambient N concentrations in fine particulates of [NH₄]₂SO₄ and NH₄NO₃ ([Root et al.,](#)
7 [2015](#); [Geiser et al., 2010](#)).

8 Lichen community composition and lichen thallus N concentrations shift continuously
9 with all increments of N addition and the response is generally unimodal. In the latter
10 case, the fastest rate of change occurs with the earliest increments of N addition and
11 slows as only tolerant species are left in the community. As N deposition increases,
12 dominance of lichen communities shift from oligotrophic to eutrophic species (i.e., the
13 number of oligotrophs decrease and the number of eutrophs increase). At very high
14 deposition levels, total biodiversity decreases.

15 Critical loads for lichen range between 0.26 to 10.2 kg N/ha/yr based on [Pardo et al.](#)
16 [\(2011c\)](#) and a number of studies for lichens published since 2008 ([Figure 6-6,](#)
17 [Table 6-25](#)). In the USDA-FS CL assessment, [Pardo et al. \(2011c\)](#) documented CLs for
18 lichens of 1 to 9.2 kg N/ha/yr for Level 1 ecoregions. These CLs were predominantly
19 based on the shift in community composition toward eutrophic lichen species and away
20 from oligotrophs. The certainty associated with the lichen CL estimates for each
21 ecoregion varied considerably, in part because of differences in sampling scheme and
22 intensity. There were highly reliable CL estimates in the Pacific Northwest and
23 California, where sampling intensity was high and the linkages between N deposition and
24 lichen community composition have been well documented. Assessments in the eastern
25 U.S. are more problematic due to historical and contemporary S emissions and acidifying
26 deposition. Historical information necessary to identify a “pristine” or “clean” state has
27 been lacking, making it difficult to determine the CL, and the resulting confidence
28 associated with the CL was low.

CL = critical loads; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: the range of critical loads reported for lichens is shown for each ecoregion. The hatch marks indicate increasing level of uncertainty: no hatch marks for the most certain "reliable" category, single hatching for the "fairly reliable" category, and double hatching for the "expert judgement" category. White areas lack data for CL determination for lichens.

Source: [Pardo et al. \(2011c\)](#).

Figure 6-6 Map of critical loads for lichens by ecoregion in the U.S.

Table 6-25 Lichen critical loads.

Type of Ecosystem	Critical Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Chaparral and oak woodland	5.5	Shift to nitrophyte dominance in the lichen community	California	Epiphytic lichens	Pardo et al. (2011c) Fenn et al. (2010)
		Relating total N in throughfall to lichen biodiversity	Southern California, north of Los Angeles	Epiphytic lichens	Jovan et al. (2012) Linder et al. (2013)
Forest	0.26 to 0.33 kg inorganic N/ha/yr and 0.044–0.055 mg/L of ammonium wet deposition	Declines in presence and abundance of sensitive lichen communities	Western Oregon and Washington	Lichens	Glavich and Geiser (2008)
Forest	<4.1	Poorer thallus condition	Wind River Range, WY, including the Class I Bridger Wilderness	Epiphytic lichens	McMurray et al. (2013)
Forest	4–6 for total N deposition	Decreases in lichen species richness and N sensitive species, and poorer thallus condition	Northeastern U.S. Class I areas	Epiphytic lichens	Cleavitt et al. (2015)
Forest	4	Degradation to lichen communities	Northern Rocky Mountains	Epiphytic lichens	McMurray et al. (2015)
Forest	1.54 and 2.51 kg N/ha/yr of through-fall dissolved inorganic N deposition	Lichen communities and lichen N concentration	Pacific Northwest	Epiphytic lichens	Root et al. (2015)
Mixed conifer forests	3.1	Enhanced lichen tissue N concentrations	California	Epiphytic lichens	Fenn et al. (2008) Fenn et al. (2010)

Table 6 25 (Continued): Lichen critical loads.

Type of Ecosystem	Critical Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Mixed conifer forests	5.2	Lichen community shifted from acidophyte dominance to neutrophyte dominance	California	Epiphytic lichens	Fenn et al. (2008) Fenn et al. (2010)
Mixed conifer forests	10.2	Lichen species classified as acidophytes were extirpated	California	Epiphytic lichens	Fenn et al. (2008) Fenn et al. (2010)
Temperate forest	3–9	Sensitive species declines of 20–40%	Western Oregon and Washington	Epiphytic lichens	Geiser et al. (2010)
Various	1–9.2	Lichen health and community composition	U.S. (national)	Epiphytic lichens	Pardo et al. (2011c)

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

1 In addition to the USDA-FS assessment by [Pardo et al. \(2011c\)](#), there have been a
2 number of N deposition CL studies for lichens published since 2008, including research
3 in the northeastern U.S. ([Cleavitt et al., 2015](#)), California ([Fenn et al., 2010](#); [Fenn et al.,
4 2008](#)), the Pacific Northwest ([Root et al., 2015](#); [Geiser et al., 2010](#); [Glavich and Geiser,
5 2008](#)), and the Rocky Mountains ([McMurray et al., 2013](#)). In the northeastern U.S.,
6 [Cleavitt et al. \(2015\)](#) studied four Class I areas and found annual mean and cumulative
7 deposition of N were strongly negatively correlated with lichen species richness, the
8 abundance of N sensitive species, and thallus condition. The work by ([Cleavitt et al.,
9 2015](#)) supported the CL of 4–6 kg N/ha/yr of total N deposition for epiphytic lichens in
10 the Northern Forest Ecoregion created by [Pardo et al. \(2011c\)](#).

11 Based on sampling in mixed conifer forests in the Sierra Nevada and San Bernardino
12 Mountains in California, [Fenn et al. \(2008\)](#) developed a CL estimate of 3.1 kg N/ha/yr for
13 throughfall N deposition based on increases in thallus N concentration for the lichen
14 *Letharia vulpina*. Above this CL, there were shifts in lichen community composition
15 away from acidophytic lichen species and toward lichen species considered to be
16 neutrophytic and nitrophytic. [Fenn et al. \(2010\)](#) later applied these and other previously
17 published CL values for lichens in California to estimate that 53 and 41% of the chaparral
18 and oak woodland ecosystems in the state received N deposition in excess of the lichen
19 CL of 5.5 kg N/ha/yr.

20 In the Wind River Range in western Wyoming, [McMurray et al. \(2013\)](#) developed a
21 lichen CL based on study sites adjacent to the Bridger Wilderness, a Class I area
22 downwind of an area experiencing oil and gas production. Above a threshold of
23 4.0 kg N/ha/yr of throughfall N deposition, [McMurray et al. \(2013\)](#) observed a
24 degradation of lichen communities in this area that included necrotic and bleached thalli
25 and decreased growth.

6.5.3. Herbaceous and Shrub Species

26 Herbaceous species and shrubs are found in grasslands, shrublands, forests, deserts, and
27 wetlands, and comprise the majority of the roughly 26,600 vascular plant species found
28 in North America north of Mexico ([NRCS, 2009](#)). In forests, herbaceous-layer
29 (understory) vegetation can be important contributors to ecosystem processes such as
30 litter production and N cycling ([Talhelm et al., 2013](#)), and can comprise up to 90% of
31 forest plant biodiversity, including endangered or threatened species ([Gilliam, 2007](#)). As
32 described in [Appendix 6.3.3.2](#), there is abundant evidence that forest understory
33 vegetation composition can be sensitive to N deposition ([Table 6-13](#)).

1 Critical loads for herbaceous and shrub species range between 0.9 to 33 kg N/ha/yr based
2 on studies published since 2008 ([Table 6-26](#)). In the USDA-FS assessment, ([Pardo et al.,
3 2011c](#)) reported N deposition CLs of 1 to 33 kg N/ha/yr for herbaceous species and
4 shrubs across all ecoregions ([Figure 6-7](#); [Table 6-26](#)). The lowest CL was for tundra
5 (1–3 kg N/ha/yr), while the highest was for the Mediterranean California ecoregion,
6 specifically a mixed conifer forest ecosystem in the San Bernardino Mountains ([Pardo et
7 al., 2011c](#)).

8 Among the new research published since the USDA-FS assessment was completed,
9 [Simkin et al. \(2016\)](#) examined the influence of N deposition on species richness of
10 grasses and forbs in over 15,000 plots located across the continental U.S. Notably, they
11 found different relationships between N deposition and species richness in open canopy
12 and closed canopy ecosystems, likely a function of different species loss mechanisms
13 ([Appendix 6.3.2](#)) operating in these systems. In open canopy systems (e.g., grasslands,
14 shrublands, and woodlands), N deposition above an average of 8.7 kg N/ha/yr led to a
15 reduction in species richness (5th–95th percentile: 6.4–11.3 kg N/ha/yr). These rates of N
16 deposition are common across much of the eastern and central U.S., as well as areas in
17 the western U.S. that are downwind of major urban and agricultural areas ([Figure 6-8](#)).
18 Average CLs for grasses and forbs did not differ widely among the grassland, shrubland,
19 and woodland ecosystems (8.9, 8.5, and 8.5 kg N/ha/yr). The calculated CL for closed
20 canopy systems was considerably higher: 13.4 kg N/ha/yr (5th–95th percentile:
21 6.8–22.2 kg N/ha/yr). At higher levels of N input, processes such as competitive
22 exclusion and soil acidification occur, decreasing species richness. There are two
23 important observations from this analysis. First, increases in N deposition below the CL
24 levels could increase species richness, particularly in open canopy ecosystems. Second,
25 the effects of N deposition on species richness were often pH dependent (see
26 [Appendix 6.3.2](#)). [Simkin et al. \(2016\)](#) also developed more localized CL estimates. In
27 forests, these ranged from a low of 7.9 kg N/ha/yr in open canopy eastern forests to a
28 high of 15.3 kg N/ha/yr in northwestern forest mountains. In the Great Plains region,
29 ([Simkin et al., 2016](#)) estimated CLs for grasses and forbs of 8.3–9.8 kg N/ha/yr in the
30 open canopy systems to 11.3–19.6 kg N/ha/yr in closed canopy systems. In arid
31 ecosystems, [Simkin et al. \(2016\)](#) estimated a CL of 8.3–9.9 kg N/ha/yr for open canopy
32 ecosystems and 13.5–17 kg N/ha/yr for closed canopy ecosystems.

Table 6-26 Herbaceous and shrub critical loads.

Type of Ecosystem	Critical Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Alpine tundra	3.0	Protection of natural community cover	Rocky Mountain National Park	Alpine grasses and forbs	Bowman et al. (2012)
Alpine and subalpine ground vegetation	1 to 2	ForSAFE-VEG modeled changes in alpine and subalpine plant community (modeled from 1750 to 2500)	Northern and central Rocky Mountains	Alpine and subalpine ground vegetation, including two tree species (Engelmann spruce and White spruce- <i>Picea engelmannii</i> and <i>Picea glauca</i>)	Sverdrup et al. (2012)
Desert	2.1 and 3.6	Exponential increase in the probability of biomass (simulated using the DayCent model) exceeding the fire threshold of 1,000 kg/ha	Southern CA Joshua Tree National Park	Creosote bush (<i>Larrea tridentata</i>) other shrubs, forbs, and grasses; two tree species included (California juniper and Single leaf pinyon- <i>Juniperus californica</i> and <i>Pinus monophylla</i>)	Rao et al. (2010)
North American desert	Open: 8.3–9.9 (mean = 9.2, n = 240) Closed: 13.5–17.0 (mean = 16.5, n = 32)	Decreasing species richness grasses and forbs	Ecoregion	Various	Simkin et al. (2016)

5
6
7
8

Within the Colorado Rocky Mountains, there were several efforts to develop CLs based on both empirical and modeled data. In the Rocky Mountain National Park, [Bowman et al. \(2012\)](#) calculated an empirical CL of 3 kg N/ha/yr to protect natural community cover based on large increases in the abundance of the sedge *Carex rupestris* to additional N deposition. [McDonnell et al. \(2014a\)](#) applied the ForSAFE-VEG model to develop a long-term CL estimate aimed at avoiding future (2010–2100) changes (of more than 10%) in subalpine plant biodiversity in Rocky Mountain National Park. The estimated

1 CL to protect future plant diversity was 1.9–3.5 kg N/ha/yr, a value already exceeded in
2 the study area. [Sverdrup et al. \(2012\)](#) also used the ForSAFE-VEG model to understand
3 how long-term CLs would be influenced by climate change, but worked from a synthetic
4 alpine and subalpine vegetation data set developed from observations at national parks in
5 the northern and central Rocky Mountains region of the U.S. They determined CL values
6 of 1 to 2 kg N/ha/yr to protect against a future change in plant diversity of 5–20%.

7 Notably, CLs protecting against future biodiversity changes may not be comparable
8 directly to other CLs protective against current changes to herbaceous and shrub
9 biodiversity ([Table 6-26](#)). Critical loads are expressed on an annual basis, and CLs
10 protective of future biodiversity may be lower generally than shorter-term CLs to avoid
11 the accumulating effects of deposition over longer periods of time. Consideration of
12 future temperature increases, among other factors, however, may complicate this
13 relationship. In their simulations, ([McDonnell et al., 2014a](#)) concluded that where the CL
14 was between 1.9 and 3.5 kg N/ha/yr depended upon future temperatures. Higher
15 simulated temperatures resulted in CL values higher in the range, closer to
16 3.5 kg N/ha/yr. They attributed this to the increased N uptake of the vegetation with
17 higher temperatures, allowing an increase in deposition while protecting against shifts in
18 plant diversity. Thus, among other factors, comparison of CLs protecting against future
19 versus current changes likely requires a consideration of the underlying assumptions
20 about future conditions.

21 In addition to the CL estimates for plant species richness ([Simkin et al., 2016](#)), two other
22 CL estimates have been developed for arid and semiarid ecosystems. [Pardo et al. \(2011c\)](#)
23 determined a CL of 3–8.4 kg N/ha/yr for North American deserts based on a decrease in
24 native forbs. [Rao et al. \(2010\)](#) developed unique CL estimates for the rate of N deposition
25 that would increase the probability of vegetation productivity in two arid ecosystems
26 within Joshua Tree National Park in southern California exceeding a wildfire risk
27 threshold. To do this, [Rao et al. \(2010\)](#) applied the DayCent model. The risk of exceeding
28 the wildfire risk threshold of 1,000 kg of biomass/ha increased rapidly above CLs of 2.1
29 and 3.6 kg N/ha/yr for the two ecosystem types. The risk of exceeding the threshold
30 increased until N deposition levels reached 5.5 and 8.8 kg N/ha/yr for the two ecosystem
31 types. Notably, contemporary rates of N deposition at the study sites were 3 to
32 8 kg N/ha/yr, and up to 16 kg N/ha/yr has been observed in areas adjacent to these desert
33 ecosystems and downwind from or near urban areas ([Fenn et al., 2010](#)). In southern
34 California, [Cox et al. \(2014\)](#) modeled the influence of environmental factors such as
35 climate, land use, and N deposition on the conversion of CSS ecosystems to exotic annual
36 grasslands from 1930 to 2009. Here, conversion of CSS to exotic grasslands was more
37 likely to occur if N deposition exceeded 11 kg N/ha/yr. This CL estimate was similar to a
38 CL of 10 kg N/ha/yr for CSS developed by [Pardo et al. \(2011c\)](#).

6.5.4. Trees

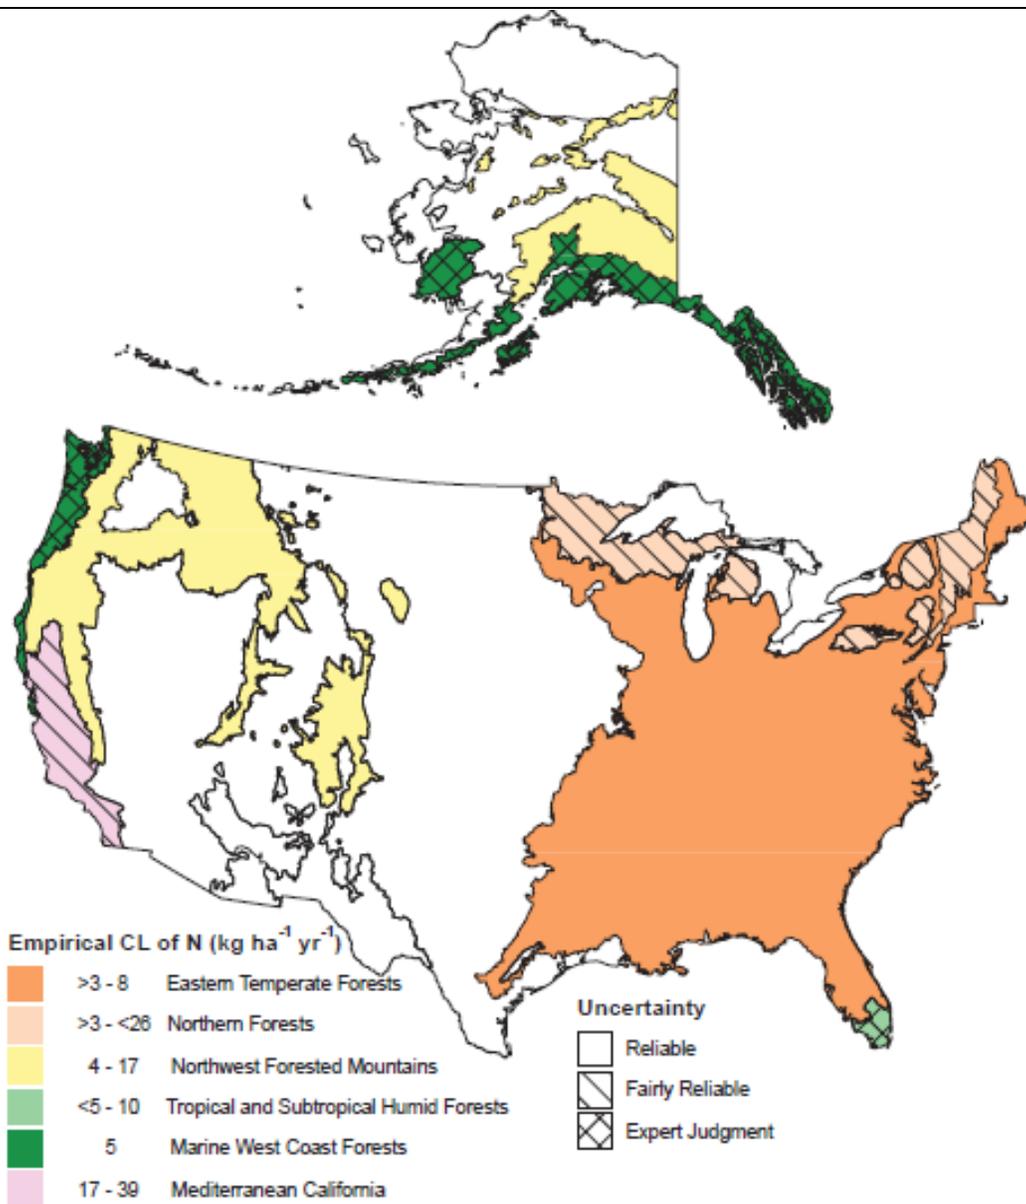

1 As noted in [Appendix 6.3.3.1](#), there are relatively few direct observations of overstory
2 tree community composition change, likely because it is difficult to observe changes for
3 long-lived organisms in slowly developing communities. However, there is more
4 abundant evidence of changes in tree growth, mortality, and physiology
5 ([Appendix 6.2.3.1](#)). Notably, CLs for trees due to N + S deposition are presented in
6 [Appendix 5](#).

7 Nitrogen CLs for trees range between >3 to 39 kg N/ha/yr based on studies compiled in
8 [Pardo et al. \(2011c\)](#) and one other study published since 2008 ([Table 6-27](#)). In the
9 USDA-FS assessment, [Pardo et al. \(2011c\)](#) reported that N CLs for forest ecosystems
10 ranged from >3 to 39 kg N/ha/yr ([Figure 6-9](#)). Estimates of 3–26 kg N/ha/yr for declining
11 forest growth and increased mortality were based on the forest inventory data analysis
12 conducted by [Thomas et al. \(2010\)](#) and a chronic N addition experiment conducted in red
13 spruce forests in the northeastern U.S. (McNulty, 2005, 092173). In California mixed
14 conifers, [Pardo et al. \(2011c\)](#) reported a CL of 17 kg N/ha/yr for decreased fine root
15 biomass and 39 kg N/ha/yr for forest sustainability, both developed from observations
16 reported by [Fenn et al. \(2008\)](#). In one additional study subsequent to the USDA-FS
17 assessment, [Fleischer et al. \(2013\)](#) reported that greater rates of N deposition increased
18 canopy photosynthetic capacity in evergreen needleleaf forests below a CL threshold of
19 8 kg N/ha/yr.

Table 6-27 Tree critical loads.

Type of Ecosystem	Critical Load kg N/ha/yr	Biological and Chemical Effects	Study Site	Study Species	Reference
Evergreen forest	~8	Saturation of photosynthetic capacity of the canopy	32 forest sites around the globe	Conifer	Fleischer et al. (2013)
Various forests	>3-39	Tree growth and survival; other various effects	U.S. (national)	Various	Pardo et al. (2011c)

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: the range of CLs reported for forest ecosystems is shown for each ecoregion; this map does not include the responses of mycorrhizal fungi, lichens, or understory herbaceous plants already represented. The hatch marks indicate increasing level of uncertainty: no hatch marks for the most certain "reliable" category, single hatching for the "fairly reliable" category, and double hatching for the "expert judgment" category. White areas lack data for CL determination for forest ecosystems.

Source: [Pardo et al. \(2011c\)](#).

Figure 6-9 Map of critical loads for forest ecosystems by ecoregion in the U.S.

6.5.5. Critical Loads Exceedance Studies

1 In the USDA-FS assessment of N deposition CLs, [Pardo et al. \(2011c\)](#) evaluated the CL
2 exceedances for mycorrhizal fungi, lichens and bryophytes, herbaceous plants and
3 shrubs, and forests using N deposition estimates produced by the Community Multiscale
4 Air Quality (CMAQ) model v.4.3. This CMAQ model used data reported in 2001 for the
5 simulations of wet plus dry N deposition. [Pardo et al. \(2011c\)](#) concluded that large parts
6 of the eastern U.S., as well as localized areas in the West, experience rates of N
7 deposition that exceed the CL for sensitive ecosystem components. In this assessment,
8 [Pardo et al. \(2011c\)](#) determined that the resources most threatened by elevated N
9 deposition included freshwater diatoms, lichens, bryophytes, and herbaceous plants.

10 In addition to [Pardo et al. \(2011c\)](#), several studies have quantified N deposition CL
11 exceedance at the regional scale for herbaceous plants. In the [Simkin et al. \(2016\)](#)
12 analysis of herbaceous species richness in over 15,000 plots over the continental U.S.,
13 approximately 41% of grassland plots were experiencing N deposition in exceedance of
14 the CL for plant species richness. [Clark et al. \(2013\)](#) used 26 years (1985–2010) of N
15 deposition data with ecosystem-specific functional responses from local field
16 experiments and a national CLs database to generate estimates of herbaceous species
17 loss. In scenarios using the low end of the CL range, N deposition exceeded CLs over
18 0.38, 6.5, 13.1, 88.6, and 222.1 million ha for the Mediterranean California, North
19 American Desert, Northwestern Forested Mountains, Great Plains, and Eastern Forest
20 ecoregions, respectively, with corresponding species losses ranging from <1 to 30%.
21 When scenarios assumed less sensitivity (using a common CL of 10 kg N/ha/yr, and the
22 high end of the CL range) minimal losses were estimated. The large range in projected
23 impacts among scenarios highlights the uncertainty in current CLs estimates for plant
24 diversity in the U.S.

25 [McLauchlan et al. \(2014\)](#) analyzed a 27-year record of ecophysiological, community, and
26 ecosystem metrics for an annually burned Kansas tallgrass prairie. Despite observed rates
27 of atmospheric N deposition (7 kg N/ha/yr from 2002 to 2009) that exceed the minimum
28 estimated CL for herbaceous plants in tallgrass prairie of the Great Plains of North
29 America [5–15 kg N/ha/yr; ([Pardo et al., 2011c](#))], there were no observations of plant
30 community composition change or effects on plant physiology that signaled an obvious
31 influence of N deposition: plant N concentrations and plant N availability did not
32 increase, aboveground NPP was unchanged, forb diversity did not decline, and the
33 relative abundance of dominant grasses did not shift toward more eutrophic species.
34 Thus, current rates of N deposition do not appear to be altering ecosystem function in this
35 grassland, even though these rates exceed minimum CLs. The authors offered a couple of
36 potential explanations for this lack of response, including sequestration of the additional

1 N into soil organic matter pools and offsetting removal of N by biomass burning and/or
2 grazing.

3 Finally, [Clark et al. \(2018\)](#) estimated CL exceedance areas for the conterminous U.S.
4 over a more than 200 year period. In this study, they examined six CL types, with three N
5 CLs germane to terrestrial ecosystems: (1) changes in forest tree health, (2) changes in
6 lichen communities, and (3) changes in herbaceous and shrub plant community
7 composition. Overall, this analysis showed terrestrial N CLs have been exceeded for
8 many decades in areas across the U.S. Minimum values for these CLs were already
9 exceeded by 1855 for the first two CLs, and the latter CL was exceeded between 1935
10 and 1955. Exceedance areas peaked in 1995 for changes in lichen communities and plant
11 community composition at 3.47 and 2.87 million km², respectively, before declining
12 marginally by 2006. The minimum forest tree health CL was exceeded in 2.41 million
13 km² by 1855 and did not change much over time, primarily because the relatively low CL
14 compared to deposition values in the Eastern Temperate and Northern forest ecoregions.

6.6. Summary

6.6.1. Physiology, Growth, and Productivity Summary

15 At the time of the 2008 ISA, there was evidence sufficient to infer a causal relationship
16 between N deposition and the alteration of the biogeochemical cycling of C in terrestrial
17 ecosystems. This evidence included observations that added N increased plant
18 productivity across a broad range of terrestrial ecosystems. The 2008 ISA, however,
19 made no explicit statement regarding the effects of N deposition on physiology, growth,
20 and productivity.

21 Since the 2008 ISA, a more complete understanding of how N deposition effects
22 terrestrial organisms and ecosystems has been developed, the effects of N deposition in
23 terrestrial ecosystems in North America and Europe have been more widely documented,
24 and a significant new body of research has observed N deposition impacts in Asia
25 (particularly China). These efforts have provided further evidence that added N alters
26 plant physiological processes, stimulates the growth of most plants, and broadly increases
27 productivity ([Liu and Greaver, 2010](#); [LeBauer and Treseder, 2008](#); [Xia and Wan, 2008](#)).
28 Moreover, studies have shown species-specific effects of N deposition on tree growth and
29 mortality ([Dietze and Moorcroft, 2011](#); [Thomas et al., 2010](#)). There is also widespread
30 evidence that N additions affect soil microbial physiology and biomass (see [Appendix 4](#)
31 for soil extracellular enzyme responses), particularly by decreasing the abundance of

1 symbiotic mycorrhizal fungi ([Li et al., 2015](#); [Treseder, 2008](#)). There have also been
2 numerous observations that additional N can alter arthropod performance and abundance
3 among both detritivores and herbivores [([Throop and Lerdau, 2004](#)); [Table 6-17](#)]. Thus, it
4 is apparent that plants, microorganisms, and ecosystem-scale productivity are sensitive to
5 N availability. **This body of evidence is sufficient to infer a causal relationship**
6 **between N deposition and the alteration of the physiology and growth of terrestrial**
7 **organisms and the productivity of terrestrial ecosystems.**

8 Although plants are broadly sensitive to added N, it is clear that the effects of N on plant
9 growth and productivity vary considerably among plant tissues ([Li et al., 2015](#); [Xia and](#)
10 [Wan, 2008](#)), individual species and functional types ([Xia and Wan, 2008](#)), and biomes
11 ([LeBauer and Treseder, 2008](#)). In a meta-analysis of 1,600 observations, short-lived plant
12 functional types tended to have stronger relative responses than long-lived plants;
13 herbaceous plants responded more than woody plants, and annual herbs responded more
14 than perennial herbs [([Xia and Wan, 2008](#)); [Figure 6-1](#)]. Shrubs were notably less
15 responsive than trees ([Figure 6-1](#)), potentially because of the prevalence of shrubs in
16 more arid environments; overall, biomass responses increased linearly with mean annual
17 precipitation ([Xia and Wan, 2008](#)). There is also now more consistent and widespread
18 evidence that N additions increase aboveground biomass more than belowground
19 biomass, raising the shoot:root ratio among plants ([Li et al., 2015](#); [Lu et al., 2011b](#)).

20 The increase in aboveground growth of individual plant species is the best documented
21 response of plants to N, with fewer studies documenting belowground growth responses
22 and more complex physiological and ecosystem-scale responses (e.g., [Figure 6-1](#) and
23 [Figure 6-2](#)). [LeBauer and Treseder \(2008\)](#) found that N additions stimulated aboveground
24 productivity, but the relative stimulation was smaller than the response of individual
25 plants identified by [Xia and Wan \(2008\)](#). Belowground net primary productivity
26 responses to added N have not yet been synthesized because of lack of data ([LeBauer and](#)
27 [Treseder, 2008](#)). [Liu and Greaver \(2009\)](#) did not find a significant effect on net
28 ecosystem exchange, but forest ecosystem C content was increased by 6%.

29 In the 2008 ISA, the increase in plant growth and terrestrial productivity was attributed to
30 increases in foliar N content and related increases in photosynthesis. As noted earlier,
31 increases in plant N concentrations are widespread ([Koricheva et al., 1998](#)), particularly
32 in the foliage. [Koricheva et al. \(1998\)](#) had previously quantified increases in foliar N
33 concentrations among woody plants; [Xia and Wan \(2008\)](#) expanded this analysis to other
34 plant functional groups, with an overall stimulation of +28.5%. Aside from smaller
35 responses among legumes and broader functional groups containing legumes, there was a
36 relatively narrow range of responses across functional groups (+24–34%). Root N
37 concentrations show similar responses ([Li et al., 2015](#); [Xia and Wan, 2008](#)). Given the

1 mechanistic and empirical relationships between greater foliar N concentrations, higher
2 leaf concentrations of the C assimilating enzyme RubisCo ([Evans, 1989](#)), and greater
3 maximum rates of leaf-level photosynthesis in vascular plants ([Wright et al., 2004](#)), the
4 increases in foliar N observed with greater N supply have been linked to higher rates of
5 leaf-level photosynthesis [e.g., ([Teskey et al., 1994](#))]. Alternately, there was evidence in
6 the 2008 ISA that much of the additional foliar N could be physiologically inactive
7 ([Bauer et al., 2004](#)), consistent with the significant increase in free amino acids observed
8 by [Koricheva et al. \(1998\)](#). Increases in photosynthesis following N additions have been
9 observed across a variety of plant functional types, but higher rates of photosynthesis
10 have not been universally observed in long-term experiments [e.g., ([Talhelm et al., 2011](#);
11 [Elvir et al., 2006](#); [Chen et al., 2005b](#); [Newman et al., 2003](#); [Lajtha and Whitford, 1989](#);
12 [Gulmon and Chu, 1981](#))] and there have not been any broad syntheses or meta-analyses
13 of either leaf-level photosynthesis or gross primary productivity. There is a similar
14 mechanistic and empirical relationship between tissue N concentrations and respiration
15 rates, but this relationship has shifted in long-term N addition studies, providing further
16 evidence that much of the additional tissue N is physiologically inactive [e.g., ([Burton et](#)
17 [al., 2012](#); [Drake et al., 2008](#))].

18 Decreases in the quantity of C allocated belowground to roots, mycorrhizae, and root
19 exudation could provide a mechanism that increases aboveground plant growth in plants
20 and ecosystems that do not show gains in photosynthesis [e.g., ([Talhelm et al., 2011](#))].
21 Plants provide mycorrhizal fungal symbionts with C in exchange for nutrients, and the
22 abundance of mycorrhizal fungi and the rates at which these fungi colonize roots declines
23 when N is added to terrestrial ecosystems ([Treseder, 2004](#)), a finding that has since been
24 corroborated ([Li et al., 2015](#); [Treseder, 2008](#)). The decrease is particularly well
25 documented for ectomycorrhizal fungi ([Table 6-2](#)), but can also occur with arbuscular
26 mycorrhizal fungi [([van Diepen et al., 2010](#)); [Table 6-3](#)].

27 Nitrogen deposition can affect the physiology and abundance of soil microorganisms
28 through decreases in soil pH, increases in inorganic N availability, changes in soil food
29 webs, and shifts in the quantity and quality of available C ([Xia et al., 2015](#); [Manning et](#)
30 [al., 2008](#); [Treseder, 2008](#); [Koricheva et al., 1998](#)). There were some observations in the
31 2008 ISA that added N decreased microbial biomass. There is now more abundant
32 evidence that N deposition can affect microbial communities. In meta-analyses, N
33 additions have been shown to decrease microbial biomass ([Treseder, 2008](#)), microbial
34 biomass C ([Liu and Greaver, 2010](#)), and microbial biomass N ([Lu et al., 2011b](#)). In a
35 meta-analysis, [Treseder \(2008\)](#) found that the negative effects of added N on microbial
36 biomass increased in magnitude with the duration of the N additions and the cumulative
37 amount of added N. Notably, these observations of soil microbial biomass would include
38 the hyphal biomass of mycorrhizal fungi. There are fewer observations of N addition

1 effects at the level of individual microbial domains (e.g., bacteria, fungi), functional
2 groups (e.g., saprotrophic vs. mycorrhizal fungi), or other higher-level taxonomic groups,
3 and aside from the aforementioned decreases in mycorrhizal fungi, effects at these scales
4 appear to be less consistent ([Table 6-4](#)).

6.6.2. Biodiversity Summary

5 The 2008 ISA found evidence sufficient to infer a causal relationship between deposition
6 and the alteration of species richness, species composition, and biodiversity in terrestrial
7 ecosystems. Since 2008, there is now more widespread documentation of decreases in
8 lichen species richness as the result of N deposition in the U.S. [e.g., ([Geiser et al., 2010](#);
9 [Jovan, 2008](#))], and there are now direct observations that: (1) N deposition in the U.S. is
10 altering herbaceous plant species richness across a broad range of ecosystems, including
11 forests, grasslands, arid and semiarid ecosystems, and alpine tundra [e.g., ([Simkin et al.,](#)
12 [2016](#))], and (2) N deposition in the U.S. is changing mycorrhizal community composition
13 [e.g., ([Allen et al., 2016](#); [Lilleskov et al., 2008](#))]. Further, based on changes in mortality
14 and growth rates of overstory tree species, there is also now indirect evidence that N
15 deposition is altering overstory tree community composition [e.g., ([Dietze and Moorcroft,](#)
16 [2011](#); [Thomas et al., 2010](#))]. **The body of evidence is sufficient to infer a causal**
17 **relationship between N deposition and the alteration of species richness, community**
18 **composition, and biodiversity in terrestrial ecosystems.**

19 In forests, research since 2008 has provided evidence of altered understory plant, soil
20 microbial, arbuscular and ectomycorrhizal, and arthropod communities. Two new
21 assessments using forest inventory plots from the eastern U.S. have observed effects on
22 growth and mortality that likely impact forest overstory tree composition [e.g., ([Dietze](#)
23 [and Moorcroft, 2011](#); [Thomas et al., 2010](#))]. However, these data sets and analyses have
24 not directly been applied to assess changes in forest overstory composition either in
25 North America or Europe. Evidence for altered forest understory plant communities (also
26 known as herbaceous layer or groundcover vegetation) come from both the 2008 ISA and
27 the literature published since 2008. [Gilliam \(2006\)](#) reviewed nine studies on the effects of
28 N deposition on forest understory plant communities in North America and Europe,
29 including two European studies that documented shifts in understory plant community
30 composition along N deposition gradients ([Strengbom et al., 2001](#); [Brunet et al., 1998](#)). In
31 a new analysis of understory plant community composition, [Simkin et al. \(2016\)](#)
32 observed that N deposition increased herbaceous plant species richness where soil pH
33 was neutral or basic, but that N deposition above 11.6 kg N/ha/yr decreased herbaceous
34 species richness on acidic soils. Similar studies of plant community composition have
35 been conducted across N deposition gradients in Europe, with both [Verheyen et al.](#)

1 [\(2012\)](#) and [Dirnböck et al. \(2014\)](#) finding shifts in plant community composition toward
2 more nutrient-demanding and shade-tolerant plant species, but no loss of species
3 richness. For soil microbial communities, [Zechmeister-Boltenstern et al. \(2011\)](#) observed
4 shifts in soil microbial community composition along an N deposition gradient in Europe
5 and multiple N addition studies identified since 2008 have observed changes in microbial
6 community composition (e.g., [Zhao et al., 2014a](#); [Hobbie et al., 2012](#); [van Diepen et al.,
7 2010](#)). Among studies of how N affects forest ectomycorrhizal community composition,
8 there were changes in six out of seven studies identified ([Table 6-15](#)). This included four
9 studies where shifts in community composition could be directly or indirectly linked to N
10 deposition gradients in the U.S. or Europe.

11 Since 2008, new studies have quantified the impact of N additions on species richness,
12 species diversity, and community composition among vascular plants, bryophytes,
13 lichens, and soil microorganisms in alpine and Arctic tundra ecosystems in North
14 America, Europe, and Asia. Within the U.S., several N addition studies have documented
15 changes in plant community composition, including experiments in Colorado ([Farrer et
16 al., 2015](#); [Bowman et al., 2012](#)) and Washington ([Bishop et al., 2010](#)). In the North
17 Atlantic region of Europe, [Armitage et al. \(2014\)](#) observed shifts in community
18 composition and decreases in plant species richness among alpine heathlands located
19 along an N deposition gradient. Similarly, [Southon et al. \(2013\)](#) found decreasing
20 vascular plant species richness with increasing N deposition in heathlands in the U.K.
21 [Arens et al. \(2008\)](#) did not observe changes in community composition as a result of N
22 additions in Greenland, but shifts in plant community composition were observed in
23 longer (7 to 8 years) experiments in tundra ecosystems in China ([Song and Yu, 2015](#)),
24 Switzerland ([Bassin et al., 2013](#)), and Sweden ([Wardle et al., 2013](#)). Shifts in microbial
25 community composition were observed in several N addition experiments, including in
26 the U.S. in Colorado ([Farrer et al., 2013](#); [Nemergut et al., 2008](#)).

27 New research on lichens has added further evidence that lichen communities in the U.S.
28 and Europe are sensitive to current levels of atmospheric N deposition. Shifts in lichen
29 community composition attributable to atmospheric N pollution have been observed in
30 forests throughout the West Coast ([Jovan et al., 2012](#); [Geiser et al., 2010](#); [Jovan, 2008](#)),
31 in the Rocky Mountains ([McMurray et al., 2015](#); [Rogers et al., 2009](#)), and in southeastern
32 Alaska ([Schirokauer et al., 2014b](#)). Outside of the U.S., changes in lichen community
33 composition have been observed with increased atmospheric NO₂ concentrations in Nova
34 Scotia, Canada ([Gibson et al., 2013](#)) and experimental N additions in Sweden ([Johansson
35 et al., 2012](#)).

36 Since 2008, there have been direct observations of reduced species richness along
37 atmospheric N deposition gradients for grasslands in the U.S. ([Simkin et al., 2016](#)) and in

1 Europe ([Pannek et al., 2015](#); [Field et al., 2014](#); [Gaudnik et al., 2011](#); [Stevens et al.,](#)
2 [2011a](#); [Stevens et al., 2011b](#); [Dupre et al., 2010](#); [Stevens et al., 2010b](#); [Stevens et al.,](#)
3 [2010a](#)). Studies in both the U.S. and in Europe have found that the effects of N deposition
4 on grassland communities are often dependent on soil pH [e.g., ([Simkin et al., 2016](#);
5 [Stevens et al., 2011a](#); [Maskell et al., 2010](#); [Stevens et al., 2010b](#))]. Information about
6 changes in mycorrhizal communities in grasslands was limited and provided mixed
7 results ([Chen et al., 2014](#)); while of the five studies identified investigating compositional
8 changes to soil microbial communities in grasslands, four observed shifts in composition
9 ([Table 6-20](#)).

10 Research since 2008 from N deposition gradient studies and N addition experiments in
11 U.S. arid and semiarid regions has been dominated by research from southern California,
12 which has provided evidence that higher N availability alters plant community
13 composition through an increase in invasive annual plants ([Cox et al., 2014](#); [Allen et al.,](#)
14 [2009](#); [Rao et al., 2009](#)). Many of these studies documented changes in plant community
15 composition, with fewer observations of plant species loss. Evidence for shifts in plant
16 community composition is particularly strong for CSS and chaparral ecosystems near the
17 southern California coast and in areas of the Mojave Desert downwind of major southern
18 California population centers. An important effect of N deposition in arid ecosystems is
19 an increase in N availability in the interspaces between shrubs, allowing the growth of
20 annual grasses and forbs, which can grow and reproduce during the brief seasonal periods
21 with adequate moisture availability ([Brooks, 2003](#)). This phenomenon provides a more
22 continuous fuel bed for wildfires, increasing fire frequency and shifting plant community
23 composition away from species that are not fire-adapted ([Padgett and Allen, 1999](#); [Allen](#)
24 [et al., 1998](#)). Relative to plants, there are fewer studies of N effects on microbial
25 biodiversity in arid and semiarid ecosystems, with these studies showing mixed results
26 ([Table 6-22](#)).

6.6.3. Critical Loads Summary

27 The 2008 ISA documented efforts to develop CLs in the U.S. However, the CLs for
28 terrestrial ecosystems available in 2008 were for a subset of western ecosystems. There
29 were no published assessments of N deposition CLs spanning ecosystems across the U.S.
30 Since the 2008 ISA, there has been substantial work on CLs for N for U.S. ecoregions. A
31 large body of work has been published on CLs for N since the 2008 ISA. Notably, the
32 USDA-FS published *Assessment of Nitrogen Deposition Effects and Empirical Critical*
33 *Loads* ([Pardo et al., 2011c](#)), which reports CLs for various biological and biogeochemical
34 endpoints in terrestrial ecoregions (Omernick Level 1) in the U.S.

1 Most of the published CLs included in the [Pardo et al. \(2011c\)](#) assessment or published
2 subsequently have covered lichens, mycorrhizae, and herbaceous and understory plant
3 species. There are still relatively few observations of CLs for overstory tree species.
4 There do not appear to have been any CLs published for birds, mammals, or arthropods
5 in terrestrial ecosystems. In general, CLs were higher in regions that experienced greater
6 rates of ambient N deposition. In part, these higher critical loads may represent previous
7 ecological change caused by historical N deposition. This pattern would explain why the
8 empirical CL is often above ambient deposition even as that deposition increases in the
9 same ecosystem type across a region ([Pardo et al., 2011c](#)). The CLs published since the
10 publication of the USDA-FS assessment by [Pardo et al. \(2011c\)](#) often fall into the range
11 of CLs identified by ([Pardo et al., 2011c](#)), particularly if these CLs assess similar
12 ecological endpoints. The new information is presented in tandem with the CLs by [Pardo](#)
13 [et al. \(2011c\)](#) in [Table 6-28](#). Notably, the CLs reported for [Pardo et al. \(2011c\)](#) are a
14 range for the entire Level 1 ecoregion, whereas the new CL estimates are either for the
15 entire ecoregion or specific ecosystems within each respective ecoregion.

Table 6-28 Critical loads for nitrogen by [Pardo et al. \(2011c\)](#) and more recent critical load information.

The critical loads (CLs) reported for [Pardo et al. \(2011c\)](#) are for Level 1 Ecoregions, whereas the new CL information may be for more specific ecosystems within each respective Ecoregion (e.g., California coastal sage scrub within the Mediterranean California Ecoregion; this is noted in the 5th column of the table entitled “Type of Ecosystem”).

Ecoregion (Level 1)	Pardo et al. (2011c)		New Critical Load Information

APPENDIX 7. AQUATIC BIOGEOCHEMISTRY

1 This appendix summarizes recent advancements in understanding the effects of nitrogen
2 (N) and sulfur (S) deposition on aquatic biogeochemical processes and cycles. Freshwater
3 systems of the U.S. include lakes (lentic systems), rivers and streams (lotic systems), and
4 wetlands. The latter, including bogs, fens, marshes, and swamps, are discussed in
5 [Appendix 11](#) and [Appendix 12](#). The freshwater section ([Appendix 7.1](#)) is further
6 subdivided into N and S sources ([Appendix 7.1.1](#)); ecosystem processes, effects, and
7 indicators ([Appendix 7.1.2](#)); monitoring ([Appendix 7.1.3](#)); modeling ([Appendix 7.1.4](#));
8 national scale sensitivity and chemical recovery ([Appendix 7.1.5](#)); water quality criteria
9 ([Appendix 7.1.6](#)); and a summary ([Appendix 7.1.7](#)).

10 [Appendix 7.2](#) is an overview of the complex biogeochemical processes affected by N
11 loading to estuaries (where fresh water from rivers meets the salt water of oceans) and
12 other near-coastal areas such as lagoons and open ocean areas near coastlines. Inputs of
13 N, including atmospheric deposition ([Appendix 7.2.1](#)), to the highly variable estuarine
14 environment ([Appendix 7.2.2](#)), and factors such as dissolved oxygen (DO)
15 ([Appendix 7.2.3](#)) and pH ([Appendix 7.2.4](#)) affect N cycling. Key processes and indicators
16 of N cycling are discussed in [Appendix 7.2.5](#) and [Appendix 7.2.6](#) followed by monitoring
17 ([Appendix 7.2.7](#)), modeling ([Appendix 7.2.8](#)), national scale sensitivity ([Appendix 7.2.9](#)),
18 water quality criteria ([Appendix 7.2.10](#)) and a summary ([Appendix 7.2.11](#)).

19 Biological effects and indicators linked to altered aquatic biogeochemistry are discussed
20 in [Appendix 8](#) (Biological Effects of Freshwater Acidification), [Appendix 9](#) (Biological
21 Effects of Freshwater Nitrogen Enrichment), [Appendix 10](#) (Biological Effects of
22 Nitrogen Enrichment in Estuaries and Near-Coastal Systems), and [Appendix 12](#)
23 (Non-Acidifying Effects of Sulfur).

7.1. Biogeochemistry of Nitrogen and Sulfur in Freshwater Systems

24 As described in the *2008 Integrated Science Assessment for Oxides of Nitrogen and*
25 *Sulfur-Ecological Criteria* (hereafter referred to as the 2008 ISA), the most common and
26 well-documented aquatic effects are acidification and eutrophication, which may occur
27 simultaneously in some water bodies. Since the 2008 ISA, there have been additional
28 estimates of the proportion of total N loading in freshwater systems attributed to
29 atmospheric deposition and refinements in spatial and temporal trends of N and S
30 deposition across the U.S. Chemical indicators of N deposition identified by the 2008

1 ISA were nitrate (NO_3^-) and dissolved inorganic nitrogen (DIN) concentrations in surface
2 waters. Surface water chemistry indicative of acidic conditions and acidification effects
3 includes concentrations of sulfate (SO_4^{2-}), NO_3^- , inorganic aluminum (Al), calcium (Ca),
4 sum and surplus of base cations, acid neutralizing capacity (ANC), and surface water pH.
5 Continued monitoring of these indicators provides some evidence of chemical recovery
6 from acidification in some U.S. surface waters. A number of studies since 2008 have
7 focused on improving understanding of aquatic acidification and eutrophication processes
8 mediated by N. Many of these have focused on pathways of pollutant and other
9 constituent movement within ecosystems, including monitoring studies of various kinds.
10 **The body of evidence is sufficient to infer a causal relationship between N and S**
11 **deposition and the alteration of freshwater biogeochemistry**, which is consistent with
12 the conclusions of the 2008 ISA.

13 Acidification of freshwater ecosystems occurs in response to either S or N deposition
14 alone or in combination. This is because both N and S deposition can act as acidifying
15 agents. Acidifying deposition effects on biogeochemical processes in soils ([Appendix 4](#))
16 have significant ramifications for the water chemistry and biological functioning of
17 associated surface waters. Surface water chemistry integrates direct air-to-water
18 deposition with deposition impacts on soil chemistry of hydrologically connected
19 terrestrial ecosystems within the watershed. Deposited N and S interact with the soils and
20 sediments of terrestrial and aquatic ecosystems via oxidation and reduction reactions as
21 well as biological uptake and microbially mediated processes.

22 Acidification of fresh water may occur as a chronic or an episodic condition
23 ([Appendix 8.2](#)). The 2008 ISA defined chronic acidification by reference to annual
24 average conditions, often quantified as summer and fall chemistry for lakes and as spring
25 baseflow chemistry for streams. Episodic acidification refers to conditions during
26 rainstorms or snowmelt when water has a relatively short residence time in soil before
27 entering surface water. During these stormflow events, proportionately more water drains
28 through upper soil horizons, providing less neutralization of atmospheric acidity
29 compared with flow through deeper soil horizons. Episodes of acidification are typified
30 by lower pH, lower ANC, and higher inorganic Al concentration in surface water than
31 during baseflow conditions. The short-term change in chemical conditions may be toxic
32 or lethal to aquatic biota ([Appendix 8](#)). These conditions are caused partly by acidifying
33 deposition (SO_4^{2-} , NO_3^-) and partly by natural processes, including base cation dilution
34 and flushing of organic acids into drainage water. It is known that the biota in many
35 streams/lakes are impacted when the ANC is consistently below 50 ueq/L. For this
36 reason, the U.S. EPA National Lakes Assessment used an ANC threshold of >50 ueq/L as
37 indicative of nonacidified water bodies ([U.S. EPA, 2009b](#)).

1 In aquatic systems, N is a nutrient that stimulates growth of primary producers (algae
2 and/or aquatic plants). Even small inputs of N in low nutrient water bodies such as
3 remote headwater and lower order streams and alpine lakes can increase nutrient
4 availability, alter the balance of N and phosphorus (P) nutrients, affect biogeochemical
5 processing of N and increase the productivity of photosynthesizing organisms, resulting
6 in a increase in pool of fixed carbon (C). Nutrient enrichment leads to changes in aquatic
7 assemblages and biodiversity in freshwater ([Appendix 9](#)) and coastal regions
8 ([Appendix 10](#)). The freshwater ecosystems in the U.S. most likely to be sensitive to
9 nutrient enrichment from N deposition are headwater streams, lower order streams, and
10 alpine lakes which have very low nutrients and productivity and are far from local
11 pollution sources [[Appendix 9.1.1.2](#);[U.S. EPA, 2008a](#)]. High-elevation lakes in the
12 western U.S. are naturally oligotrophic and are considered among the aquatic ecosystems
13 most sensitive to N deposition ([Williams et al., 2017b](#)). A portion of these lakes and
14 streams in the western U.S. are in Class I wilderness areas ([Williams et al., 2017b](#); [Clow
15 et al., 2015](#); [Nanus et al., 2012](#)). In higher order streams, N deposition typically mixes
16 with N derived from other nonatmospheric sources, including urban/suburban point and
17 nonpoint sources, industrial sources, and agricultural sources. The long-held paradigm
18 that fresh waters are typically P limited has been replaced by an understanding that both
19 N and P can limit primary production, and that nutrient limitation can be a dynamic and
20 transient process ([Paerl et al., 2016b](#); [Paerl et al., 2014](#); [Conley et al., 2009](#); [Paerl, 2009](#)).
21 Although over-enrichment with P is not specifically addressed in this assessment, recent
22 trends in increased atmospheric deposition of P ([Appendix 9.1.1.2](#)) have ramifications for
23 nutrient stoichiometry.

24 The geochemical processes and associated chemical indicators discussed in this appendix
25 can be considered to indicate or suggest eutrophication or acidification. Some of the
26 biogeochemical alterations associated with N and S deposition link directly to the
27 biological effects discussed in subsequent appendices. Others do not cause direct
28 biological effects but are precursory steps to changes in soil or water chemistry that can
29 lead to biological effects. [Table 7-1](#) summarizes the key freshwater indicators for N
30 driven nutrient enrichment and acidification and the section of the ISA that discusses
31 each endpoint.

32 A separate appendix addresses the biogeochemistry of terrestrial responses to nutrient
33 and acidic additions ([Appendix 4](#)). Aquatic and terrestrial systems are interconnected and
34 many of the biogeochemical processes discussed herein bridge the transitions between
35 these two environmental compartments.

Table 7-1 Summary of key freshwater indicators of eutrophication and acidification.

Endpoint	N Driven Nutrient Enrichment	Acidification	Section of ISA That Discusses Endpoint
Chemical indicator			
Water NO ₃ ⁻ concentration	X	X	7.1.2.1
Water SO ₄ ²⁻ concentration		X	7.1.2.2
Water pH		X	7.1.2.5
Water ANC		X	7.1.2.6
Water base cation surplus		X	7.1.2.7
Water inorganic Al concentration		X	7.1.2.8
Biological indicator			
Diatoms	X		9.2.1
Nutrient ratios	X		9.2.2
Phytoplankton biomass shift	X		9.2.3
Periphyton/microbial biomass	X		9.2.4
Chlorophyll a	X		9.2.5

7.1.1. Nitrogen and Sulfur Sources

1 In fresh water, both S and N can contribute to acidification while nutrient enrichment
 2 effects are associated with N. Long-range atmospheric transport of N and S can affect
 3 remote freshwater catchments far from pollutant sources. Major sources of N and S and
 4 deposition trends are discussed in [Appendix 2](#).

7.1.1.1. Nitrogen Sources

5 Since the 2008 ISA, additional analyses have refined the understanding of N sources and
 6 deposition trends ([Appendix 2](#)) to freshwater systems. [Sobota et al. \(2013\)](#) synthesized
 7 data on N inputs to lands and waterways throughout the U.S. They found that
 8 human-caused N inputs are ubiquitous, but are spatially heterogeneous. The highest N

1 loads generally occurred in the Midwest, Mid-Atlantic region, central and southern
2 California, and portions of the Columbia River Valley. Synthetic fertilizer was estimated
3 to be the single largest source of human-caused N inputs to 41% of the water resource
4 units analyzed, followed by atmospheric deposition (33%) and biological N fixation
5 (22%). A tool for calculating net anthropogenic nitrogen inputs (NANI) was developed
6 for watersheds across the contiguous U.S. at the county level ([Hong et al., 2013](#), [2011](#)).
7 The NANI Calculator Toolbox takes into consideration fertilizer N application,
8 agricultural N fixation, net food and feed imports, and atmospheric sources of N. Unlike
9 S, geological sources of N are rare.

10 In a U.S. Geological Survey (USGS) National Water Quality Assessment (NAWQA)
11 report on occurrence and distribution of nutrients in streams and groundwater (based on
12 water quality assessments conducted from 1992 to 2001), atmospheric deposition was
13 identified as the largest nonpoint source of N in the less developed watersheds (areas
14 dominated by forest or rangeland with $\leq 5\%$ urban and $\leq 25\%$ agricultural land) in the
15 eastern part of the country where deposition rates have historically been highest, in areas
16 near the Great Lakes, and the mountainous west ([Dubrovsky et al., 2010](#)). Atmospheric
17 sources have been shown to be quantitatively important ($>33\%$ of total input) to Lake
18 Tahoe, CA/NV ([Sahoo et al., 2013](#); [Dolislager et al., 2012](#)), Flathead Lake, MT ([Ellis et
19 al., 2015](#)), and Nine Mile Run in Pittsburgh, PA ([Divers et al., 2014](#)). Even in lowland
20 lakes, N from atmospheric sources has been shown to contribute appreciably to the total
21 input of N. In a study of nutrient sources to Saginaw Bay, MI, N deposition was
22 estimated to comprise 10 to 11% of the total N input from 1987 to 2002 ([He et al., 2014](#)).

23 Nitrogen is deposited in various reduced and oxidized forms, including organic N, and, in
24 wet or dry forms as well ([Appendix 2](#)). Oxidized N is emitted into the atmosphere mainly
25 from motor vehicles, electricity generating units, and industry. Reduced N is emitted
26 mainly from agricultural sources such as livestock and fertilizer applications. Direct
27 deposition of N to open water surfaces constitutes an appreciable source of N to relatively
28 large freshwater lakes and rivers, estuaries, and coastal marine waters ([Appendix 7.2.1](#)).
29 Alternatively, N can be deposited in the watershed of receiving waters and then move
30 through soils before entering surface waters. Atmospheric deposition of reduced N has
31 increased relative to oxidized N in parts of the U.S. including the East and Midwest in the
32 last few decades, shifting from a NO_3^- dominated to an ammonium (NH_4^+) dominated
33 condition, and this trend is expected to continue under existing emissions controls ([Li et
34 al., 2016d](#); [Pinder et al., 2008](#); [U.S. EPA, 2008a](#)). Since the 2008 ISA, there is a greater
35 understanding of the potential ecological changes associated with the increase in
36 deposition of reduced N relative to oxidized N in terrestrial, freshwater and coastal
37 systems ([Chapter 1.2.2.5](#)).

1 [Table 7-2](#) summarizes key studies that have quantified total N loading in freshwater
2 systems from atmospheric deposition. In the 2008 ISA, the difficulty in determining the
3 percentage of atmospheric N in lowland waters was noted because there are so many
4 other point and nonpoint sources of N to drainage waters in these areas ([U.S. EPA,
5 2008a](#)). As described in the 2008 ISA, a large fraction of atmospheric N deposition is
6 retained in most forested ecosystems with less retention in urban, suburban, and
7 agricultural lands ([U.S. EPA, 2008a](#)). The atmospheric fraction that does leach to streams
8 can make a substantial contribution to total N inputs to downstream waters, especially in
9 the eastern U.S. ([Driscoll et al., 2003d](#)). Apportionment of N sources to identify the
10 contribution of atmospherically derived N was described in a few studies in the 2008 ISA
11 ([U.S. EPA, 2008a](#)). In Spatially Referenced Regressions on Watershed Attributes
12 (SPARROW) modeling studies, approximately 70% of the N in headwater streams in the
13 northeastern U.S. was judged to be from N deposition ([Alexander et al., 2007](#); [Alexander
14 et al., 2002](#)). This SPARROW model application used only wet deposition as the measure
15 of N deposition. A large amount of N from nonpoint source urban influences (this is most
16 likely primarily the dry deposition of exhaust N gases) often approximately doubles the
17 importance of N deposition as an N source to higher-order river systems ([Howarth,
18 2008a, b](#)).

19 Several new studies published since the 2008 ISA further quantified N sources, including
20 atmospheric contribution, to lakes and streams ([Table 7-2](#)). [Sebestyen et al. \(2008\)](#)
21 showed the dominant direct role of atmospheric NO_3^- in snowmelt runoff at Sleepers
22 River, VT. At peakflow, 48% of NO_3^- was from atmospheric sources in this forested
23 watershed. In the Uinta Mountains, UT, at least 70% of NO_3^- was atmospherically
24 deposited to high alpine lakes from distant anthropogenic sources ([Hundey et al., 2016](#)).
25 Approximately 60% of the reactive N was from agriculture, based on isotopic analysis
26 and modeling of snow, inflow and lake NO_3^- . The authors suggested these findings are
27 widely applicable to other western U.S. alpine sites based on comparison of isotope and
28 precipitation data in the region.

Table 7-2 Summary of recent studies quantifying nitrogen deposition contribution to total nitrogen loading in freshwater systems.

Region	Total N Loading Due to Atmospheric Deposition	Method	Reference
Lake Tahoe, CA	Approximately 57%, NH ₃ as the dominant component and nitric acid and NO ₃ ⁻ representing a smaller but not insignificant proportion of total N.	Field data and Lake Tahoe watershed model	Sahoo et al. (2013) Dolislager et al. (2012)
Flathead Lake, MT	Atmospheric loading of NH ₄ ⁺ averaged 44% of total load between 1985 and 2004 and was the primary form of N in deposition.	Field data and statistical analysis, linear regression	Ellis et al. (2013)
Unita Mountains, UT	At least 70% of NO ₃ ⁻ in the high alpine lakes is from atmospheric deposition. Most reactive N originates from agricultural activities (approximately 60%).	Isotopic analysis and bayesian-based stable isotope mixing model	Hundey et al. (2016)
Saginaw Bay, MI	N deposition was estimated to be 10 to 11% of total N from 1987–2002.	Multiple databases of land use/cover, hydrography, animal production, fertilizers, combined wastewater overflows	He et al. (2014)
St. Lawrence River, Quebec City	Atmospheric N contributed about 0 to 4% of total N load in the summer; in the spring, this source represented 4 to 11% of total N.	Isotopic analysis	Thibodeau et al. (2013)
Quinnipiac River, CT	Atmospherically deposited NO ₃ ⁻ represented <6% of N loading; however, during storm events, atmospheric deposition represented up to 50% of stream NO ₃ ⁻ but varied widely by site.	Stable isotope ratios	Anisfeld et al. (2007)
Baltimore Long-Term Ecological Research site	Atmospheric contributions ranged from 5 to 94% during storm flow conditions and represented approximately 50% of the highest NO ₃ ⁻ loads during storms.	N watershed mass balances and stable isotopes	Kaushal et al. (2011)
Tributary to Teff Run, MD	Contributions of atmospheric N to surface water in an Appalachian Mountain stream were most evident during hydrological episodes, but baseflow accounted for much of the NO ₃ ⁻ loss in stream water.	Isotopic analysis	Sabo et al. (2016)
Nine Mile Run in Pittsburgh, PA	34% of NO ₃ ⁻ in stream water was atmospheric in origin during storm events while 94% of stream water NO ₃ ⁻ was from sewage sources during baseflow conditions.	Stable isotope ratios	Divers et al. (2014)
Suburban watershed (Lisha Kill) in eastern New York	About 40% or more of NO ₃ ⁻ in stream water in a suburban watershed during storm runoff was attributed to direct NO ₃ ⁻ deposition.	Stable isotope ratios	Burns et al. (2009)

Table 7-2 (Continued): Summary of recent studies quantifying nitrogen deposition contribution to total nitrogen loading in freshwater systems.

Region	Total N Loading Due to Atmospheric Deposition	Method	Reference
Sleepers River watershed, northeastern Vermont	In this forested watershed 48% of NO ₃ ⁻ was from atmospheric sources at peakflow. More than half of the NO ₃ ⁻ in soil and shallow groundwater after the start of snowmelt originated directly from atmospheric deposition.	Isotopic tracers and mixing analysis Stable isotope ratios, hydrochemistry, end-member mixing analyses	Sebestyen et al. (2008)
Key pre-2008 literature			
16 northeastern watersheds	Approximately 70% of the N in headwater streams was from N deposition and the net transport of N from headwater streams was between 40 and 65% of total N.	SPARROW	Alexander et al. (2002) ; Alexander et al. (2007)
16 large northeastern river basins	N deposition contributes approximately 31% of the total N load to large river basins, although this fraction varies regionally. Values for watersheds in northern New England were substantially higher and atmospheric deposition dominated.		Boyer et al. (2002)
Eight watersheds in New York and New England	Atmospheric deposition was second largest N input for the eight watersheds (11 to 36% of total) with four watersheds ranging from 34 to 36%.	PnET-BGC and WATERS N	Driscoll et al. (2003d)

N = nitrogen; NH₃ = ammonia; NH₄⁺ = ammonium; NO₃⁻ = nitrate; SPARROW = Spatially Referenced Regressions on Watershed Attributes.

1 Additional information is available since the 2008 ISA on atmospheric contributions of
2 reduced versus oxidized N to lakes. In Lake Tahoe, where a total maximum daily load
3 (TMDL) allocation was adopted in 2011 by California and Nevada to reduce nutrient
4 loading, atmospheric N represented approximately 57% of the total N loading to the lake
5 ([Sahoo et al., 2013](#)). In this large alpine lake in the Sierra Nevada mountain range, an
6 estimated 185 metric tons of N was directly deposited from the atmosphere, with NH₄⁺ as
7 the dominant component and nitric acid plus NO₃⁻ representing a smaller, but not
8 insignificant, proportion of total N ([Dolislager et al., 2012](#)). In Flathead Lake, MT,
9 atmospheric loading of NH₄⁺ averaged 44% of the total load between 1985 and 2004 and
10 was the primary form of N in atmospheric deposition ([Ellis et al., 2013](#)). There was an
11 increase in atmospheric loading of NO₃⁻ + nitrite (NO₂⁻; +48%) and NH₄⁺ (+198%) and
12 decrease in total P loading (-135%).

13 In the studies reviewed in the 2008 ISA, the role of atmospheric deposition in
14 downstream urban and residential water bodies was rarely addressed ([U.S. EPA, 2008a](#)).

1 New studies using stable isotope ratios to quantify N loading in streams have
2 characterized the contributions of atmospheric N in these systems. Several of these
3 studies have shown shifts to higher atmospheric N contributions during storm events. In
4 the Quinnipiac River in Connecticut which drains into Long Island Sound,
5 atmospherically deposited NO_3^- averaged <6% of average N loading during baseflow
6 conditions; however, during storm events, atmospheric deposition represented up to 50%
7 of stream NO_3^- , although the amount varied widely by site ([Anisfeld et al., 2007](#)). In the
8 St. Lawrence River outlet at Quebec City, Canada, isotopic analysis of N inputs indicated
9 that atmospheric N contributed about 0 to 4% of total N load in the summer, while in the
10 spring this source was 4 to 11% of total N ([Thibodeau et al., 2013](#)). In forested,
11 agricultural and urban watersheds at the Baltimore Long-Term Ecological Research site,
12 atmospheric N contributions ranged from 5 to 94% during storm flow conditions and
13 represented approximately 50% of peak storm NO_3^- ([Kaushal et al., 2011](#)). In Nine Mile
14 Run in Pittsburgh, PA, 34% of NO_3^- in stream water was atmospheric in origin during
15 storm events, whereas during baseflow conditions 94% of stream water NO_3^- was from
16 storm drain and wastewater treatment sources ([Divers et al., 2014](#)). In another study in
17 Pennsylvania, stream water from Spring Creek was monitored at sites from upstream to
18 downstream during storm flow events to assess changes in N sources ([Buda and](#)
19 [DeWalle, 2009](#)). For the forested upstream site, the atmospheric contribution varied by
20 storm size. In the downstream urbanized watershed, atmospheric NO_3^- was an important
21 N source at peak flow, especially during short-duration storms when overland flow was
22 prevalent.

23 [Burns et al. \(2009\)](#) applied dual isotope analysis of NO_3^- to determine the dominant
24 sources and processes that affect NO_3^- concentrations in six streams on different land
25 uses in New York. The dual isotope data revealed varying sources and processes that
26 affect NO_3^- concentration among the six stream watersheds. Atmospheric NO_3^- was
27 about half of stream NO_3^- during storms because of rapid shunting of runoff through
28 storm drains. The suburban watershed that had no septic or wastewater influence showed
29 NO_3^- concentrations only slightly higher than those observed in two forested watersheds.
30 Overall, these studies appear to have characterized relatively well the atmospheric
31 contribution of N to water bodies that have multiple sources of N. Results show
32 substantial variability, with atmospheric sources typically being most pronounced during
33 high-flow conditions.

7.1.1.2. Sulfur Sources

34 The 2008 ISA reported that there were both depositional and geological sources of SO_4^{2-}
35 to aquatic ecosystems. SO_x deposition to ecosystems is primarily in the chemical form

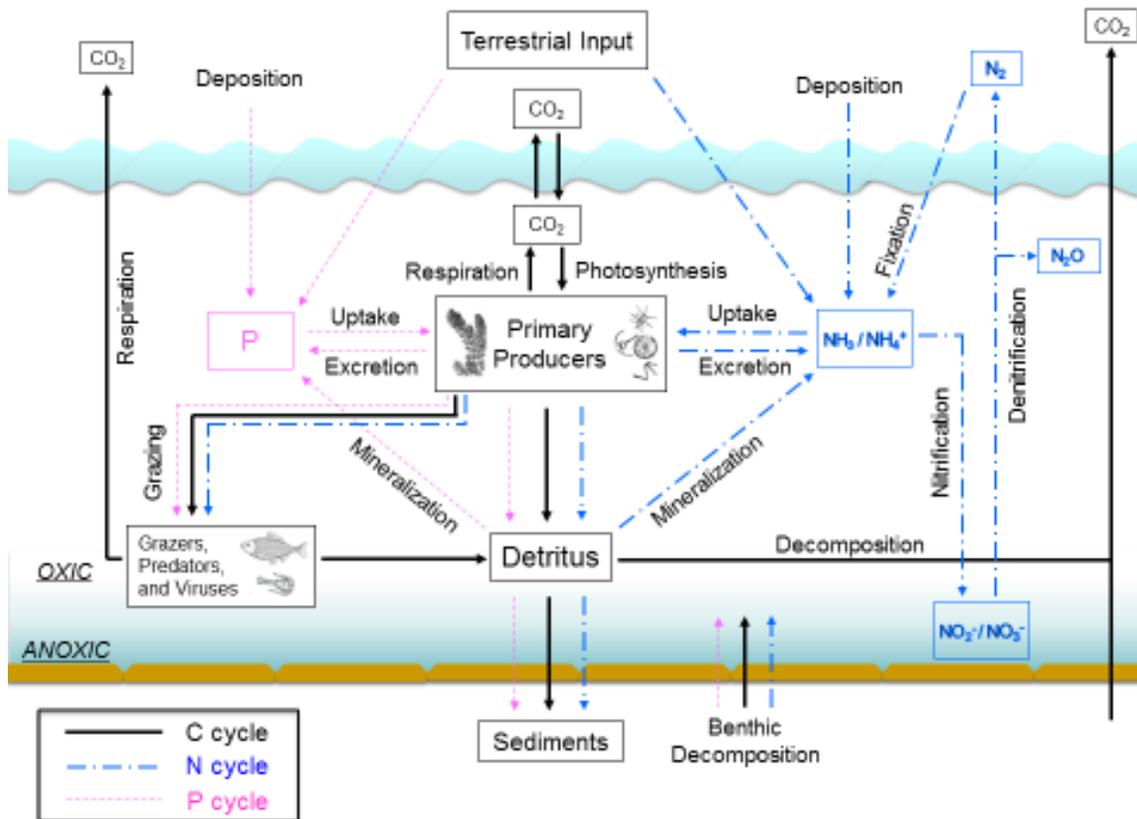

1 SO₄²⁻, which is a moderately mobile anion in the soil solution and surface water of many
2 glaciated acid-sensitive watersheds in the northeastern U.S. Note that SO₄²⁻ is less mobile
3 in unglaciated watersheds of the southeastern U.S. ([Rice et al., 2014](#)). Other major
4 sources of SO₄²⁻ in ecosystems include mineralization of S from organic matter and
5 weathering of geologic sources of S, including pyrite minerals. Anthropogenic soil and
6 rock disturbance in the form of road cuts or mine tailings can increase geological
7 contributions of SO₄²⁻ to soil or surface water by exposing S bearing minerals to oxygen
8 (O₂), promoting mineral oxidation and the release of SO₄²⁻. Acid mine drainage is one
9 result of this process, and is prevalent in many parts of the Appalachian Mountain region.
10 New published evidence regarding the influence of geologic sources of S or acid mine
11 drainage on stream chemistry has not been reviewed for this ISA.

12 The 2008 ISA described how SO_x deposition causes the release of S from terrestrial to
13 aquatic ecosystems via SO₄²⁻ leaching, and other changes in surface water chemistry
14 caused by increasing SO₄²⁻ concentrations. At that time, acidification of surface waters at
15 most locations in the U.S. where acidification has been documented in response to
16 deposition was caused mainly by SO₄²⁻ ([Driscoll et al., 2001b](#); [Sullivan, 2000](#)). This was
17 partly due to the mobility of SO₄²⁻ in many (especially northeastern) waters draining
18 from terrestrial ecosystems to aquatic ecosystems. It was also known that the mobility of
19 SO₄²⁻ varies geographically, with S adsorption on soils most significant in regions that
20 were unglaciated during the most recent glaciation. This includes many acid-sensitive
21 watersheds in the southeastern U.S. In the most recently glaciated Northeast and upper
22 Midwest, a substantial component of the atmospherically deposited S accumulates in
23 organic pools in soil, although microbial mineralization can transform this organic S back
24 into more mobile SO₄²⁻.

25 A mass balance study by [Mitchell et al. \(2011\)](#) of 15 watersheds located in the
26 northeastern U.S. and southeastern Canada suggested substantial sources of SO₄²⁻ in
27 watershed soils. The internal S sources were attributed mainly to mineralization of S
28 stored in soils in response to decades of atmospheric S deposition. In a study of 16 lakes
29 from the original Adirondack Long-Term Monitoring program from 1984 to 2010
30 [Mitchell et al. \(2013\)](#) observed discrepancies in the calculated S mass balances that were
31 associated with discharge. These results suggested that internal S sources have become
32 more important to the watershed S budget as atmospheric S deposition has decreased.
33 Declines in lake SO₄²⁻ concentrations have been observed in locations where S deposition
34 has decreased significantly, such as in the Adirondack Mountains [([Mitchell et al., 2013](#));
35 [Appendix 7.1.5.1](#)].

7.1.2. Ecosystem Processes, Effects, and Indicators

1 New information on biogeochemical indicators and processes of eutrophication and
2 acidification are presented in the following sections, along with summaries of
3 information from the 2008 ISA. These processes may occur either in sequence or
4 simultaneously in a given geographic area. Impacts of N and S deposition on aquatic
5 ecosystems can be described by changes in acid-base chemical indicators including SO_4^{2-}
6 concentration, NO_3^- concentration, DIN concentration, inorganic Al concentration, base
7 cation concentrations, base cation surplus (BCS), pH, and ANC. Surface water NO_3^-
8 concentration can reflect both eutrophication and acidification. Water pH and the
9 concentrations of ANC, SO_4^{2-} , and inorganic Al are commonly used indicators of the
10 likelihood of surface water acidification ([U.S. EPA, 2008a](#)). As reported in the 2008 ISA
11 and summarized in [Figure 7-1](#), the biogeochemical cycles of N, P, and C are linked in
12 freshwater ecosystems. Nitrogen deposition can alter the pools and fluxes of the C, N,
13 and P cycles, including nitrification and denitrification. Sulfur deposition adds SO_4^{2-}
14 directly to soil solutions and to surface waters with effects on ecosystems ([Appendix 12](#)),
15 but many ecological effects are mediated through the indirect effects of SO_4^{2-} on the
16 exchange of acidic and basic cations on soils. The chemical indicators of deposition
17 discussed below also link to biological effects of acidifying deposition ([Appendix 8](#)) and
18 freshwater N enrichment ([Appendix 9](#)).

C = carbon; CO₂ = carbon dioxide; N = nitrogen; P = phosphorus.
 Modified from [U.S. EPA \(2008a\)](#).

Figure 7-1 Nitrogen cycle in freshwater ecosystem.

7.1.2.1. Nitrogen in Surface Waters

1 As reviewed in the 2008 ISA and supported by more recent studies, the fate and transport
 2 of deposited N is influenced by characteristics of the catchment and the receiving waters.
 3 Retention of N varies among watershed types such that similar amounts of deposition can
 4 result in different rates of N leaching, depending on catchment characteristics
 5 [[Appendix 9.1.1.2;\(Bergström, 2010\)](#)]. In most surface waters of the U.S., dissolved
 6 inorganic N (DIN, the sum of the concentrations of NO₃⁻, NH₄⁺, and nitrite) is
 7 overwhelmingly dominated by NO₃⁻. As summarized in the 2008 ISA, high
 8 concentrations of NO₃⁻ in lakes and streams, indicative of terrestrial ecosystem N
 9 saturation, have been found at a variety of locations throughout the U.S. Surface water
 10 NO₃⁻ is a chemical indicator for both eutrophication and acidification. Nitrate contributes

1 to the acidity of many lakes and streams in the eastern U.S. that have been affected by
2 acidifying deposition, especially during spring snowmelts and under high-flow
3 conditions.

4 In the 2008 ISA, a study evaluating the relationship between wet deposition and DIN
5 concentration in 4,296 lakes across Canada, Europe, and the U.S. showed a significant
6 correlation between increases in N wet deposition and increases in lake DIN
7 concentration ([Bergström and Jansson, 2006](#)). More recent studies from some regions of
8 the U.S. [(e.g., [Driscoll et al., 2016](#); [Eshleman and Sabo, 2016](#); [Strock et al., 2014](#);
9 [Eshleman et al., 2013](#)); [Appendix 7.1.5.1](#)] showed recent declines in concentrations of
10 NO_3^- in surface waters that are consistent with declines in N deposition. Using the Lake
11 Multi-Scaled Geospatial and Temporal Database of the Northeast Lakes of the U.S.
12 (LAGOS-NE) containing water quality data from 2,913 lakes, [Oliver et al. \(2017\)](#)
13 identified atmospheric deposition as the main driver of declines in total N (TN)
14 deposition and lake TN:total P (TP) ratios from 1990 to 2011.

15 Reactive N can be taken up by terrestrial and aquatic biota or stored in soils and/or
16 sediments, be re-emitted back to the atmosphere by the microbial process of
17 denitrification ([Appendix 7.1.2.3](#)), or carried downstream in a dissolved state, most
18 typically as NO_3^- , because much of the deposited NH_4^+ is either taken up by biota or
19 nitrified to NO_3^- . Typically, a rather large percentage of the N deposition to a given
20 watershed is taken up or stored and is not denitrified or made available for leaching to
21 surface waters. On average, for a large watershed with mixed land use, it has been
22 estimated that roughly 75% of N inputs are retained in the watershed and 25% are
23 exported downstream regardless of the dominant N input, including deposition ([Howarth](#)
24 [et al., 2012](#); [Howarth et al., 1996a](#)). This stored N does not contribute directly to water
25 acidification or eutrophication and represents a significant portion of the incoming N
26 deposition to forested ecosystems in the U.S. The portion of the N deposition that is not
27 retained or lost to denitrification can contribute to water acidification or eutrophication,
28 both on a chronic and especially an episodic basis.

29 It was well understood at the time of the 2008 ISA that streams and their associated
30 sediments can transform nutrients, store them for the short term, or serve as a sink for N
31 loss from the watershed through denitrification. It is important to consider the balance
32 between how much and how long streams retain elements versus transport them
33 downstream. This balance is key to modeling watershed nutrient export. Headwater
34 streams can play disproportionately large roles in N transformation and N cycling in
35 aquatic ecosystems, and they are important to predicting effects of N loading on
36 downstream ecosystems. Atmospheric deposition may represent a significant source of N
37 to some headwater streams [([Lawrence et al., 2015b](#)); [Table 7-2](#)], which often have

1 increased water residence time and solute retention due to increased interactions between
2 surface and groundwater in the hyporheic zone.

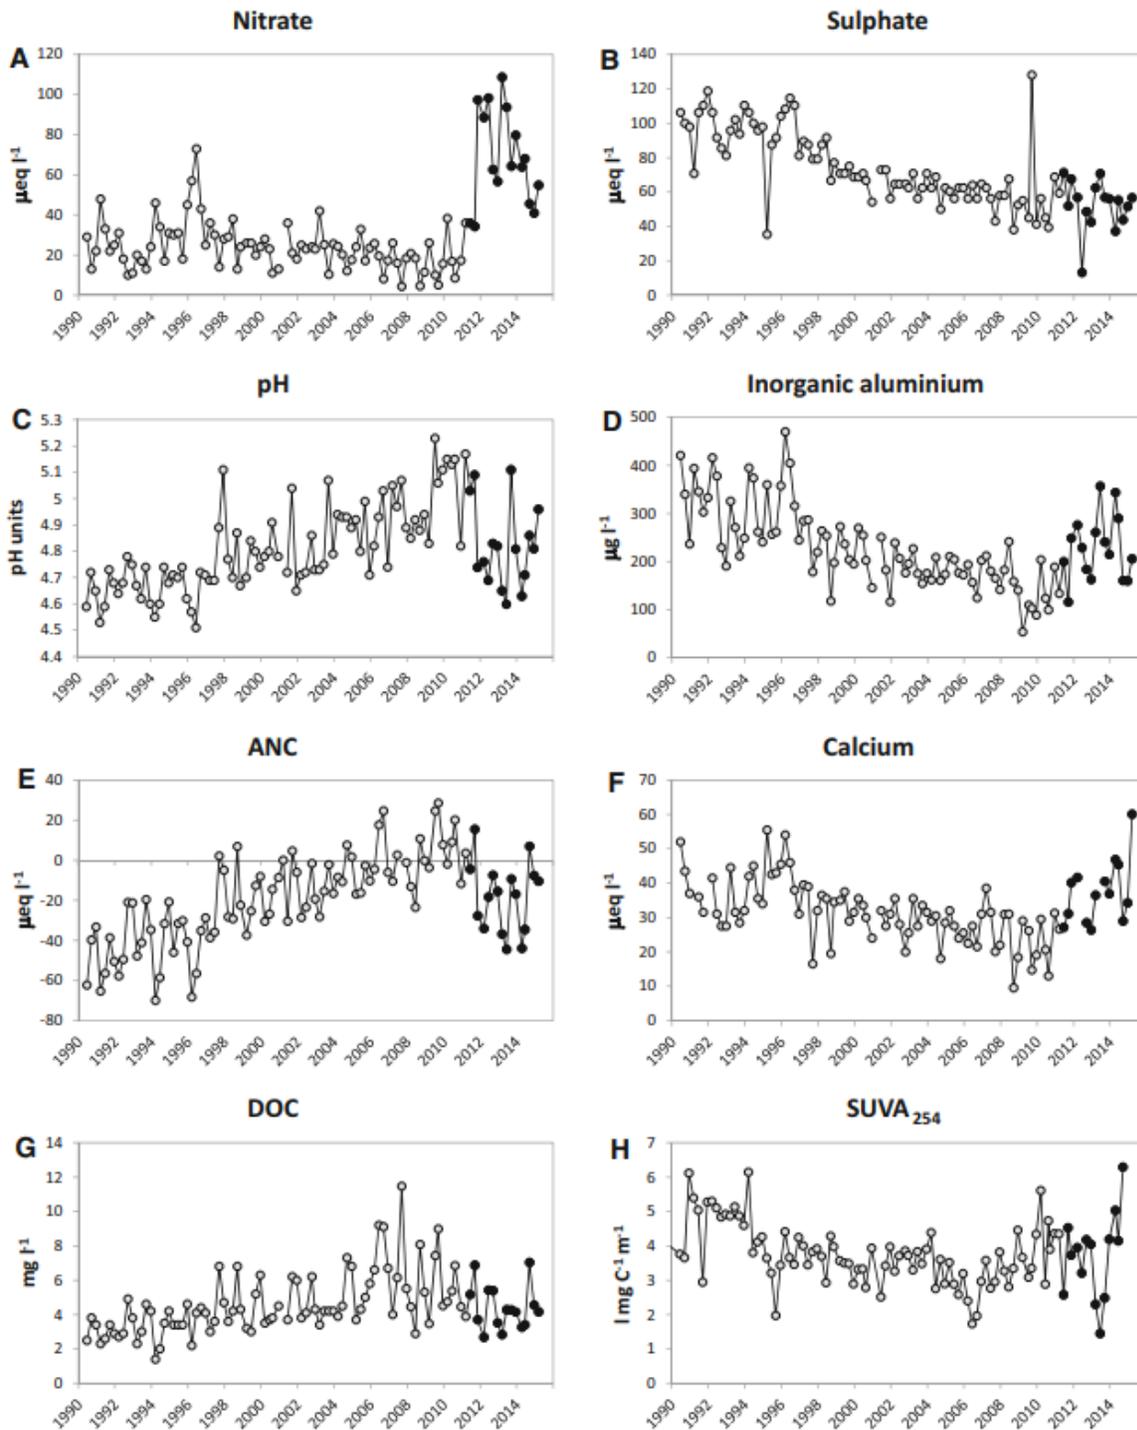

3 The majority of atmospherically deposited N is either denitrified or accumulates in
4 watershed soils, vegetation, or groundwater ([Galloway et al., 2008](#)). The relative
5 partitioning of N loss via denitrification versus watershed storage is poorly known
6 ([Galloway et al., 2004](#)). Watershed denitrification hot spots and hot-moments tend to
7 occur in areas characterized by wet conditions, including wetlands and riparian zones.
8 Such ecosystems can be highly efficient in removing N from surface waters via
9 denitrification ([Galloway et al., 2003](#)). Nitrogen in fresh waters is also controlled by
10 hydrological conditions. For example, [Lusardi et al. \(2016\)](#) showed that spring-fed rivers
11 of northern California had higher NO_3^- and PO_4^{3-} concentrations and cooler temperatures
12 than rivers that were fed more by runoff. Recent studies have added more quantitative
13 context to hydrologic processes that control nutrient cycling, including hydrologic
14 exchange between the streams and the groundwater. This hyporheic exchange can
15 contribute to N retention in streams because it promotes denitrification associated with
16 anoxic flow paths through organic stream bottom substrates. For example, [Hall et al.](#)
17 [\(2009b\)](#) observed in a tracer study in the Sawtooth Mountains of Idaho that assimilation
18 and hydrologic storage can be important for retaining N at the watershed scale. The study
19 stream was not solely a conduit for nutrients at high flow. It had as high an uptake
20 velocity for N during the snowmelt high flow as during summer baseflow.

21 Influence of beaver and human-made dams on NO_3^- uptake in a small headwater stream
22 in the Rocky Mountains was investigated by [Hubbard et al. \(2010\)](#). Dams influenced
23 stream water geochemistry because a portion of the stream water flow was diverted into
24 the more reactive hyporheic zone. Highly oxic and anoxic regions of the streambed
25 developed around the more permanent structures. This enhanced N cycling in the
26 hyporheic zone and increased the potential for denitrification and NO_3^- uptake. In parts of
27 the western U.S. Rocky Mountains, there was a strong positive correlation between
28 surface water NO_3^- concentration and atmospheric N deposition ([Elser et al., 2009b](#);
29 [Bergström and Jansson, 2006](#)). Such a correlation does not always occur elsewhere
30 because nonatmospheric watershed sources of N are often larger than atmospheric
31 sources, depending mainly on land use. Analysis of increasing NO_3^- trends over three
32 decades in streams draining into Lake Ontario, Canada, [Eimers and Watmough \(2016\)](#)
33 suggested that tributary loading, rather than atmospheric deposition, may have played a
34 dominant role in causing the recent observed increase in NO_3^- concentrations in the
35 waters of Lake Ontario. The authors pointed to an observed trend in Ontario towards
36 more annual grain crop production that required more N fertilizer addition and less
37 reliance on perennial crops. This shift in crops could be contributing to the observed
38 increase in NO_3^- concentration in the lake.

1 Studies have been conducted in recent years to elucidate processes affecting surface
2 water NO_3^- concentrations, including experimental studies, isotopic analyses, monitoring,
3 and observational studies. The concentration of NO_3^- may vary widely between baseflow
4 and peakflow conditions ([Table 7-2](#)). Seasonality in surface water chemistry can be
5 caused, in part, by differential hydrologic flows from watershed seeps and glaciers. These
6 flows can influence NO_3^- leaching to surface waters. [O'Driscoll and DeWalle \(2010\)](#)
7 showed that seeps are generally NO_3^- sinks with NO_3^- concentrations decreasing
8 downslope from seep locations in Baldwin Creek in southwestern Pennsylvania. During
9 cold and wet periods, however, the seeps frequently acted as NO_3^- sources to the stream.
10 Locations where upwelling groundwater saturates the surface for most of the year and
11 excess groundwater can be delivered to the stream channel via surface flow paths may
12 provide seasonally linked water quality functions that can modify the effects of N
13 deposition.

14 Changes in the amount of NO_3^- leaching and disruption of N cycling can occur with
15 events in the watershed, including wildfire and timber extraction. Human activities have
16 contributed to greater frequency and magnitude of wildfire in many parts of the U.S.,
17 which is well known to increase NO_3^- leaching. The area impacted by fire has increased
18 in response to climate change, past fire suppression, and increased human presence in
19 forested ecosystems ([Bladon et al., 2014](#)). Extreme events have the potential to delay
20 ecosystem recovery from past water acidification. [Evans et al. \(2017\)](#) assessed the role of
21 wildfire in regulating the chemistry of a mountain lake in a moorland catchment in the
22 U.K. affected by a large fire. The lake had been subjected to more than two decades of
23 ecosystem monitoring prior to the fire. The most pronounced change in lake chemistry
24 was a substantial increase in lake NO_3^- concentration to peak values of 111 $\mu\text{eq/L}$
25 (1.55 mg/L) 2 years after the fire. Past N deposition may have been high enough to make
26 the catchment more susceptible to NO_3^- leaching and accompanying reacidification in
27 response to the fire ([Figure 7-2](#)). The increase in the concentration of this mobile acid
28 anion increased lake acidity and the concentration of inorganic Al. These changes
29 represented a reversal in the ongoing documented recovery from past acidification. Forest
30 disturbance, including clear-cut logging, also contributes to increased leaching of
31 inorganic N, with potential impacts on downstream nutrient concentrations and acid-base
32 chemistry. [Schelker et al. \(2016\)](#) evaluated N dynamics in Sweden over a 10-year period
33 after tree harvesting. DIN leaching in first order streams increased substantially
34 (~ 15 times) subsequent to logging. In the larger streams, NO_3^- leaching was seasonal and
35 increased in response to logging in the mid-sized, but not the largest, streams. Thus, the
36 increased mobilization of NO_3^- in first-order streams caused by logging can affect some
37 downstream locations at some times.

1 Nitrogen deposition to snow and glaciers is an important source of N to alpine lakes and
2 streams which are fed by meltwaters. Since the 2008 ISA, several studies indicate that
3 glacial meltwater has higher NO_3^- than snowmelt water in some regions of the U.S. This
4 may influence interpretation of biological data from high elevation lakes and streams
5 [([Slemmons et al., 2015](#); [Slemmons et al., 2013](#); [Saros et al., 2010](#); [Baron et al., 2009](#));
6 [Appendix 9.3.2.1](#)]. In two sets of high-elevation lakes in the U.S. Rocky
7 Mountains—those fed by snowpack melt alone and those fed by both glacial and
8 snowpack meltwaters—the NO_3^- concentrations in the glacially influenced lakes were
9 one to two orders of magnitude higher than in the lakes that were fed only by snowmelt
10 ([Saros et al., 2010](#)). The higher concentration of NO_3^- in glacial meltwater relative to
11 seasonal snowpack meltwater was attributed, at least in part, to reduced contact with
12 watershed soils where microbial communities could rapidly assimilate the available N.
13 This contrasts with snowmelt watersheds where the meltwater typically percolates
14 through soils before reaching the streams ([Saros et al., 2010](#)). [Williams et al. \(2007\)](#)
15 found that, in the Colorado Front Range, rock/glacier outflow had NO_3^- concentrations of
16 $69 \mu\text{eq/L}$ compared to snow with $7 \mu\text{eq/L}$. In two proximal lakes in the central Rocky
17 Mountains, NO_3^- concentration from glacier-fed Jasper Lake, was $2 \mu\text{eq/L}$ compared to
18 the snowpack-fed Lake Albino where NO_3^- concentration was only $0.03 \mu\text{eq/L}$
19 ([Slemmons et al., 2015](#)). In contrast, in the Northern Cascade Mountains, WA,
20 differences in NO_3^- concentration between glacier-fed and snowpack-fed lakes were
21 much smaller and not statistically significant in some years ([Williams et al., 2016b](#)).

Notes: samples collected before the May 2011 fire are denoted by grey circles, and those from after the fire by black circles.
 Source: [Evans et al. \(2017\)](#).

Figure 7-2 Quarterly measured concentrations of a range of water chemistry variables at Blue Lough from 1990 to 2014.

1 Advances in isotopic analyses have improved techniques for investigating the role of
2 NO_3^- in N cycling. [Curtis et al. \(2012\)](#) used the dual isotope technique at four moorland
3 watersheds in Great Britain to investigate NO_3^- production in surface waters. An
4 estimated 79–98% of the annual median NO_3^- had been microbially produced, indicating
5 that both reduced and oxidized N deposition may cycle through the microbial flora and
6 contribute similarly to NO_3^- leaching. This is important because atmospheric deposition
7 of NH_4^+ has been increasing in many areas of the eastern U.S. while deposition of
8 oxidized N forms (NO_y) has decreased ([Appendix 2](#)). [Goodale et al. \(2009\)](#) characterized
9 the amount, form, isotopic composition (^{15}N and ^{18}O), and seasonality of stream N in
10 forested subwatersheds of the Susquehanna River. Atmospheric deposition contributed
11 substantial N to this river, which provides two-thirds of the annual N load to Chesapeake
12 Bay. Retention of atmospherically deposited N in the watershed was estimated to be
13 higher than 95%. Nevertheless, stream NO_3^- patterns exhibited substantial seasonality.
14 Peak values of NO_3^- (14–96 $\mu\text{eq/L}$) were reached during summer. Lowest values
15 (<1 $\mu\text{eq/L}$) occurred in October. The summer's increase in net soil nitrification and
16 in-stream heterotrophic N uptake in response to litterfall during autumn were identified as
17 likely important drivers of the observed NO_3^- seasonality. Other studies that included
18 mixed land uses found far lower N retention at larger spatial scales, including the
19 Susquehanna River ([Howarth et al., 2006](#); [Boyer et al., 2002](#)). Using stable isotope
20 analysis, atmospheric deposition was identified as an important source of stream NO_3^-
21 concentration at a low NO_3^- site at Fernow Experimental Forest, WV ([Rose et al.,](#)
22 [2015b](#)). Based on more than 30 years of monitoring data, three hardwood watersheds
23 appeared to be less responsive to changes in N deposition than the one study watershed
24 that had coniferous vegetation. The percentage of stream NO_3^- concentration contributed
25 by atmospheric deposition in the study watersheds increased during high-flow periods.

26 Watershed N budgets and empirical models can be useful for assessing the relative
27 magnitude and sources of N inputs and losses to watersheds via riverine export. A variety
28 of computational approaches can be used. [Alexander et al. \(2002\)](#) compared predictions
29 of total N and stream N transport of six watershed models and showed that models with
30 greater precision were those that had the most detailed descriptions of N sources, water N
31 attenuation, and water flow paths. [Han and Allan \(2008\)](#) compared N budget estimation
32 approaches for 18 catchments located in the vicinity of Lake Michigan. The most robust
33 model suggested that riverine N export constituted about 21% of N inputs. Using a larger
34 data set, [Howarth et al. \(2012\)](#) estimated that 25% of N inputs are exported from the
35 watershed on average. The improved ability to predict N export using methods that
36 incorporated description of agricultural N sources was particularly noticeable when
37 applied to watersheds that had pronounced diversity of land use and geology ([Han and](#)
38 [Allan, 2008](#)). Comparisons of watershed N budgets across the U.S. indicates that there is
39 geographic variation in the proportion of N inputs that are exported, and the scaling of

1 export with runoff indicates that drier conditions may lead to lower proportions of N
2 inputs that are exported by rivers([Sobota et al., 2009](#)).

3 Overall, some studies show recent declines in concentrations of NO_3^- and TN in surface
4 waters that are consistent with declines in N deposition. Advances in isotopic analysis
5 have allowed for greater characterization of how NO_3^- in surface waters affects N cycling
6 and has led to improved understanding of how factors such as seasonality and
7 contribution of snowmelt affect NO_3^- concentrations.

7.1.2.2. Sulfate in Surface Waters

8 Measurements of SO_4^{2-} concentration in surface waters provide important information
9 regarding the probable extent of cation leaching in soils and how SO_4^{2-} concentrations
10 relate to ambient and past levels of atmospheric S deposition. The 2008 ISA documented
11 widespread declines in surface water SO_4^{2-} concentration in response to decreasing S
12 deposition over previous decades. Assessments of acidifying deposition effects reported
13 in the 2008 ISA dating from the 1980s showed SO_4^{2-} to be the primary strong acid anion
14 in most, but not all, acid-sensitive waters in the U.S. ([Webb et al., 2004](#); [Driscoll et al.,
15 2001b](#); [Driscoll et al., 1988](#); [Driscoll and Newton, 1985](#)). At the time of the 2008 ISA,
16 available data indicated that before the peak of S emissions in the 1970s and 1980s, SO_4^{2-}
17 concentrations in surface waters increased in response to S deposition. After the
18 emissions peak, there were decreasing regional trends in SO_4^{2-} surface water
19 concentrations in the 1980s, 1990s, and thereafter, particularly in the Northeast. In some
20 regions, especially the Blue Ridge Mountains region in Virginia, surface water SO_4^{2-}
21 remained relatively stable even as emissions declined, due to changes in S adsorption on
22 soils and the release of historically deposited S from soils into surface water. The rate of
23 surface water response was variable by watershed, and some model results suggested that
24 chemical recovery may be delayed as adsorption decreases and accumulated S leaches
25 from watersheds, even as emissions and deposition decline. Recent studies on SO_4^{2-}
26 concentration in surface waters continue to show evidence of chemical recovery
27 consistent with reductions in S deposition ([Appendix 7.1.5.1](#)).

28 Drought has been shown in some situations, where geological S sources are prevalent, to
29 be a partial cause of lake acidification. This was documented at lakes in the
30 Murry-Darling Basin in Australia by [Li et al. \(2017b\)](#). Pyritic sediment rewetting after
31 the drought (2007–2010) caused an extreme decrease in the water pH around the lake
32 margins from above 7 to near 3.

7.1.2.3. Nitrogen Transformations

1 Nitrogen in surface waters can undergo various chemical transformations in the water
2 column ([Appendix 7.1.2.3.1](#)) and sediments ([Appendix 7.1.2.3.2](#)). It was well known at
3 the time of the 2008 ISA that nitrification and denitrification are quantitatively important
4 portions of the N cycle and that these processes can be influenced by atmospheric inputs
5 of oxidized and reduced N. Nitrification can be important even when N deposition is low
6 (*cf.*, [Fenn et al., 2005](#)). More recent research has further substantiated earlier findings and
7 provided additional quantitative context. At some locations, new research suggests that
8 denitrification may play a larger role than was previously recognized in removing
9 oxidized N from the watershed.

7.1.2.3.1. Water Column Transformations

10 Much of the deposited NH_4^+ is either taken up by vegetation or nitrified to NO_3^- , which is
11 more mobile in soils than NH_4^+ . The NO_3^- , in turn, can be leached to drainage water or
12 denitrified and released back to the atmosphere as gaseous N_2O or N_2 . During the
13 nitrification process, NH_4^+ is oxidized to NO_3^- and the NO_3^- that is produced can
14 contribute to acidification of soil and drainage waters. The 2008 ISA concluded that
15 nitrification in soil solution is stimulated at soil C:N ratios less than about 20 to 25. ([U.S.](#)
16 [EPA, 2008a](#); [Aber et al., 2003](#)). Since the 2008 ISA, additional isotope, modeling,
17 observational, and experiment studies have further characterized denitrification
18 processes.

19 Only a small portion of the N added to the land surface by human activities is carried by
20 stream flow to estuaries and the ocean ([Boyer et al., 2002](#); [Howarth et al., 1996a](#)).
21 Streams have been shown to provide an important ecosystem service by acting as N sinks
22 ([Mulholland et al., 2008](#)). Denitrification is a critical process that removes N from stream
23 water. Changes in N_2 concentration over space or time have been used to estimate the
24 denitrification rate at the scale of stream reaches ([Mccutchan et al., 2003](#); [Laursen and](#)
25 [Seitzinger, 2002](#)) to large river basins ([Mulholland et al., 2008](#); [Alexander et al., 2000](#)).

26 Nitrous oxide (N_2O), which is emitted to the atmosphere during the process of
27 denitrification, is a potent greenhouse gas. [Beaulieu et al. \(2011\)](#) presented results of ^{15}N
28 tracer addition to 72 headwater streams draining multiple land uses across the U.S.
29 Denitrification in the streams produced N_2O at rates that increased with stream NO_3^-
30 concentration. The study streams were mostly sources of N_2O to the atmosphere. Results
31 of this study reiterated previous findings that suggested that the process of denitrification
32 may be quantitatively important. In another isotopic study, [Mulholland et al. \(2009\)](#)
33 measured denitrification rates using ^{15}N tracer addition to 49 streams, including

1 reference, agricultural-impacted, and suburban/urban streams. The fraction of total NO_3^-
2 removed from stream water by denitrification ranged from 0.5 to 100%, with a median of
3 16%. Removal was related to NH_4^+ concentration and the ecosystem respiration rate.
4 Although the areal denitrification rate increased with increasing NO_3^- concentration, the
5 efficiency of NO_3^- removal from water via denitrification declined. This resulted in a
6 smaller proportion of stream water NO_3^- load removed over a given length of stream at
7 higher N loading.

8 Freshwater nutrient cycling studies have also focused some attention on N fixation. In
9 Waco Reservoir, TX, [Scott et al. \(2008\)](#) measured N fixation over a 19-month period and
10 linked those data with nutrient-loading estimates derived from a physically based
11 watershed model. Readily available topographic, soil, land cover, effluent discharge, and
12 climate data were used in the Soil and Water Assessment Tool (SWAT) model in order to
13 derive estimates of nutrient loading from the watershed to the reservoir. Results
14 suggested that human activities in the watershed can exert significant control over
15 planktonic N fixation.

7.1.2.3.2. Sediment Nitrogen Transformations

16 The deposition and transport of N derived from human sources is partially ameliorated by
17 bacterially mediated denitrification in sediments. The conversion of NO_3^- to N_2 gas
18 permanently removes N from the watershed ([Seitzinger et al., 2006](#); [Galloway et al.,
19 2003](#)). It has been estimated that denitrification in lakes may remove up to about 30% of
20 the inputs to surface waters ([McCrackin and Elser, 2012](#); [Harrison et al., 2009](#); [Wollheim
21 et al., 2008](#)).

22 Residence time of water in the sediments and hydraulics can be important controls on
23 nutrient uptake in headwater streams. [Drummond et al. \(2016\)](#) characterized water
24 transient storage zones and their effects on nutrient uptake in the sediments of two
25 headwater streams in Spain. These zones represented regions of slow-moving water and
26 temporary water retention in stream sediments. Modeled exchange between the water
27 column and retention zones explained more than 40% of the variation in NH_4^+ uptake.

28 A study by [Bellinger et al. \(2014\)](#) provided additional evidence that bacterially mediated
29 denitrification in lake sediments can partly ameliorate the effects of N loading from the
30 atmosphere by permanently removing some of the N inputs. [McCrackin and Elser \(2012\)](#)
31 also measured denitrification in sediments, in this case from lakes in the Colorado Rocky
32 Mountains. The study lakes received either elevated (357–571 eq N/ha/yr) or low
33 (<142 eq N/ha/yr) inputs of atmospheric N deposition. The NO_3^- -N concentration was
34 significantly higher in high-deposition lakes (0.1582 mg/L) compared to low deposition

1 lakes (0.0462 mg/L). The researchers concluded that the sampled lakes were capable of
2 removing a significant portion of N inputs via denitrification in the lake sediment. They
3 found no difference between high- and low-deposition lakes in the extent to which
4 chronic N loading has altered sediment denitrification capacity. The abundance of
5 denitrifying bacteria in this study was largely related to light availability. An earlier study
6 by [McCrackin and Elser \(2010\)](#) measured rates of denitrification and N₂O production
7 during denitrification in the sediments of 32 Norwegian lakes at the high and the low
8 ends of a gradient of atmospheric N deposition. They also found that denitrification
9 varied with N loading. The findings also suggested that lake sediments may be an
10 important source of N₂O emissions, which play a role in climate warming, particularly in
11 areas that are subject to elevated N deposition levels. Results of new research by
12 [McCrackin and Elser \(2012\)](#) support growing evidence that lake sediments can play
13 important roles in N removal, although it appears that recent levels of N deposition have
14 not altered the abundance of denitrifying bacteria or saturated the capacity for sediment
15 denitrification in Rocky Mountain lakes.

16 Organic matter can also influence the rate of denitrification in sediments. [Fork and](#)
17 [Heffernan \(2014\)](#) investigated how DOC derived from terrestrial ecosystems affects the
18 rate of denitrification in river sediments. They examined the extent to which higher
19 concentrations of DOC in black water rivers stimulate or inhibit denitrification. Results
20 supported the hypothesis that terrestrially derived DOC might indirectly inhibit
21 denitrification via a decrease in autochthonous production. Therefore, changes in DOC
22 concentration might change the ability of inland waterways to remove reactive N from
23 the aquatic ecosystem.

7.1.2.4. Sulfur Transformations

24 Studies of S cycling reported in the 2008 ISA emphasized the importance of S adsorption
25 and desorption and their interactions with soil pH ([Appendix 4](#)). The importance of S
26 adsorption on soils in the southern Appalachian Mountains was further confirmed by S
27 budget studies reported by [Rice et al. \(2014\)](#). In addition, internal watershed sources of
28 SO₄²⁻ (e.g., S mineralized from soil organic matter), which were previously relatively
29 minor sources to surface water in the northeastern U.S., have become proportionately
30 more important as S deposition has declined ([Appendix 4](#)).

31 Both chronic and episodic leaching of SO₄²⁻ from terrestrial ecosystems influence surface
32 water acidification. The literature reviewed in the 2008 ISA did not fully address how
33 terrestrial S cycling affects water sulfate concentrations. More recently, [Rice et al. \(2014\)](#)
34 calculated SO₄²⁻ mass balances for 27 watersheds in the Appalachian Mountain region.

1 Results suggested that many watersheds where SO_4^{2-} inputs are currently retained will
2 begin releasing more SO_4^{2-} to drainage water in the near future. [Dewalle et al. \(2016\)](#)
3 evaluated Appalachian forested watersheds and estimated the lag times between changes
4 S deposition and consequent watershed responses. Lag times were generally consistent
5 and significant for S in the forest basins that demonstrated relatively high soil S retention
6 and high N retention. [Strock et al. \(2016\)](#) investigated the effects of extreme (wet or dry)
7 weather on the chemistry of 84 lakes across the northeastern U.S. The average
8 differences in lake water SO_4^{2-} concentrations were about 2–3 $\mu\text{eq/L}$ higher in 2001 (dry
9 year) as compared with the average observed during the entire study period 1990–2010.
10 This has implications for S cycling as the climate changes.

11 Some of the SO_4^{2-} leached from soil, as well as the SO_x deposited directly into surface
12 water, is reduced and retained in aquatic sediments as hydrogen sulfide, especially in
13 wetlands. However, S stored in reduced form in sediments can be subsequently
14 reoxidized and become available for down-gradient transport as SO_4^{2-} during periods of
15 high discharge, particularly during hydrologic events that follow periods of drought. The
16 leaching of SO_4^{2-} then can contribute to a variety of ecological effects ([Appendix 8](#) and
17 [Appendix 12](#)). When SO_4^{2-} is released from catchment soils to drainage water, it is
18 accompanied by an equivalent amount of cationic counter-charge in the form of acidic
19 (H^+ , Al^{3+}) or basic (Ca^{2+} , Mg^{2+} , K^+ , and Na^+) cations ([U.S. EPA, 2008a](#)), affecting the
20 concentrations of parameters addressed in the following sections of this report.

7.1.2.5. Surface Water pH

21 Surface water pH is commonly used as an indicator of acidification. This was the case in
22 the 2008 ISA, and nothing has changed in that regard in more recent years. It correlates
23 with other biologically important components of surface water acid-base chemistry,
24 including estimates of organic acidity and concentrations of inorganic Al and Ca^{2+} . Low
25 pH can have direct toxic effects on aquatic species [([U.S. EPA, 2008a](#); [Driscoll et al.,](#)
26 [2001b](#)); [Appendix 8.3](#)] and this was widely understood at the time of the 2008 ISA. Low
27 pH can disturb normal ion osmoregulation in aquatic biota. Threshold pH levels for
28 adverse biological effects are described in [Appendix 8](#) and [Table 8-2](#). A pH value of 6.0
29 is often considered the level below which biota are at increased risk from acidification,
30 but some waters can have pH below this threshold in the absence of acidic deposition.
31 This is most commonly caused by relatively high levels of natural organic acidity. Below
32 pH 5.5, inorganic Al often becomes the greatest threat to aquatic biota, especially in
33 low-DOC waters. In the 2008 ISA, increasing trends in pH in surface waters in the
34 northeastern U.S. were common through the 1990s up to 2004 and have continued in

1 more recent times at many locations ([Appendix 7.1.5.1](#)). Rates of change have generally
2 been relatively small.

3 Surface water pH (as well as other parameters) is sensitive to hydrological conditions at
4 the time of sampling. [Burns et al. \(2008b\)](#) sampled 12 Catskill mountain streams within
5 the Neversink River watershed in New York for stream chemistry. The measured pH
6 values in 2003 were generally lower than those in 1987 and this was attributed to higher
7 stream flow during the summer of 2003, rather than to chronic acidification during the
8 intervening period. There were no significant differences in biota observed between 1987
9 and 2003. Although surface water pH is a common alternative to ANC as an indicator of
10 acidification, at pH values above about 6.0, pH is of less value as an indicator of either
11 sensitivity to acidification or level of effect. In addition, pH measurements (especially at
12 these higher values) are sensitive to levels of dissolved CO₂ in the water, which is
13 influenced by plant root respiration.

7.1.2.6. Surface Water Acid Neutralizing Capacity

14 The most widely used measure of surface water acidification, and subsequent recovery
15 under reduced acid deposition, is ANC. Most aquatic critical load (CL) studies conducted
16 in the U.S. have used surface water ANC as the principal metric of water quality change
17 in response to changes in acidic deposition ([Appendix 7.1.5.2](#)). It is typically either
18 determined by Gran titration in a laboratory (titrated ANC) or calculated from the charge
19 balance (calculated ANC or CALK). Titrated ANC is useful because it reflects the ANC
20 of the complete chemical system, which is typically decreased by acidic deposition in
21 acid-sensitive landscapes. The ANC is associated with the surface water constituents that
22 directly cause or reduce acidity-related stress, in particular pH, Ca²⁺, and inorganic Al
23 concentrations. The ANC is generally a more stable measurement than pH because ANC
24 is insensitive to changes in CO₂ and it reflects sensitivity and effects of acidification in a
25 linear fashion across the full range of ANC values. Therefore, ANC is usually the
26 preferred indicator for assessment of surface water acidification and recovery. Both
27 titrated and calculated ANC values are commonly determined in studies aimed at
28 resource characterization or long-term monitoring. Models simulate calculated ANC. The
29 two measures can differ greatly, depending mainly on the amount of organic acidity and
30 dissolved Al in the water. The BCS ([Lawrence et al., 2007](#)) is an alternate index to ANC
31 that integrates acid-base status and accounts for the influence of natural organic acidity.

32 As described in the 2008 ISA, ANC is typically used as the primary chemical indicator
33 for assessing past effects of acidifying deposition on aquatic biota and the recovery
34 expected from decreasing acidic atmospheric deposition ([Sullivan et al., 2006a](#); [Aber et](#)

1 [al., 2003](#); [Bulger et al., 2000](#)). Notably, the ANC level that reflects recovery of pH or
2 inorganic Al may differ between the acidification and recovery phases ([Hesthagen et al.,](#)
3 [2008](#))([Appendix 7.1.5.1](#)). In general, ANC measures over the past two to three decades in
4 the northeastern U.S. ([cf., Driscoll et al., 2016](#)) suggest rather modest increases in ANC
5 in many surface waters in response to large decreases in acidic deposition and surface
6 water SO_4^{2-} concentration ([Appendix 7.1.5.1](#)).

7 Information on biological indicators of acidification such as fish species richness that are
8 associated with changes in ANC are presented in [Appendix 8](#). There is often a positive
9 relationship between ANC and number of fish species, at least for ANC values between
10 about 0 and 50 to 100 $\mu\text{eq/L}$ ([Cosby et al., 2006](#); [Sullivan et al., 2006a](#); [Bulger et al.,](#)
11 [1999](#)). Lakes and streams having ANC <0 $\mu\text{eq/L}$ generally do not support fish. Loss of
12 fish species seems to occur with decreases in ANC below a threshold of approximately
13 50 to 100 $\mu\text{eq/L}$ ([Sullivan et al., 2006a](#)).

14 Sensitive water bodies can be defined as those that have ANC of 100 $\mu\text{eq/L}$ or less.
15 Sensitivity increases with further decreases in ANC. Al mobilization is largely confined,
16 however, to waters that have pH less than about 5.5, which corresponds with ANC in the
17 range of about 10 to 30 $\mu\text{eq/L}$ in low-DOC to moderate-DOC (less than about 400 μM)
18 waters in the Northeast. Therefore, inorganic Al is not a useful indicator of acidification
19 or chemical recovery in waters that have ANC higher than about 10–30 $\mu\text{eq/L}$. Thus,
20 evaluation of improvement in biologically relevant water chemistry in response to
21 decreases in acidic deposition should perhaps include assessment of response using both
22 the ANC and inorganic Al metrics.

23 [Povak et al. \(2013\)](#) reported the ANC of over 900 streams in the southern Appalachian
24 Mountains, and estimated ANC at other stream segments throughout the region using
25 observed relationships between ANC and watershed characteristics. Low stream ANC
26 was commonly found at locations that exhibited siliciclastic geology; cool, short, and
27 moist growing seasons; high clay soil content; low soil pH; and small forested
28 watersheds.

29 [Sullivan \(2017\)](#) constructed a map of surface water ANC across the U.S. that included
30 nearly 20,000 unique locations sampled between 1980 and 2011 ([Figure 8-11](#)). Samples
31 expected to be strongly influenced by acid mine drainage, sea salt spray, or road salt
32 application were excluded. He found 6,065 sites that had ANC <100 $\mu\text{eq/L}$. Waters
33 having ANC ≤ 0 $\mu\text{eq/L}$ were mostly restricted to northern New York, New England, the
34 Appalachian Mountain chain, upper Midwest, and Florida. In addition, low, but positive,
35 ANC values were found in high-elevation portions of the West and parts of Arkansas and
36 the Gulf states. These spatial patterns in surface water ANC are thought to mainly reflect
37 the influence of soil base cation supply on ANC.

7.1.2.7. Base Cation Concentrations

1 Quantitatively, the most important component of the overall surface water acidification
2 and chemical recovery response to atmospherically deposited S and N (and associated
3 SO_4^{2-} and NO_3^- concentrations) has been a change in base cation supply ([Charles and](#)
4 [Christie, 1991](#)). As stated in the 2008 ISA, decreases in base cation concentrations in
5 surface waters in the eastern U.S. over the past two to three decades have been ubiquitous
6 and closely tied to trends in SO_4^{2-} concentrations in surface waters. In most regions, rates
7 of decrease for base cations have been similar to those for SO_4^{2-} plus NO_3^- , with the
8 exception of streams in western Virginia and in Shenandoah National Park, which are
9 strongly affected by SO_4^{2-} adsorption on soils. The 2008 ISA concluded that acidifying
10 deposition has been an important cause of decreasing amounts of exchangeable base
11 cations on soils. This influences base cation leaching to surface waters and soil buffering
12 of deposition acidity. Surface water base cation concentrations increase with acidification
13 and generally decrease under reduced levels of acidic deposition. However, in some
14 watersheds that have acidified, concentrations of Ca^{2+} and other base cations have
15 become substantially reduced from likely preindustrial levels, in response to depletion by
16 many years of acidic deposition. This base cation depletion constrains surface water ANC
17 and pH recovery, as described in the 2008 ISA. Recent results have further corroborated
18 these earlier findings. More recent studies have included experiments (liming), modeling,
19 and gradient studies with geographical focus on the Adirondack Mountains, southern
20 Appalachian Mountains, Rocky Mountains, and the Hubbard Brook Experimental Forest
21 (HBEF) in New Hampshire.

22 Base cations are contributed to soils and surface waters through weathering and
23 atmospheric base cation deposition ([Appendix 4](#)). Estimates of base cation weathering
24 (BC_w) largely control simulated base cation concentrations in drainage water and are
25 needed for evaluating CLs of surface water acidity using steady-state models
26 ([Appendix 8](#)). [McDonnell et al. \(2012\)](#) developed an approach for regionalizing BC_w
27 using regionally specific empirical relationships. The dynamic model MAGIC was used
28 to calibrate BC_w in 92 watersheds distributed across the southern Appalachian
29 Mountains. About one-third of the study region had BC_w estimates that were less than
30 1,000 eq/ha/year, with lowest values for watersheds located in national parks and
31 wilderness areas.

32 Base cation surplus is defined as the difference between the summed concentrations of
33 base cations (Ca, Mg, Na, K) and strongly acidic inorganic anions (SO_4^{2-} , NO_3^- ,
34 chloride), minus an estimate of the strongly acidic organic anions estimated from
35 dissolved organic C and an assumed charge density. These strongly acidic organic anions
36 are dissociated at low pH, and function essentially as mineral acid anions in terms of their

1 effect on ANC. The BCS is an alternative statistic to ANC for use mainly in waters that
2 have appreciable natural organic acidity.

3 In high-elevation portions of three watersheds in the southern Appalachian Mountains,
4 [Knoepp et al. \(2016\)](#) found that stream acid-base chemistry was related to the
5 concentrations of N and Al in the soil O-horizon and to the total amount of C and Ca in
6 the soil. Each watershed contained four to six first-order catchments with moderate to
7 high levels of acid sensitivity (ANC 11–50 $\mu\text{eq/L}$). Differences across catchments in
8 stream ANC, pH, and the ratio of Ca:Al concentrations were also significantly correlated
9 with watershed vegetation, as reflected in basal area, tree height, and diameter at breast
10 height.

11 In the Muskoka River Watershed in Ontario, Canada, further improvement in lake ANC
12 and pH might be limited by Ca depletion, which can be made worse by tree harvesting
13 ([Reid and Watmough, 2016](#)). More than 60% of the tree Ca is commonly found in the
14 bark and boles, which are largely removed from the watershed during timber extraction.
15 The authors estimated that timber harvesting at planned levels will cause approximately a
16 30% increase in the number of sampled lakes that decline to Ca levels below 1 mg/L.

17 Changes in acidic deposition exert complex effects on the concentration of Ca in surface
18 waters. During the early phases of soil and water acidification, acidic deposition increases
19 the leaching of Ca from soil to drainage water. This Ca leaching causes increased
20 concentrations of Ca in streams and lakes. In base-poor watersheds having thin soils, the
21 rate of Ca leaching can exceed the resupply via weathering and atmospheric input. Over
22 time, soil base saturation decreases, and the concentration of Ca in runoff decreases,
23 perhaps to levels lower than what existed prior to the advent of acidic deposition.
24 Decreases in acidic deposition will further accentuate this Ca depletion. Decline in lake
25 water Ca concentration has severe consequences for some species of zooplankton,
26 especially *Daphnia* species that have high Ca requirements. [Jeziorski et al. \(2008\)](#)
27 documented major reductions in abundance of Ca rich *Daphnia* spp., keystone herbivores
28 in pelagic food webs, in association with decreases in the concentration of Ca in lake
29 water. They reported that a high proportion of Canadian Shield lakes had Ca
30 concentration near or below the threshold level (1.5 mg/L) for decreased survival and
31 fecundity in laboratory studies. Ecological impacts of these changes on food webs may be
32 substantial.

33 Increased atmospheric transport of dust enriched with nutrients, metals, and base cations
34 to alpine watersheds in the western U.S. has been shown to alter lake biogeochemical
35 processes. [Ballantyne et al. \(2011\)](#) examined temporal trends in dust deposition from
36 sediment cores collected from two lakes in Colorado with distinct physical and chemical
37 properties. Recent increases in dust deposition and its enrichment in various elements,

1 including Ca, has contributed base cations to drainage water and altered the
2 biogeochemistry of the two study lakes.

3 Liming studies confirm ecosystem responses when depleted base cation pools in soils are
4 restored by addition of base cations experimentally or for management purposes. In a
5 base cation addition study (45,000 kg of calcium silicate [wollastonite, CaSiO₃]) in
6 HBEF, increases in the concentrations of Ca and decreases in the concentrations of H⁺
7 and inorganic Al in stream water were observed and stream ANC increased ([Cho et al.,
8 2012](#)). By the end of 2010, an estimated 3 to 5% of added Ca was exported in stream
9 water and the Ca retained in the watershed was detected in lower soil horizons or taken
10 up by vegetation ([Shao et al., 2016](#); [Johnson et al., 2014](#)). Exchangeable Ca increased
11 significantly and exchangeable Al decreased significantly in the organic and upper
12 mineral soils over the years following wollastonite addition ([Johnson et al., 2014](#)).

7.1.2.8. Surface Water Aluminum

13 As stated in the 2008 ISA, the concentration of dissolved inorganic monomeric Al in
14 surface waters is an especially useful indicator of acidifying deposition effects because
15 (1) it is toxic to many species of aquatic biota ([Appendix 8](#)) and (2) it generally does not
16 leach from soils to surface waters in the absence of input of strong acids (e.g., sulfuric
17 acid, nitric acid, strong organic acid anions)([Lawrence et al., 2007](#); [Driscoll et al., 1988](#)).
18 It has well-documented effects on aquatic biota at specific thresholds ([Appendix 8](#)). In
19 the 2008 ISA, limited data suggested that some acid-sensitive surface waters in regions of
20 the northeastern U.S. have elevated inorganic Al concentrations, which have been
21 induced by years of acidifying deposition and pose threats to aquatic life. Since the 2008
22 ISA, several monitoring studies have reported decreases in inorganic Al suggestive of
23 chemical recovery of surface waters [([Baldigo et al., 2016](#); [Driscoll et al., 2016](#); [Strock et
24 al., 2014](#); [Warby et al., 2008](#)) ([Appendix 7.1.5.1](#))].

7.1.2.9. Surface Water Dissolved Organic Carbon Concentration

25 An especially important, and relatively new, area of research focus in the context of
26 recovery from surface water acidification has been the observed increase in DOC or total
27 organic carbon (TOC) concentration in many surface waters recovering from
28 acidification. This has implications with respect to water toxicity and cycling of C, Al,
29 and N. Changes in lake DOC are important because DOC helps to regulate biological,
30 chemical, and physical lake characteristics by adding C, changing pH, affecting nutrient
31 cycling, and changing the availability of toxic metals, including Al. Lake DOC regulates

1 UV light penetration into the water column and the amount and depth of
2 photosynthetically active radiation (PAR), which affects the lake mixing depth, especially
3 in small lakes. Increased DOC contributes to shallower mixing depth and greater
4 fluctuation in diel temperature and may affect lake nutrient status ([Gerson et al., 2016](#)).
5 Increases over the past two to three decades in lake DOC in the northeastern U.S. have
6 likely been part of the chemical recovery from previous lake acidification ([SanClements
7 et al., 2012](#); [Monteith et al., 2007](#)) and/or caused or exacerbated by changes in climate,
8 including precipitation patterns ([Couture et al., 2012](#); [Weyhenmeyer and Karlsson, 2009](#)).

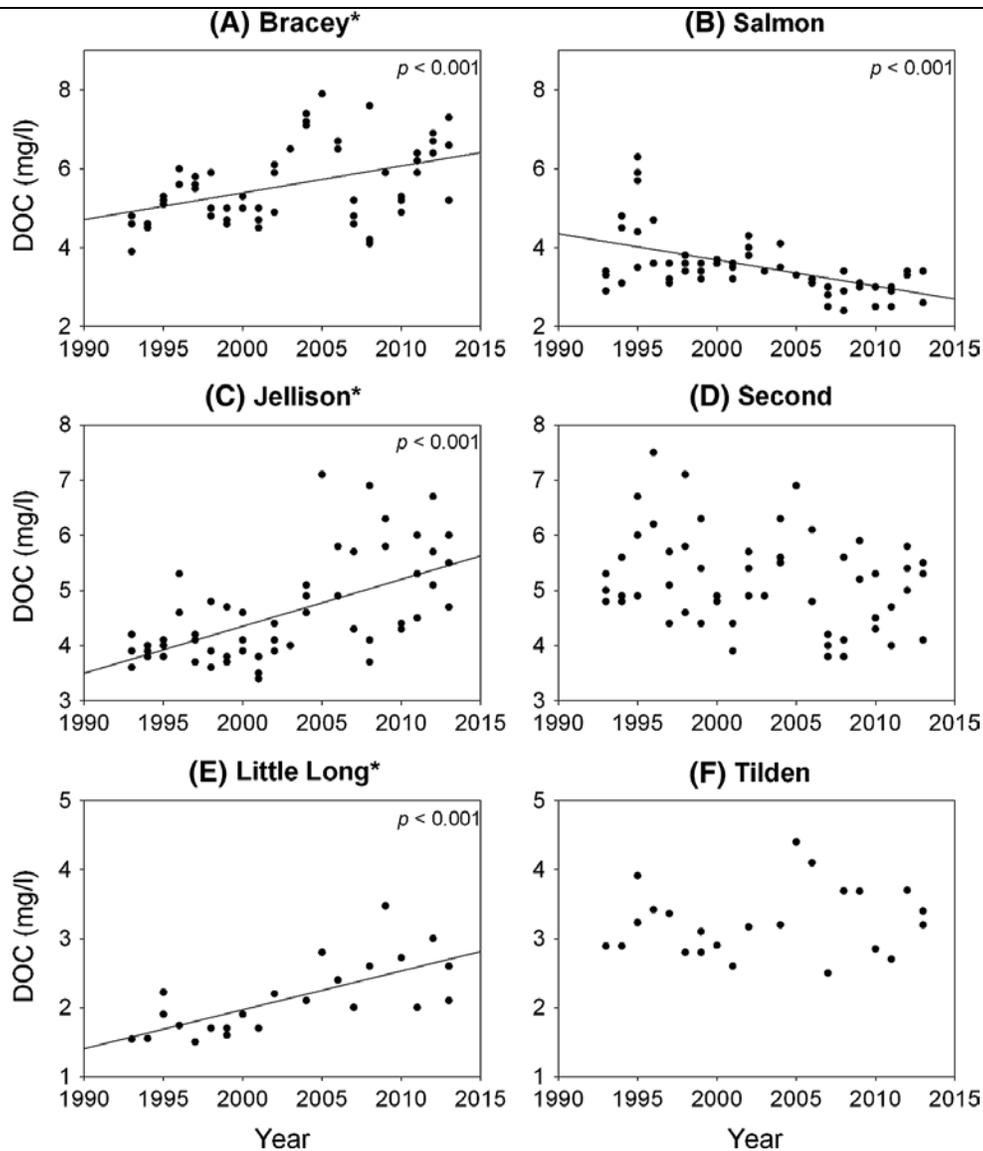

9 The 2008 ISA reported widely observed increased concentrations of DOC or TOC in
10 surface waters across North America and Europe and that these increases were at least
11 partly related to changes in atmospheric deposition of S and N. Thus, it has been
12 recognized for well over a decade that surface water organic carbon concentrations have
13 decreased to some extent in many water bodies that previously experienced water
14 acidification. Therefore, DOC concentration would likely increase with recovery. More
15 recent research on this topic has been diverse and has included experiments, observation,
16 isotope studies, and synthesis and integration work. Overall, they illustrate relatively
17 large increases in DOC with acidification recovery in some aquatic systems. This
18 response constrains the level of ANC, and especially pH, recovery, but decreases the
19 toxicity of dissolved Al by converting some of it from inorganic to organic forms
20 ([Lawrence et al., 2013](#)). As a result of this widely observed pattern, surface water DOC
21 concentration has become an important focus of water acidification and recovery research
22 ([Appendix 7.1.5.1](#)).

23 DOC is comprised of a diverse mix of organic matter and functional groups. [Wood et al.
24 \(2011\)](#) noted that dark, aromatic-rich organic matter with relatively high humic content
25 and of allochthonous origin may be more effective in ameliorating metal bioavailability
26 and toxicity than other organic materials. In addition, part of the protection provided by
27 DOC may involve physiological mechanisms other than metal complexation ([Wood et
28 al., 2011](#)). Soil mechanisms that contribute to higher DOC in surface waters are discussed
29 in [Appendix 4](#). At the Niwot Ridge Long-Term Ecological Research site in Colorado,
30 [Miller and Mcknight \(2015\)](#) reported downstream transport of dissolved organic matter
31 (DOM) that had been produced in alpine lakes during low-flow periods.

32 Recent research suggested that increases in lake DOC may have changed key functions of
33 affected lakes, causing decreased vertical distribution of phytoplankton and changes in
34 phytoplankton species composition. This was investigated by [Brown et al. \(2017\)](#), who
35 demonstrated that increases in lake DOC can potentially change the thermal structure of
36 lakes, but that effects are variable. They analyzed fossil diatom remains in sediment cores
37 collected from three pairs of small remote Maine lakes. Each pair consisted of one lake

1 that showed recent increases in DOC since the early 1990s and a similar lake that did not
2 show increasing DOC. The focus was on changes in the relative abundances of diatom
3 taxa that were known to reflect effects on thermal stratification, specifically *Discostella*
4 *stelligera* and *Aulacoseira* spp. [Saros et al. \(2012\)](#) had constructed a diatom inference
5 model for reconstructing past lake mixing depth based on the relative abundance of *D.*
6 *stelligera*, which prefers shallower mixing depth. [Stone et al. \(2016\)](#) expanded this model
7 and included species of *Aulacoseira*. [Brown et al. \(2017\)](#) hypothesized that those lakes
8 that had experienced recent DOC increases (shown in [Figure 7-3](#)) would show increased
9 diatom turnover and increases in the relative abundance of *D. stelligera* and *Aulacoseira*
10 spp. since the 1990s. The three study lakes that had no increase in DOC also showed
11 minimal change in the identified sensitive taxa. The three lakes that experienced recent
12 increases in DOC showed variable diatom responses. Results were interpreted as being
13 indicative of the potential of DOC to change the physical and biological structure of lakes
14 that have experienced past or ongoing chemical recovery from prior lake acidification.
15 The largest changes in diatom taxa occurred in two of the lakes that had experienced
16 recent increases in DOC.

17 DOC effects on N cycling have been further elucidated since the 2008 ISA. [Rodriguez-](#)
18 [Cardona et al. \(2016\)](#) and [Wymore et al. \(2016\)](#) suggested greater NO_3^- removal from
19 drainage water under conditions of relatively high DOC and high ratio of $\text{DOC}:\text{NO}_3^-$
20 concentration. Results of the study of [Fork and Heffernan \(2014\)](#) further suggested that
21 the indirect effects of DOC on light will be important in determining how N cycling
22 responds to increasing concentrations of DOC in surface waters. Under conditions of
23 increased DOC, the quality of DOM may change, as may its binding with dissolved Al
24 ([Fakhraei and Driscoll, 2015](#)). Dynamics of DOC may also have consequences for
25 eutrophication of downstream ecosystems, but interactions appear to be complex.

Notes: linear regression lines are shown for significant trends ($p < 0.05$). Asterisk indicates lakes with a significant DOC increase. Source: [Brown et al. \(2017\)](#).

Figure 7-3 Dissolved organic carbon (DOC) concentrations from 1993 to 2013 for Bracey Pond (a), Salmon Pond (b), Jellison Pond (c), Second Pond (d), Little Long Pond (e), and Tilden Pond (f) in Maine.

1 Short-term studies to characterize acid-base chemistry have provided information on
 2 surface water quality and biogeochemistry of organic materials. [Kang and Mitchell](#)
 3 [\(2013\)](#) studied spatial and temporal variation in the quantity and quality of DOC, N, and
 4 S in Adirondack Mountain surface waters over a 14-month period. This investigation

1 included the sampling of two upland streams, two wetland-influenced streams, and one
2 lake outlet (Arbutus Lake). The DOC and dissolved organic N (DON) concentrations
3 increased as water was transported through wetland areas. Results highlighted the value
4 of applying multiple approaches for understanding the biogeochemistry of DOM. The
5 acid-base chemistry of DOC has been further investigated in several other studies. [Porcal
6 et al. \(2009\)](#) confirmed that DOC concentrations in lakes and streams throughout much of
7 Europe and North America have increased over the last three decades. Possible reasons
8 for this change proposed by [Porcal et al. \(2009\)](#) included increased atmospheric CO₂
9 concentration, climate warming, decreased S deposition (and associated changes in water
10 pH and ionic strength), and hydrologic changes caused by drought and precipitation. Any
11 changes in DOC concentration or properties will impact the acid-base chemistry of
12 surface waters and perhaps the composition of aquatic biota. In a laboratory study, [Al-
13 Reasi et al. \(2013\)](#) performed titrations for a range of freshwater DOM isolates. In
14 general, the proton site density (L_T) exhibited maxima near proton binding constants
15 (pK_a) values of 3.5 and 10, reflecting the presence of both strong and weak organic acids.
16 The Proton Binding Index parameter was described to summarize the chemical reactivity
17 of DOM based on the pK_a values and the L_T . Results of this study provided a rationale for
18 describing the protection provided by DOM against metal, including inorganic Al,
19 toxicity. Recent additional research has also focused on improving scientific
20 understanding of variation in the importance of organic versus mineral acids in
21 controlling the acidity of soil water and surface water. [Chapman et al. \(2008\)](#) analyzed
22 seasonality in soil water and surface water chemistry in two U.K. headwater watersheds.
23 Strong seasonal patterns were observed for both ANC and DOC. Acidic deposition
24 controlled acidity during winter, whereas organic acids were more important during
25 summer. The observed increase in DOC concentration in drainage water over the
26 previous two decades was attributed mainly to climate warming, increased CO₂, and/or
27 decreased acidic deposition.

28 [SanClements et al. \(2012\)](#) used a chemical signature of terrestrial DOM to investigate the
29 extent to which increased DOC concentrations in surface water since about 1993 in the
30 northeastern U.S. have been driven by decreasing acidic deposition and increasing
31 solubility of soil organic matter. They used fluorescence spectroscopy to characterize the
32 quality of DOM in stored samples that had been collected from nine acid-sensitive lakes
33 in Maine. Decreases in lake water SO₄²⁻ concentration were associated with increases in
34 DOC concentration and a shift during ecosystem recovery from microbial to terrestrially
35 derived DOM. Changes in the quality or quantity of DOM can affect aquatic ecosystem
36 functions. Dissolved organic matter is important for providing food for microbes,
37 attenuating light, buffering pH, binding Al, and controlling the cycling of nutrients
38 ([SanClements et al., 2012](#)).

1 The amount and composition of DOC mobilized from upland soils to surface waters is an
2 important link in the global C cycle. The relationship between ultraviolet (UV)
3 absorbance and DOC concentration has been shown to reflect the aromaticity of the
4 DOC. [Dawson et al. \(2009\)](#) reported a change in correspondence between UV absorbance
5 and DOC concentration over a period of 22 years at two moorland watersheds in
6 Scotland. The DOC concentration has increased over time, while the proportion of
7 hydrophobic DOC has decreased. A model analysis by [Dawson et al. \(2009\)](#) suggested
8 that S deposition was the only factor that could reasonably explain the observed
9 long-term DOC trend at both sites.

10 [Valinia et al. \(2015\)](#) used visible near-infrared spectroscopy of lake sediments to
11 reconstruct the reference condition TOC in Swedish lakes. Long-term monitoring data
12 were used to simulate recent changes in TOC and then analyzed using two empirical
13 models. The first predicted historical TOC trends between reference conditions in the
14 year 1860 and peak acidification in approximately the year 1980. The second model
15 predicted TOC between 1988 and 2012 in conjunction with partial chemical recovery
16 from acidification. The models were driven by lake and watershed area, the amount of
17 wetlands, historical S deposition, and current water chemistry. The researchers estimated
18 that the present-day TOC concentrations are similar to reconstructed reference conditions
19 in Swedish lakes. Thus, it was deemed unlikely that the TOC concentrations in Swedish
20 lakes will continue to increase with continued controls on acidic deposition.

21 In a monitoring study from the Czech Republic, [Hruška et al. \(2009\)](#) reported high DOC
22 in two watersheds: 18.8 mg/L and 20.2 mg/L at the acidic and base-rich watersheds,
23 respectively. Between 1993 and 2007, the concentrations of DOC in stream water
24 increased by about 65% at both streams. Increases in stream water DOC were associated
25 with small increases in stream pH, but large decreases in ionic strength due to declining
26 acidic deposition. Although neither of the catchments showed changes in soil water pH,
27 DOC concentrations in soil water tripled. [Hruška et al. \(2009\)](#) concluded that the change
28 in ionic strength of soil water and stream water, rather than acidity, was the major cause
29 of increased stream water DOC. Changes in temperature, precipitation, and discharge
30 during the study suggested that climate change may be an additional important control of
31 DOC dynamics. The role of ionic strength in modifying temporal patterns of surface
32 water DOC in the U.S. has not been studied at the time of this writing. [Evans et al. \(2017\)](#)
33 also documented decreased lake DOC in response to reacidification of a moorland lake
34 catchment in the U.K. In addition, the quality of the DOC changed towards higher levels
35 of aromatic organic compounds and an increase in particulate organic C.

7.1.2.10. Climate Modification of Ecosystem Response to Nitrogen and Sulfur

1 Surface water chemistry and chemical recovery ([Appendix 7.1.5.1](#)) of fresh waters are
2 occurring within the context of projected changes in annual mean temperature and
3 magnitude of precipitation associated with climate change ([Greaver et al., 2016](#)). In acid
4 sensitive regions, altered hydrologic regimes are likely to affect weathering rate of base
5 cations, lake water levels, and organic matter inputs to catchments ([Adrian et al., 2009](#);
6 [Porcal et al., 2009](#)). Projected shifts in runoff, timing, and quantity of flushing will alter
7 the frequency and duration of episodic events and the concentrations of nutrients and
8 chemical indicators in surface waters ([Adrian et al., 2009](#); [Whitehead et al., 2009](#)).
9 Extreme weather years (wet or dry) can shift water chemistry responses such as DOC and
10 SO_4^{2-} concentrations ([Strock et al., 2016](#)). Increased loading of DOC to surface waters,
11 attributed in part to increasing temperatures and changes in precipitation, may affect
12 biogeochemical processes and nutrient availability ([Daggett et al., 2015](#); [Zhang et al.,](#)
13 [2010](#); [Weyhenmeyer and Karlsson, 2009](#)). [Appendix 13](#) includes a more detailed
14 discussion of how climate (e.g., temperature and precipitation) modifies ecosystem
15 response to acidification.

7.1.3. Freshwater Monitoring and Databases

16 Long-term monitoring of surface water chemistry over time has enabled a greater
17 understanding of ecosystem response to deposition of N and S, including chemical and
18 biological responses. Monitoring data inform determination and quantification of
19 temporal trends and many monitoring studies for acidification have been ongoing for one
20 or two decades, in some cases longer. Such data were available and incorporated into the
21 2008 ISA. Since that time, nearly a decade's worth of additional data have been added to
22 some of these databases. This is noteworthy because short-term temporal variability can
23 mask small changes that are part of a long-term trend. The availability of these additional
24 data facilitates trend detection now, compared with 2008. A number of monitoring
25 studies have been conducted or continued in recent years that document nutrient
26 dynamics in water bodies in response to N inputs. Recent evidence that P deposition is
27 increasing ([Appendix 9.1.1.4](#)) may contribute to total nutrient loading and affect shifts in
28 lake nutrient status.

7.1.3.1. Acidification

29 A number of freshwater monitoring studies have been conducted using data collected
30 over the previous one to three decades that have documented ecosystem chemical damage

1 and recovery ([Appendix 7.1.5.1](#)) caused by acidifying deposition of S and/or N. Many of
2 these studies have been conducted in the U.S., especially in the Northeast and the
3 southern Appalachian Mountains ([Table 7-3](#)), including a number of studies since 2008.
4 Two surface water chemistry monitoring programs that have been especially useful to
5 inform the assessment of aquatic ecosystem responses to changes in acidic atmospheric
6 deposition have been Temporally Integrated Monitoring of Ecosystems (TIME)
7 ([Stoddard et al., 1996](#)) which is no longer operating, and the U.S. EPA Long-Term
8 Monitoring (LTM) project ([Stoddard et al., 1998](#); [Ford et al., 1993](#)). These U.S. EPA
9 monitoring efforts focus on portions of the U.S. most affected by the acidifying influence
10 of S and N deposition, including lakes in the Adirondack Mountains of New York and in
11 New England, and streams in the Northern Appalachian Plateau and the Blue Ridge
12 physiographic provinces in Virginia and West Virginia. Both projects are operated
13 cooperatively with numerous collaborators in state agencies, academic institutions, and
14 various federal agencies.

15 The Adirondack Lakes Survey Corporation (ALSC) has been monitoring Adirondack
16 lakes for about 30 years. This work has mainly focused on acid-base chemistry, but has
17 also involved some fish monitoring and measurement of parameters relevant to nutrient
18 enrichment. Monitoring data have shown some chemical recovery from lake
19 acidification, reflected in increased pH and ANC and decreased inorganic Al
20 concentrations ([Appendix 7.1.5.1](#)). HBEF in NH also has several decades of monitoring
21 data. The central and southern Appalachian Mountains region is important because (1) it
22 contains an abundance of low-ANC streams situated on base-poor geology,
23 (2) atmospheric S and N deposition have been high, (3) S adsorption on soils complicates
24 acidification/recovery responses, and (4) much of the acid-sensitive landscape is
25 managed as national park and wilderness area. New studies have been conducted of
26 stream acid-base chemistry throughout this region in West Virginia, Maryland, Virginia,
27 and Tennessee. More recent monitoring studies are highlighted below and in [Table 7-3](#).

28 Since the early 2000s, U.S. EPA, together with states, tribes, other entities, and
29 individuals, have collaborated on a series of statistically representative surveys (National
30 Aquatic Resource Surveys [NARS]) of the nation's waters, including surveys of lakes
31 ([U.S. EPA, 2016h, 2009b](#)), streams ([U.S. EPA, 2016i](#)), wetlands ([U.S. EPA, 2016j](#)), and
32 coastal waters ([U.S. EPA, 2016g](#)). Based on standard sampling and analysis protocols
33 and consistent quality assurance, these surveys periodically assess the magnitude and
34 spatial extent of water quality issues and concerns across the U.S.

Table 7-3 Monitoring and resurvey results of aquatic acidification and/or chemical recovery since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.

Process	Acidification Indicator	Nutrient Enrichment Indicator	Type of Ecosystem	Region	Time Period	Ambient N/S Deposition kg/ha/yr	Effect of Deposition	Publication
Chemical recovery	pH, ANC, SO ₄ ²⁻ , DOC	N/Ap	12 streams	Adirondack Mts.	1980s–2008	Variable	On average, pH increased by 0.28; ANC increased 13 µeq/L; rate of decrease in stream SO ₄ ²⁻ concentration was 2 µmol/L/yr between 1999 and 2008 at a high-DOC stream and 0.73 µmol/L/yr at a low-DOC stream.	Lawrence et al. (2011)
Chemical recovery	pH, ANC, SO ₄ ²⁻ , DOC, NO ₃ ⁻ , Ali	NO ₃ ⁻	48 lakes (16 lakes that were part of the original ALTM monitoring project and addition of new lakes in 1992)	Adirondack Mts.	1982–2015		All study lakes showed significant decreases in the concentration of SO ₄ ²⁻ in lake water consistent with reductions in S deposition. Concentration of NO ₃ ⁻ declined at variable rates in 33 of the 48 study lakes. Widespread increases in ANC in 42 of the 48 study lakes and in lab pH in 33 of the 48 study lakes. Ali decreased in 45 of the 48 lakes. Dissolved organic C increased in 29 of the 48 lakes. Most of the 48 ALTM lakes showed significant decreases in the concentrations of base cations. Eleven of the 16 original ALTM lakes showed increases in lake ANC between 1982 and 2013.	Driscoll et al. (2016)

Table 7-3 (Continued): Monitoring and resurvey results of aquatic acidification and/or chemical recovery since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria.

Process	Acidification Indicator	Nutrient Enrichment Indicator	Type of Ecosystem	Region	Time Period	Ambient N/S Deposition kg/ha/yr	Effect of Deposition	Publication
Chemical recovery	ANC, DOC	NO ₃ ⁻	TIME lakes	Adirondack Mts.	1991–2007	Variable	Percentage acidic lakes decreased from 15.5 to 8.3%; calculated ANC increased at more than twice the rate as Gran ANC, which was attributed to increase in DOC.	Waller et al. (2012)
Chemical recovery	SO ₄ ²⁻ , DOC	N/Ap	Nine lakes	Maine	1993–2009	Wet S = 6.2 (1980) to 1.5 (2010) N = 3	Decreases in lake SO ₄ ²⁻ correlated with increases in DOC and a shift from microbial to terrestrially derived organic matter.	SanClements et al. (2012)
Chemical recovery	NO ₃ ⁻	NO ₃ ⁻	Lakes	Adirondack Mts. and New England	2000–2010	N/Av	Lake NO ₃ ⁻ concentrations declined at rate of -0.05 µeq/L/yr and there was a shift to nontoxic (organic) Al.	Strock et al. (2014)
Chemical recovery	Al _i	N/Ap	Resurvey of 113 lakes	Northeastern U.S.	1986–2001	N/Av	In 2001, only 7 lakes, representing 130 lakes in population, had Al _i >2 µmol/L (toxic threshold to brook trout), compared with 20 sampled lakes (representing 449 lakes in population) in 1986.	Warby et al. (2008)

Table 7-3 (Continued): Monitoring and resurvey results of aquatic acidification and/or chemical recovery since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria.

Process	Acidification Indicator	Nutrient Enrichment Indicator	Type of Ecosystem	Region	Time Period	Ambient N/S Deposition kg/ha/yr	Effect of Deposition	Publication
Chemical recovery	SO ₄ ²⁻ , NO ₃ ⁻ , ANC	NO ₃ ⁻	Two streams	Western MD	1990–2005	N/Av	Concentrations of SO ₄ ²⁻ in stream water decreased at a rate of about 3 µeq/L/yr in response to 34% reduction in wet S deposition. Trends in stream NO ₃ ⁻ appeared to be related to watershed factors, especially forest disturbance. Rate of ANC increase during the period 1996–2005 was about half the rate of the entire study period, suggesting that chemical recovery may be slowing or coming to an end.	Eshleman et al. (2008)
Chemical recovery	Ca ²⁺ , Mg ²⁺ , SO ₄ ²⁻	NO ₃ ⁻	Two streams (manipulated and control)	Bear Brook, ME	1988–2006	Wet S = 6 (1987) to 2.3 (2006)	Concentrations of Ca and Mg in stream water decreased more than SO ₄ ²⁻ concentration, causing stream acidification in control stream.	Navrátil et al. (2010)
Chemical recovery	ANC	N/Av	64 streams	Western Virginia	1987–2011	Wet S = 9 (1980) to 3.7 (2010) Wet N = 4.7 (1980) to 3.0 (2010)	At most sites underlain by base-poor bedrock, ANC decreased despite reductions in S deposition. This response was related to depletion of base cations.	Robison et al. (2013)
S adsorption	SO ₄ ²⁻	NO ₃ ⁻	Stream watershed	Noland Divide, GSMNP, TN	1991–2006	S = 28	Sulfur adsorption on soil is important on average. During large precipitation events, SO ₄ ²⁻ was more mobile and caused stream acidification.	Cai et al. (2010)

Table 7-3 (Continued): Monitoring and resurvey results of aquatic acidification and/or chemical recovery since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria.

Process	Acidification Indicator	Nutrient Enrichment Indicator	Type of Ecosystem	Region	Time Period	Ambient N/S Deposition kg/ha/yr	Effect of Deposition	Publication
Pyrite weathering	SO ₄ ²⁻	N/Ap	High elevation lakes	Colorado	1985–2008	N/Av	Lake SO ₄ ²⁻ concentration decreased at a rate of –0.12 to –0.27 µeq/L/yr. Climate warming appears to have affected pyrite weathering and lake SO ₄ ²⁻ concentration.	Mast et al. (2011)
ANC production	Alkalinity, Ca ²	N/Ap	Streams and rivers	Eastern U.S.	Varies, at least 25 yr of monitoring data per site	Varies	Acidifying deposition is one contributor along with carbonate lithology and watershed topography to significantly increasing alkalinity trends (in 64% of 97 river and stream sites). Most rapid rates of alkalization occurred at sites with the highest elevation and greatest inputs of acidifying deposition.	Kaushal et al. (2013)
ANC production	Alkalinity, SO ₄ ²⁻ , NO ₃ ⁻ , Ca ²⁺ , Mg ²⁺	N/Ap	Rivers	U.S.	Varies, average monitoring data spanned 50 yrs (range 27 to 65 yr)	Varies	Increasing alkalinity observed in 14 of 23 rivers attributed to recovery from acidification, agricultural processes and changing land uses.	Stets et al. (2014)

1 In the most recent U.S. EPA National Lakes Assessment, based on lake surveys
2 conducted in 2012, more than 1,000 lakes, ponds, and reservoirs (representing
3 approximately 100,000 water bodies) were sampled for their water quality and biological
4 and habitat conditions using generally comparable field and laboratory protocols ([U.S.
5 EPA, 2016h](#)). Inclusion criteria were water bodies >1 hectare, at least 1 m deep, a
6 minimum of 0.1 hectare open water and minimum water residence time of 1 week.
7 Chemical indicators in the lake surveys included acidification. This survey updated the
8 previous National Lakes Assessment ([U.S. EPA, 2009b](#)). In the earlier National Lakes
9 Assessment that was conducted in 2007 ([U.S. EPA, 2009b](#)), ANC and pH were among
10 the chosen chemical indicators used to assess biological integrity. However, due to
11 logistical considerations, included sites were restricted to lakes larger than 10 acres
12 (4 ha). This constraint eliminated from consideration many of the most acid-sensitive and
13 acid-impacted lakes. In the more recent 2012 lakes survey, the size criterion for inclusion
14 was decreased to lakes >1 hectare ([U.S. EPA, 2016h](#)).

15 The U.S. EPA also conducted a National Rivers and Streams Assessment (NRSA) during
16 the period 2008–2009 ([U.S. EPA, 2016i](#)). Nearly 2,000 perennial river and stream sites
17 were sampled, representing nearly 1.2 million miles of stream reach. Stream size ranged
18 from very small headwaters to very large rivers. The NRSA reported four chemical
19 stressors: total N, total P, salinity, and acidification along with biological indicators
20 including benthic macroinvertebrates and fish. In the 2012 survey, 97% of lakes were
21 classified in the least disturbed condition for acidification. During the period 2008–2009
22 ([U.S. EPA, 2016i](#)) acidification was found to be a problem in less than 1% of the stream
23 and river length in the U.S. ([U.S. EPA, 2016i](#)). These results emphasize the finding that
24 acidification impacts are largely confined to relatively small areas of high sensitivity
25 and/or to relatively small lakes and tributary streams.

26 The U.S. Geological Survey (USGS) has operated several long-term monitoring efforts,
27 including the National Ambient Water Quality Assessment (NAWQA) program that was
28 created in 1991 to assess the nation's water quality in 51 study units defined primarily by
29 major drainage divides. These units comprise approximately 50% of the conterminous
30 U.S. Major objectives of the NAWQA program have been to determine the condition of
31 the nation's streams, rivers, and groundwater; whether these conditions are changing over
32 time; and how these conditions are affected by natural features and human activities. The
33 major priority of the NAWQA program since its inception has been the study of
34 watersheds that have experienced impacts from agriculture and various forms of
35 development. The location of sites, sampling frequency, and types of measurements all
36 reflect this priority. The NAWQA data set has also been used to develop predictive
37 models for occurrence of macroinvertebrates and fish in U.S. streams and identify the
38 relative importance of factors, including nutrients, in species distributions ([Carlisle and](#)

1 [Meador, 2007](#); [Carlisle et al., 2007](#); [Meador and Carlisle, 2007](#)). Additional USGS
2 monitoring programs have included the Hydrologic Benchmark Network (discontinued in
3 1997), the New York District of the USGS for the water supply watershed for New York
4 City (in the Catskill Mountain region), and a monitoring project conducted by USGS in
5 the Adirondack Mountains at Buck Creek, NY.

6 Studies by [Kaushal et al. \(2013\)](#) and [Stets et al. \(2014\)](#) assessed changes in, and controls
7 on, carbonate alkalinity of rivers in the U.S. Alkalinity was defined (in equivalent
8 concentrations, expressed as $\mu\text{eq/L}$) as:

$$[\text{ALK}] = [\text{HCO}_3^-] + [\text{CO}_3^{2-}] + [\text{OH}^-] - [\text{H}^+]$$

Equation 7-1

9 which is mathematically equivalent to ANC defined as the difference between the
10 equivalent sum of the base cations and the mineral acid anions ([Charles and Christie,
11 1991](#)). [Kaushal et al. \(2013\)](#) reported trends in alkalinity in 97 rivers and streams in the
12 eastern U.S. They found significant increases in alkalinity, a product of chemical
13 weathering, at 62 (64%) of the study sites, with no sites showing significant decreases.
14 Trends of increasing alkalinity were weakly related to the presence of carbonate lithology
15 in the watershed, acidic deposition, and topography. The authors interpreted the generally
16 increasing alkalinity as reflective of human impacts on weathering rates. The role of
17 temperature in modifying weathering rates was not assessed.

7.1.3.2. Eutrophication

18 A number of monitoring studies have been conducted or continued in recent years that
19 have documented the effects of N input on the NO_3^- flux and/or trophic state of fresh
20 waters. Monitoring studies linked to eutrophication response and published since the
21 2008 ISA are highlighted in this section. In the most recent National Lakes Assessment,
22 about one-third of the lakes in the continental U.S. were judged to have excess N,
23 suggesting that N nutrient pollution is a widespread concern across the country ([U.S.
24 EPA, 2016h](#)). Chemical indicators in the lake surveys included DO, N, and P. Benthic
25 macroinvertebrates, chlorophyll *a*, and zooplankton were the biological indicators
26 assessed by the sampling protocols. Algal toxin (microcystin) and cyanobacteria were
27 also evaluated in the water bodies. Lakes that had high levels of N were 1.6 times as
28 likely to have a degraded benthic macroinvertebrate community. Increases in both
29 cyanobacteria (8.3% increase) and microcystin toxin (9.5% increase) were reported in the
30 most recent lake sampling compared to the previous National Lakes Survey conducted in
31 2007 ([U.S. EPA, 2016h, 2009b](#)). In the NRSA, 41% of the nation's river and stream
32 miles were rated poor for N compared to least-disturbed reference conditions ([U.S. EPA,](#)

1 [2016i](#)). Streams in the Plains and Lowlands were most impacted by N, followed by the
2 mountainous areas east of the Mississippi River (Eastern Highlands).

3 Since the 2008 ISA, surface water chemistry data from long-term monitoring by federal,
4 state, and local agencies as well as university research groups and nonprofits has been
5 combined into publically available metadatabases. The Lake Multi-Scaled Geospatial and
6 Temporal Database of the Northeast Lakes of the U.S. (LAGOS-NE) is an integrated
7 database that includes lake surface water chemistry data from a 17-state region ([Soranno
8 et al., 2015](#)). A Georeferenced Lake Nutrient Chemistry (GLNC) database containing N
9 and P water chemistry from 1964–2015 from 3,602 western U.S. mountain lakes has
10 combined data from the National Park Service (NPS), U.S. Fish and Wildlife Service
11 (USFS), the U.S. EPA National Lakes Assessments, and academic researchers for
12 assessing nutrient deposition effects in the region ([Williams et al., 2017b](#)). These
13 databases have been used to assess temporal and spatial trends of lake nutrient chemistry
14 in response to environmental stressors including atmospheric deposition.

15 Research published since the 2008 ISA and described in detail in [Appendix 9.1.1.4](#)
16 provided evidence suggesting that predominantly dry deposition of fine (<10 µm) and
17 coarse (<100 µm) particulates containing P “dust”, play a role in the enrichment effects
18 of N deposition to fresh waters and their catchments. Among the large natural P emission
19 sources are soils, vegetation, and biomass combustion ash. Other notable sources include
20 industry, agriculture, and mining. Although P is not a criteria pollutant, inputs of P may
21 contribute to eutrophication and affect shifts in lake trophic status from P to N limitation
22 or to colimitation. Data from the U.S. EPA National Lakes surveys and National Rivers
23 and Streams surveys were analyzed by [Stoddard et al. \(2016\)](#) to determine whether total
24 P (TP) concentrations changed between 2000 and 2014. They found increases in TP
25 continentally and especially at sites that exhibited low disturbance ([Appendix 9.1.1.2](#)). In
26 addition, they observed that TN was strongly correlated with TP in lakes and streams on a
27 national scale. Although the authors determined that TP was increasing at “minimally
28 disturbed sites,” they observed that TN was not increasing at those sites. A 5-year,
29 Community Atmospheric Model (CAM₄) simulation by [Brahney et al. \(2015\)](#) suggested
30 that P deposition may play a large role in alpine lake trophic status and that TP deposition
31 may have increased globally by 1.4 times the preindustrial deposition rate. A global-scale
32 analysis by [Tipping et al. \(2014\)](#) suggested that oligotrophic lakes are most likely to
33 experience effects of atmospheric P deposition, with implications for changes in
34 productivity in response to anthropogenically emitted N.

35 Regional monitoring data have been used to infer the N saturation status of watersheds in
36 forested ecosystems based on NO₃⁻ leaching to surface waters. [Yanai et al. \(2013\)](#)
37 conducted a detailed time-series analysis of precipitation and stream chemistry data

1 (1965–2007) to examine the N budget of a forested reference watershed at HBEF in New
2 Hampshire. They found that decreases in stream NO_3^- preceded decreases in atmospheric
3 N deposition. [Eshleman et al. \(2013\)](#) evaluated changes in the concentrations of NO_3^- in
4 streams impacted by atmospheric N deposition in the Appalachian Mountains during the
5 period 1986–2009. Long-term monitoring of nutrient dynamics has also been conducted
6 in the western U.S. [Mast et al. \(2014\)](#) measured long-term changes in stream NO_3^-
7 concentration over three decades at the Loch Vale watershed in Rocky Mountain
8 National Park. During the last 15 years, surface waters in the Green Lakes Valley at the
9 Niwot Ridge Long-Term Ecological Research site in Colorado have been subjects of a
10 wide variety of monitoring and process studies that focused on surface waters as
11 integrators of changes in environmental conditions and the response to external stressors,
12 including atmospheric deposition and climate change ([Miller and Mcknight, 2015](#); [Elser
13 et al., 2009b](#); [Elser et al., 2009a](#); [Gardner et al., 2008](#)).

7.1.4. Models

14 Models used to assess the effects of N and S deposition on U.S. ecosystems were
15 described in the 2008 ISA (Annex A) and [Appendix 4](#) of this ISA. The most frequently
16 used ecosystem models for aquatic systems situated in small watersheds have included
17 the Model of Acidification of Groundwater in Catchments (MAGIC) and the
18 Photosynthesis and Evapotranspiration-Biogeochemical (PnET/BGC) model [([U.S. EPA,
19 2008a](#)); [Appendix 4.5](#)]. ForSAFE [Wallman et al. \(2005\)](#) has also been applied widely,
20 especially in Europe, and has been linked with a terrestrial plant biodiversity model,
21 VEG, and recently applied at several locations in the U.S. [([Phelan et al., 2016](#);
22 [McDonnell et al., 2014a](#)); [Appendix 4.5.1.4](#)]. The Very Simple Dynamic (VSD) soil
23 acidification model is used in Europe to simulate acidification effects in soils when
24 observed data are sparse ([Appendix 4.5.1.3](#)). It has not been used widely in the U.S.
25 Three other models, SPARROW, Watershed Assessment Tool for Evaluating Reduction
26 Scenarios for Nitrogen (WATERS-N), and the Surface Water Assessment Tool (SWAT)
27 have been used to evaluate N loading to large river systems. Another model that has been
28 applied to analysis of nutrient enrichment in aquatic systems is AQUATOX ([Carleton et
29 al., 2009](#)), which simulates nutrient dynamics and effects on aquatic biota. Such models
30 were earlier summarized in Table A-8 in the 2008 ISA ([U.S. EPA, 2008a](#)).

31 In the 2008 secondary NAAQS review for oxides of N and S, an aquatic acidification
32 index (AAI) was developed to relate (1) atmospheric concentrations of SO_x and
33 $\text{NO}_y + \text{NH}_y$ to N and S deposition levels using transference ratios ([Appendix 2](#)) and
34 (2) to relate deposition to ANC values, using a modified Steady-State Water Chemistry
35 (SSWC) model ([Appendix 4](#)) and water chemistry data for over 6,000 sites in the U.S.

1 The ANC values were grouped by site into ecoregions and evaluated by considering the
2 distribution of predicted ANC values ([Scheffe et al., 2014](#)).

7.1.4.1. Updates to Key Previously Identified Models

3 [Zanchi et al. \(2016\)](#) developed an approach to include lateral flow in ForSAFE. Results
4 were assessed by comparison with research values at the Vindela Research forest in
5 northern Sweden. Simulation of both saturated and unsaturated soil zones improved
6 agreement between measured and modeled water flows. This model improvement will
7 likely enhance the ability to simulate the export of elements from soil to drainage water
8 using ForSAFE. In 2011, The SPARROW modeling group published a new set of
9 regional models as a special issue ([Preston et al., 2011](#)). Other models have been used for
10 assessing nutrient loading to freshwater systems. SWAT has been adopted as part of
11 U.S. EPA's Better Assessment Science Integrating Point and Nonpoint Sources
12 (BASINS) platform in support of TMDL model development ([Gassman et al., 2007](#)).

7.1.4.2. New Models (Published since 2008)

13 Several new freshwater acidification or eutrophication models have been developed and
14 published since 2008. The Watershed Analysis Risk Management Framework (WARMF)
15 is a model for evaluating point and nonpoint pollution, including N fate and transport
16 ([Dayyani et al., 2013](#); [Herr and Chen, 2012](#)). A new national water quality modeling
17 system (Hydrologic and Water Quality System [HAWQS]) is under development by
18 Texas A&M University and U.S. Department of Agriculture (USDA) for U.S. EPA's
19 Office of Water (<https://epahawqs.tamu.edu/>). The model is intended to assist resource
20 managers and policy makers in evaluating the effectiveness of water pollution control
21 efforts. HAWQS will support application of SWAT and SPARROW and will include
22 simulations of nutrients and other pollutants. [Table 7-4](#) summarizes recent process-based
23 model estimates of surface water acidification and chemical recovery in the U.S.

Table 7-4 Recent process-based model estimates of surface water acidification and chemical recovery in the U.S.

Model	Nutrient Enrichment	Acidification	Type of Ecosystem	Region	Model Application and Findings	Publication
PnET-BGC		X	30 watersheds in Great Smoky Mts. NP	Southern Appalachian Mtns.	Stream recovery has been limited.	Fakhraei et al. (2016)
PnET-BGC		X	44 representative watersheds	Adirondack Mtns.	Larger historical lake acidification in lakes having lower ambient ANC.	Zhai et al. (2008)
MAGIC		X	66 stream watersheds	Southern Blue Ridge Mtns.	All modeled streams had preindustrial ANC >30 µeq/L. Median stream lost about 25 µeq/L of ANC between 1860 and 2005.	Sullivan et al. (2011b)
PnET-BGC		X	128 acid-impaired lakes	Adirondack Mtns.	Of 128 acid-impaired lakes that were modeled, 97 had ambient ANC below target of 20 µeq/L and 83 were below target of 11 µeq/L. TMDL corresponding to a moderate emissions control scenario (60% decrease in S deposition) was 7.9 meq/m ² /yr.	Fakhraei et al. (2014)
PnET-BGC		X	Streams, watershed	HBEF, NH	Simulations under changing climate reflected later snowpack development, earlier spring snowmelt, greater ET, and slight increase in water yield. Net soil mineralization and nitrification caused simulated soil and water acidification.	Pourmokhtarian et al. (2012)
PnET-BGC, SAFE, VSD, MAGIC			Inter-model comparison	HBEF, NH	Hindcast and forecast projections were qualitatively similar, but temporal patterns of simulated change in chemistry differed substantially among models.	Tominaga et al. (2010)

Table 7-4 (Continued): Recent process based model estimates of surface water acidification and chemical recovery in the U.S.

Model	Nutrient Enrichment	Acidification	Type of Ecosystem	Region	Model Application and Findings	Publication
PnET-BGC		X	Three multipollutant scenarios	Adirondack Mtns.	Predicted ANC recovery closely related to percentage of watershed in conifers, elevation, and lake area.	Wu and Driscoll (2009)

ANC = acid neutralizing capacity; ET = evapotranspiration; HBEF = Hubbard Brook Experimental Forest; L = liter; m = meter; µeq = microequivalent; meq = milliequivalent; MAGIC = Model of Acidification of Groundwater in Catchments; PnET-BGC = Photosynthesis and Evapo Transpiration-Biogeochemical; S = sulfur; SAFE = Soil Acidification in Forest Ecosystems; TMDL = total maximum daily load; VSD = Very Simple Dynamic; yr = year.

1

7.1.5. National Scale Sensitivity and Response

2 The 2008 ISA documented that by the end of the 1980s, the regions of the U.S. with
 3 many acid-sensitive waters and ecosystems were well recognized. These acid-sensitive
 4 ecosystems are mostly located in upland mountainous terrain in the eastern and western
 5 U.S. and are underlain by bedrock that is resistant to weathering, such as granite or
 6 quartzite sandstone. However, a similar map for areas sensitive to the eutrophication
 7 effects of N were not available. There is strong evidence demonstrating that
 8 biogeochemical sensitivity to deposition-driven eutrophication and acidification is the
 9 result of historical loading, geologic/soil conditions (e.g., mineral weathering and S
 10 adsorption), and nonanthropogenic sources of N and S loading to the system. There is no
 11 single deposition level applicable to all ecosystems in the U.S. that can describe the onset
 12 of eutrophication or acidification. There are new publications that address recovery of
 13 freshwater ecosystems at either the national scale or in specific regions. National scale
 14 sensitivity of freshwater systems to N-nutrient effects is discussed in [Appendix 9.1.1.2](#).

7.1.5.1. Chemical Recovery

15 Chemical recovery of previously acidified surface water is required to support biological
 16 recovery. An aquatic ecosystem in chemical recovery will have trends in water quality
 17 indicators (NO₃⁻, SO₄²⁻, pH, ANC, inorganic monomeric Al) towards inferred
 18 preindustrial values ([Chapter 1](#)). Preindustrial water quality indicator values are inferred
 19 from models, paleolimnology samples, or historical samples of biological communities.
 20 Preindustrial water quality varied across the conterminous U.S. in response to variation in
 21 climate, geology, and biological communities. In general, biological recovery has lagged

1 behind chemical recovery in previously acid-impacted and more recently recovering
2 surface waters ([Appendix 8](#)).

3 Surface water NO_3^- is a chemical indicator for both eutrophication and acidification.
4 Several studies since the 2008 ISA have documented decreased surface water NO_3^-
5 concentration attributed to decreases in atmospheric deposition. [Eshleman et al. \(2013\)](#)
6 evaluated changes in the long-term concentration of NO_3^- in surface waters impacted by
7 atmospheric N deposition in the Appalachian Mountains during the period 1986–2009.
8 Regional NO_x emissions progressively decreased during the study period. Decreases in
9 the annual surface water NO_3^- concentration and the NO_3^- yield were observed over the
10 study period, which corresponded to generally comparable declines in annual wet N
11 deposition. [Eshleman and Sabo \(2016\)](#) evaluated changes in NO_3^- concentration over
12 time in tributary streams of the upper Potomac River. The basin-wide decrease, based on
13 results at the Washington, D.C. station was -0.023 mg N/L/year over 26 years (total
14 change of -0.59 mg N/L). They attributed observed decreases in discharge-weighted
15 annual mean NO_3^- concentrations across the basin (mean decrease was 37%) largely to
16 decreases in atmospheric N deposition. [Mast et al. \(2014\)](#) measured long-term changes in
17 stream NO_3^- concentration over three decades at the Loch Vale watershed in Rocky
18 Mountain National Park. The concentrations of NO_3^- in stream water increased during
19 the early 1990s, peaked in the mid 2000s, and then declined by more than 40%. The
20 recent decreases in stream NO_3^- corresponded with decreases in NO_x emissions and N
21 deposition. As was found by [Eshleman et al. \(2013\)](#) in Maryland, similarities in the
22 timing and magnitude of NO_3^- concentrations in stream water and N deposition
23 suggested that stream chemistry is responding to changes in atmospheric deposition of N.
24 However, the response was complicated in this case by a drought in the early 2000s that
25 enhanced N export for several years. In the Adirondack region concentration of NO_3^-
26 declined at variable rates in 33 of the 48 study lakes since 1992 ([Driscoll et al., 2016](#)).
27 [Strock et al. \(2014\)](#) analyzed recent trends in lake chemistry using long-term data from
28 lakes in the Adirondack Mountains and New England. Lake NO_3^- concentration showed
29 no trend prior to 2000. During the 2000s, the wet deposition of NO_3^- declined more than
30 50%, and lake NO_3^- concentration declined subsequent to 2000 at a rate of
31 -0.05 $\mu\text{eq/L/yr}$. TN declined in surface waters at a rate of 1.1% per year from 1990 to
32 2011 in an analysis of lake data from 17 states in the Midwest and northeastern U.S.
33 ([Oliver et al., 2017](#)). Random forest analysis of the data showed atmospheric deposition
34 was the top driver of observed declines in TN.

35 Evidence of chemical recovery from acidification has been provided by monitoring
36 efforts spanning several decades ([Appendix 7.1.3](#)) and the use of models to hindcast and
37 forecast the acid-base chemistry and N response in soils and surface waters
38 ([Appendix 7.1.4](#)). Model projections of past and future changes in surface water

1 chemistry in response to changes in acidic deposition using the MAGIC and PnET-BGC
 2 models are summarized in [Table 7-5](#).

Table 7-5 Model projections of surface water sulfate and associated acid neutralizing capacity, shown as changes between dates, for Adirondack and Shenandoah streams.

Region	Water Bodies	Dates	Model	Pollution Scenario	Change in Median Surface Water SO ₄ ²⁻ µeq/L	Change in Median Surface Water ANC µeq/L	Reference
Hindcasts							
Adirondacks, NY	38 lakes	1850 to 2003	PnET-BGC		+72.9	-39.9	Zhai et al. (2008)

As reported in the 2008 ISA, lake and stream ANC values decreased throughout much of the 20th century in a large number of acid-sensitive lakes and streams throughout the eastern U.S. This effect has been well documented in monitoring programs, paleolimnological studies, and model simulations. Since about 1990, the ANC values of many previously acidified lakes and streams have shown some increases, but such increases have been relatively modest in most cases. [Kahl et al. \(2004\)](#) summarized 20 years of chemical monitoring data from regional U.S. EPA programs in the northern and eastern U.S. Surface water chemistry improved over the 20-year period in many lakes and streams; moderate, but significant increases in ANC and pH were observed. [Stets et al. \(2014\)](#) found widespread increasing alkalinity concentrations at 14 of 23 sites across the conterminous U.S. over the last half of the 20th century and the early 21st century. Results showing decreases in NO₃⁻ and SO₄²⁻ concentrations and cation:alkalinity ratios at many sites were consistent with recovery from water acidification. Agricultural lime contributed alkalinity at some locations. These findings are important because large rivers constitute important pathways for transport of nutrients and other constituents to coastal waters and may influence coastal acidification and Ca supply.

Trends in surface water chemistry, including evidence for chemical recovery, are reported in several acid-sensitive regions of the U.S. where long-term monitoring programs have been in place several decades. These include the Adirondacks and the northeastern U.S. (see [Appendix 16](#)). In some portions of the Appalachian Mountains, chemical recovery of

1 surface waters has not always followed decreases in deposition due to high S absorption in
2 watershed soils ([Appendix 16 Smoky Mountains Case Study](#)).

3 A long-term delay in surface water recovery from past acidification has been noted by
4 [Likens et al. \(1996\)](#) at HBEF. This delay was attributed mainly to changes in base cation
5 concentration. Similarly, based on an analysis of Adirondack lakes, [Lawrence et al. \(2013\)](#)
6 concluded that chemical recovery processes in response to decreases in acidic deposition
7 are complex and require evaluation of multiple chemical metrics in addition to ANC,
8 including DOC, inorganic Al, and BCS. As an example of the complexity, the lower
9 threshold of ANC required to protect brown trout in Norway against acidification damage
10 was earlier estimated to be 20 µeq/L ([Lien et al., 1996](#)). This critical ANC limit may be
11 lower in humic lakes (~8 µeq/L) because about one-third of the organic acid anions may act
12 essentially as strong acid anions ([Lydersen et al., 2004](#); [Driscoll et al., 1994](#)). Inclusion of
13 strong organic acids in the ANC calculation can be useful because the relationships
14 between pH, inorganic Al, and ANC may have changed in response to increased
15 concentrations of DOC and TOC. This is particularly true in lakes having higher DOC and
16 TOC compared with clear water lakes. [Hesthagen et al. \(2008\)](#) estimated that threshold
17 ANC values to prevent damage to brown trout had increased by 1995 to 48 µeq/L. The
18 authors suggested that the higher ANC threshold for 1995 was attributable to lower pH and
19 higher inorganic Al at a given ANC level.

7.1.5.1.1. Adirondacks

20 At the time of the 2008 ISA, several studies reported chemical recovery from acidification
21 in Adirondacks lakes ([Driscoll et al., 2007a](#); [Momen et al., 2006](#); [Driscoll et al., 2003c](#))
22 based on long-term monitoring efforts in the region ([Appendix 7.1.3.1](#)). [Driscoll et al.](#)
23 [\(2003c\)](#) evaluated changes from 1982 to 2000 in the original 16 Adirondack LTM lakes
24 and from 1992 to 2000 in the complete set of 48 Adirondack LTM lakes. They found that
25 nearly all study lakes showed marked decreases in SO_4^{2-} concentration and several lakes
26 showed declines in NO_3^- concentration. They found that 7 of the 16 original monitoring
27 lakes showed statistically significant increases in ANC, with a mean rate of increase of
28 0.78 µeq/L/year. In a study of 30 of the 48 lakes studied by [Driscoll et al. \(2003b\)](#), pH
29 increased in 25 lakes and ANC increased in 12 of the 30 lakes ([Momen et al., 2006](#)).
30 Concentrations of dissolved NO_3^- were inversely correlated with concentrations of
31 chlorophyll *a* in 11 lakes. Chlorophyll *a* increased in concentration in 9 lakes. The increase
32 in pH observed in most of these lakes may have stimulated productivity so that N
33 assimilation by plankton increased, indicating recovery from acidification to
34 eutrophication, rather than to preindustrial conditions.

1 Monitoring data since the 2008 ISA continues to show chemical recovery in the
2 Adirondack region. As described in the Adirondacks case study ([Appendix 16](#)), significant
3 decreases in lake SO_4^{2-} concentrations ($-2.14 \mu\text{mol/L/year}$) corresponding to significant
4 declines in total S deposition were observed in monitoring data from 1984 to 2010
5 ([Mitchell et al., 2013](#)). Surface water ANC and pH recovery has been documented by
6 [Lawrence et al. \(2013\)](#) and [Lawrence et al. \(2011\)](#) in studies of Adirondack streams and
7 lakes. On average, the pH increased by only 0.28 pH units and ANC by $13 \mu\text{eq/L}$ in
8 12 streams that were monitored over a period of 23 years. During that period, there was an
9 approximate 50% reduction in atmospheric deposition of S in the Adirondack region. The
10 percentage of Adirondack lakes that were acidic decreased from an estimated 15.5 to 8.3%
11 using data from the TIME monitoring program ([Waller et al., 2012](#)). Decreases in lake
12 water SO_4^{2-} , and to a lesser extent NO_3^- , concentrations generally were accompanied by
13 increases in lake ANC. [Driscoll et al. \(2016\)](#) observed increases in ANC and pH and
14 marked decreases in dissolved inorganic Al in 45 of 48 study lakes in the Adirondack
15 region from 1982 to 2015, corresponding to decreases in acidifying deposition. Changes
16 were most pronounced in the acid-sensitive thin-till drainage lakes. In another Adirondack
17 long-term study that focused on 43 lakes sampled by the Adirondack Lakes Survey
18 Corporation during three time periods (1984–1987, 1994–2005, and 2008–2012), the
19 average concentration of inorganic Al decreased from $2.2 \mu\text{M}$ (a level above that generally
20 considered toxic to brook trout, $2 \mu\text{M}$) to $0.66 \mu\text{M}$ ([Baldigo et al., 2016](#)).

21 Interpretation of long-term trends in Adirondack surface water chemistry, as summarized
22 above, has also been augmented by results of repeated surveys of the chemistry of lakes
23 initially surveyed several decades previously. [Warby et al. \(2008\)](#) resurveyed 113 lakes
24 throughout the Northeast in 2001 that had previously been sampled by the U.S. EPA in
25 1986 to assess chemical recovery from lake acidification. Decreases in total Al and
26 inorganic Al concentrations were widespread, and were largest in the Adirondack
27 Mountains (-2.59 to $-4.60 \mu\text{mol/L}$). In 2001, only 7 study lakes (representing 130 lakes in
28 the population) had inorganic Al concentrations above a toxic limit of $2 \mu\text{mol/L}$, compared
29 with 20 sampled lakes (representing 449 lakes in the population) in 1986. Thus, it was
30 estimated that in 2001 more than 300 northeastern lakes no longer had summer inorganic
31 Al concentrations at levels considered harmful to aquatic biota. [Michelena et al. \(2016\)](#)
32 reported changes in the water chemistry of 30 Adirondack lakes in response to reductions
33 in acidic deposition from 1994 to 2012. The water quality of the study lakes generally
34 improved during the study period, but the responses were sporadic and complex. Lake pH
35 values increased until about 2002 and then fluctuated. Inorganic Al concentrations
36 generally decreased throughout the period of record. During the early years of monitoring,
37 the average pH increased dramatically from about 5.5 to 6.0. This increase was followed by
38 a period of reacidification for about 5 years, followed by another period of increased pH.

1 This 5-year cycle was then repeated to a muted extent, even though acidic deposition
2 continued to decline.

3 Chemical recovery from surface water acidification in the Adirondack Mountains has been
4 accompanied by increasing concentrations of DOC, including organic acids, which have
5 complicated and restricted recovery from acidification (Section DOC). Long-term
6 monitoring of 48 Adirondack lakes by [Driscoll et al. \(2016\)](#) showed patterns of increasing
7 DOC in 29 study lakes concurrent with decreases in acidic deposition. [Lawrence et al.](#)
8 [\(2013\)](#) evaluated long-term changes in DOC and BCS (which reflects the calculated ANC
9 and includes an adjustment for strong organic acid anions). Increases in DOC concentration
10 from 1994 to 2011 contributed to organic complexation of Al. This reduced the fraction of
11 monomeric Al that was in the inorganic (and potentially toxic) form from 57% in 1994 to
12 23% in 2011. Thus, the higher DOC found during latter sampling increased the organic
13 acidity of the lake water and limited ANC recovery, but at the same time it decreased the
14 toxicity of dissolved Al to aquatic biota. Similarly, [Strock et al. \(2014\)](#) reported trends in
15 recovery from toxic Al levels caused by acidification of surface waters. They analyzed
16 recent trends in lake chemistry using long-term data from lakes in the Adirondack
17 Mountains and New England. During the 2000s, the wet deposition of NO_3^- declined more
18 than 50%. The lake NO_3^- concentration, which showed no trend prior to 2000, declined
19 subsequent to 2000 at a rate of $-0.05 \mu\text{eq/L/year}$. There was a shift to nontoxic (organic)
20 forms of Al. Despite the Al recovery, both the ANC and pH in the study lakes failed to
21 show evidence of appreciable chemical recovery; rather, the lakes continued to exhibit
22 variable trends in ANC and pH.

23 The PnET-BGC model has been applied in the Adirondack region to assess chemical
24 recovery. Model results from [Fakhraei et al. \(2014\)](#) suggested that ambient ANC values
25 were below the target value of $20 \mu\text{eq/L}$ in 97 of the 128 lakes that were judged to be acid
26 impaired under Section 303(d) of the Clean Water Act (CWA); 83 lakes had ANC below
27 the target value of $11 \mu\text{eq/L}$. A moderate emissions control scenario (60% decrease from
28 the ambient atmospheric S deposition) was projected to recover the ANC of lakes by 0.18
29 and $0.05 \mu\text{eq/L/year}$ on average during the periods 2022 to 2050 and 2050 to 2200,
30 respectively. Model results suggested that controlling S deposition to Adirondack lake
31 watersheds was more effective as a means to recover acidic lakes than was controlling N
32 deposition in this region. [Wu and Driscoll \(2009\)](#) applied the PnET-BGC model to predict
33 the responses of lake ANC during the period 2001 to 2050. Based on three multipollutant
34 scenarios, predicted ANC recovery was associated with higher elevation, smaller lake area,
35 and higher percentage of watershed area in coniferous vegetation. The variables lake depth
36 and the square of the lake elevation explained 40% of the variation in predicted lake water
37 ANC.

7.1.5.1.2. Northeast

1 The Northeast U.S. also has several decades of monitoring data, especially for HBEF
2 ([Appendix 7.1.3.1](#)). [Strock et al. \(2016\)](#) documented decreases in water transparency and
3 increases in DOC in lakes in Acadia National Park in Maine over a period of 14 years
4 (1995–2008). Larger transparency decreases were noted in clear water lakes (–0.3 m/year)
5 compared with the brown water lakes (–0.1 m/year). In the Catskill Mountains, NY,
6 23 years of stream water chemistry data showed significant decreasing SO_4^{2-} (mean trend
7 of –2.5 $\mu\text{eq/L/year}$), while no significant trends were observed for NO_3^- ([Mchale et al.,](#)
8 [2017](#)). A decreasing trend in inorganic Al and increasing trends in pH and ANC were
9 evident under both low- and high-flow conditions. [Fuss et al. \(2015\)](#) examined long-term
10 trends in soil solutions and surface waters from the early 1980s to 2011 at the HBEF in
11 New Hampshire. They found that rates of annual average ANC increase during the period
12 1982–2011 were similar to what was observed during snowmelt, although the ANC during
13 snowmelt was 10 $\mu\text{eq/L}$ lower than annual averages. In a summary of 20 years of data at
14 Bear Brook, [Norton et al. \(2010\)](#) observed decreases in pH, base cation concentrations, and
15 ANC, and increases in inorganic Al concentration in the East Bear reference watershed.
16 These observations indicate that under ambient deposition conditions acidification
17 continues even though S deposition and stream SO_4^{2-} concentrations have declined. [Laudon](#)
18 [and Norton \(2010\)](#) analyzed 212 hydrological episodes in Bear Brook using the ANC
19 Dilution Model (ADM) of [Laudon and Bishop \(1999\)](#). The results showed that 18 years of
20 experimental addition of N and S to the West Bear Brook watershed had not altered the
21 most important natural causes of episodic stream acidification: base cation dilution,
22 processes associated with deposition of marine sea salts, and contributions of organic
23 acidity during rain and snowmelt events. The results further indicated that the contributions
24 of SO_4^{2-} to the observed ANC decreases in West Bear Brook during episodes increased
25 steadily since the beginning of experimental watershed treatment. In contrast, the role of
26 NO_3^- in episodic acidification events remained relatively constant after an early increase.
27 Model stimulations at HBEF using the PnET-BGC model showed later development of
28 snowpack, earlier snowmelt, higher evapotranspiration, and increased water yield expected
29 with current and projected trends of increasing temperature will increase net soil N
30 mineralization and nitrification ([Pourmokhtarian et al., 2012](#)). This could contribute to
31 acidification of soil and stream water. In a model study comparison, [Tominaga et al. \(2010\)](#)
32 noted that hindcast (1850–1992) and forecast (2005–2100) projections were qualitatively
33 similar across MAGIC, PnET-BGC, SAFE, and VSD watershed acidification models at
34 HBEF, although projected stream ANC and soil base saturation differed substantially
35 through time.

7.1.5.1.3. West

1 Surface water acidification, and presumably also chemical recovery, have been limited in
2 the western U.S. Although acidification sensitivity has been shown to be high at many
3 locations, acidic deposition levels have also mostly been lower. [Mast et al. \(2011\)](#)
4 examined trends in precipitation chemistry and other factors that influence long-term
5 changes in chemistry of high-elevation lakes in three Colorado wilderness areas during the
6 years 1985 through 2008. Sulfate concentrations in precipitation decreased at rates of -0.15
7 to -0.55 $\mu\text{eq/L/year}$ at 10 monitoring stations in Colorado. In lakes where SO_4^{2-} was
8 primarily derived from atmospheric sources, the lake SO_4^{2-} concentrations decreased by
9 -0.12 to -0.27 $\mu\text{eq/L/year}$. In lakes where SO_4^{2-} likely originated primarily from watershed
10 weathering, the SO_4^{2-} concentrations in lake water increased, rather than decreased, from
11 1985 to 2008.

7.1.5.1.4. Appalachians

12 Not all acid-sensitive regions of the U.S. have shown improvements in surface water
13 quality with decreasing deposition trends. Monitoring data from the Great Smoky
14 Mountains NP ([Appendix 16](#)) indicate that the high S absorption in watershed soils in this
15 region delay recovery from previous stream acidification ([Cai et al., 2010](#)). The majority
16 (about 61%) of the net SO_4^{2-} entering the study watershed was retained. However, during
17 large precipitation events, SO_4^{2-} in wet deposition moved more directly and rapidly to
18 streams, contributing to episodic stream acidification. [Cai et al. \(2010\)](#) concluded that base
19 cation depletion from soils could limit chemical recovery from acidification of streams in
20 the study watershed. Stream chemistry from 1993–2014 at 42 monitoring sites in the park
21 did not show substantial changes over the recent period of long-term monitoring ([Fakhraei](#)
22 [et al., 2016](#)). An empirical modeling study by [Robinson et al. \(2008\)](#) of baseflow water
23 chemistry at 90 streams in Great Smoky Mountains National Park during the years
24 1993–2002 indicated significant decreasing trends in stream pH and SO_4^{2-} at lower
25 elevation sites over time, but no long-term trends in stream NO_3^- or ANC. An estimated
26 30% of the sample sites were simulated to decrease pH to less than 6 within 10 years. The
27 models explained 71% of the variability in pH and 86% of the variability in ANC. Soil
28 retention of SO_4^{2-} and assimilation of NO_3^- into plants were important biogeochemical
29 processes regulating stream chemistry. The stream pH at base flow has not yet shown signs
30 of recovery in response to recent decreases in acidic deposition. The model developed for
31 elevations between 305 and 1,070 m predicted that median pH values will decrease below 6
32 within 34 years if the observed statistical trends continue. The state of Tennessee currently
33 lists streams within the park with mean pH below 6 as impaired under the Clean Water Act

1 Section 303d ([Appendix 16](#), Southeast case study), so the model by [Robinson et al. \(2008\)](#)
2 indicated biologically significant ongoing acidification.

3 [Singh et al. \(2016\)](#) assessed DOC trends in a forested stream at the Coweeta Hydrologic
4 Laboratory in the southeastern U.S. over a period of 25 years. Concentrations and fluxes of
5 DOC decreased by 34 and 56%, respectively, between 1988 and 2001, corresponding with
6 the stream acidification phase. During the period 1997 to 2012, DOC concentration
7 increased in association with increases in precipitation and the number and intensity of
8 short-duration storms during the early part of the growing season.

9 Several model applications have been conducted in the southern Appalachian Mountains to
10 simulate stream chemistry and critical or target loads. These studies have employed the
11 MAGIC, PnET-BGC, and SSWC models. Results of these studies have reinforced the
12 widespread acid sensitivity of this region and the importance of S adsorption and base
13 cation depletion to stream responses to changes in levels of acidic deposition. Critical and
14 target loads ([Chapter 1.2.2.3](#)) for resource recovery/protection were quantified [[Fakhraei et al., 2016](#);
15 [McDonnell et al., 2014b](#); [McDonnell et al., 2013](#); [McDonnell et al., 2012](#);
16 [Sullivan et al., 2011c](#); [McDonnell et al., 2010](#)]; [Appendix 8.5.4](#)]. An important outcome of
17 critical load modeling studies in the Appalachian Mountains is the suggestion that complete
18 stream acid base chemistry recovery may not be possible ([Appendix 8.5.4](#)). [Sullivan et al.](#)
19 [\(2011b\)](#) applied the MAGIC model to estimate the S target load for protecting aquatic
20 resources in 66 stream watersheds in the Southern Blue Ridge province of the Appalachian
21 Mountains at different points in the future. For some of the modeled sites, if S deposition
22 was decreased to zero and maintained at that level throughout the simulation, one or more
23 of the selected critical ANC levels (0, 20, 50, 100 µeq/L) could not be achieved by 2100.
24 This was likely largely due to the simulation result suggesting that many of the streams did
25 not exhibit such a high ANC during preindustrial times, in the absence of acidic deposition.
26 For other sites with large watershed acid buffering capacity, even very high-sustained S
27 deposition would not reduce stream ANC below thresholds associated with biological
28 harm.

29 Monitoring studies suggested that the rate of stream ANC recovery in this region may be
30 slow in the Southeast and that base cation depletion in soils contributed in the last two
31 decades to further aquatic acidification despite reductions in S deposition ([Robison et al.,](#)
32 [2013](#); [Cai et al., 2010](#)). [Rice et al. \(2014\)](#) examined the source-sink behavior of SO_4^{2-} in
33 27 unglaciated forested watersheds across a latitudinal gradient from Pennsylvania to
34 Georgia and found that many of the watersheds still retain SO_4^{2-} under conditions of
35 decreased S deposition. The specific years when the watersheds will likely cross over from
36 retaining to releasing SO_4^{2-} varied from north to south, with the south generally showing
37 later cross-over dates. [Eshleman et al. \(2008\)](#) used data from two long-term monitoring

1 stations in western Maryland to assess the recovery of stream water ANC due to declines in
2 acidic deposition. Stream water SO_4^{2-} concentration declined at the two study sites between
3 1990 and 2005 by about $3 \mu\text{eq/L/year}$ in response to a 34% reduction in wet atmospheric S
4 deposition. However, trends in NO_3^- concentration were more strongly related to watershed
5 factors, especially forest disturbance. Although ANC increased throughout the study, the
6 rate of increase in later years (1996–2005) was only about half as large as the rate of
7 increase in ANC over the entire study period. This result might suggest a slowing of
8 chemical recovery from previous acidification ([Eshleman et al., 2008](#)). This supposition
9 was further substantiated by [Robison et al. \(2013\)](#), who analyzed the chemistry of stream
10 samples collected quarterly from 1987 to 2011 at 64 sites in the southern Appalachian
11 Mountains of western Virginia. At most of the study streams, the pH increased over time.
12 However, at most sites underlain by base-poor bedrock, ANC decreased even though S
13 deposition decreased. These decreases in stream ANC were associated with depletion of
14 base cations in watershed soils.

15 Stream acid-base chemistry from 1999 to 2014 in a group of 40 stream reaches in the
16 Upper Savage River watershed in western Maryland showed statistically significant
17 decreases in stream concentrations of SO_4^{2-} and NO_3^- that were qualitatively and
18 quantitatively consistent with decreases in wet S and N deposition ([Kline et al., 2016](#)).
19 Stream ANC increased by significant amounts in 10–20% of the monitored streams, but the
20 magnitude of recovery was too small compared with natural variability to detect a regional
21 ANC recovery. The percentage of streams having $\text{ANC} \leq 0 \mu\text{eq/L}$ decreased from about 7%
22 in 1999 to 0 in 2014. The percentages of streams having ANC values less than $50 \mu\text{eq/L}$
23 and less than $100 \mu\text{eq/L}$ also decreased markedly between 1999 and 2014. Concentrations
24 of base cations (Ca, Mg, K) decreased, moderating regional ANC recovery.

7.1.5.2. Critical Loads

25 A critical load (CL) is a quantitative estimate of exposure to one or more pollutants below
26 which significant harmful effects on specified sensitive elements of the environment do not
27 occur according to present knowledge [([Spranger et al., 2004](#); [Nilsson and Grennfelt, 1988](#))
28 ([Chapter 1.2.2.3](#))]. These CLs can be used as early warning signals to indicate likely
29 ecosystem sensitivity to change in N or S. Empirical CLs are developed from observational
30 data while steady-state and dynamic models develop relationships between deposition,
31 water quality measurements and biogeochemistry for watersheds.

32 For acidification, CLs from empirical data as well as modeling approaches are available for
33 acid-sensitive regions of the U.S. ([Appendix 8.5.3](#)). Generalized empirical estimates are
34 based on acidification or increased surface water NO_3^- leaching. Empirical CLs to protect

1 against aquatic acidification in U.S. ecosystems are summarized in [Table 8-7](#). Both
2 steady-state ([Appendix 8.5.4.1.2.1](#)) and dynamic models ([Appendix 8.5.4.1.2.2](#)) have been
3 used to quantify relationships between deposition and biogeochemistry for watersheds in
4 order to develop CL estimates to protect against acidification or promote recovery of
5 acid-base chemistry. Recent CL modeling studies in the U.S. to protect against aquatic
6 acidification are summarized in [Table 8-8](#). Most aquatic CL studies conducted in the U.S.
7 have used surface water ANC as the principal metric of water quality change in response to
8 changes in acidic deposition, although ANC should not necessarily be used as the only
9 environmental predictor of biological harm on which to base CLs. Other potentially useful
10 variables include water pH, inorganic Al, and BCS. Since the 2008 ISA, dynamic modeling
11 of CLs in the U.S. to achieve various ANC targets has been focused mostly on the
12 Adirondack and Appalachian Mountains. The CL can be calculated to represent the
13 individual or combined deposition load of S and/or N to which a stream and its watershed
14 could be subjected and still have a surface water ANC within a targeted range.

15 For nutrient enrichment, diatoms are among the most sensitive aquatic organisms, thereby
16 providing a basis for assessing aquatic ecosystem protection against nutrient enrichment
17 across ecosystems. The lake water NO_3^- concentration has been identified as a useful
18 chemical criterion indicative of biological change in the diatom community. Recently,
19 [Williams et al. \(2017b\)](#) used phytoplankton biomass N to P limitation shifts as the basis for
20 CL calculations. Critical loads ([Chapter 1.2.2.3](#)) for nutrient enrichment are described in
21 [Appendix 9.5](#) and summarized in [Table 9-4](#).

7.1.6. Water Quality Criteria

22 The term “water quality criteria” is used in two sections of the Clean Water Act:
23 Section 304(a)(1) and Section 303(c)(2). The term has a different impact in each section. In
24 Section 304, the term refers to a scientific assessment of ecological and human health
25 effects that U.S. EPA recommends to states and authorized tribes for establishing water
26 quality standards that ultimately provide a basis for controlling discharges or releases of
27 pollutants or related parameters. Ambient water quality criteria associated with specific
28 water body uses, when adopted as state or tribal water quality standards under Section 303
29 of the CWA, define the level of a pollutant (or, in the case of nutrients, a condition)
30 necessary to protect designated uses in specific water bodies.

31 U.S. EPA develops Water Quality Criteria (WQC) using existing scientific knowledge to
32 determine when water is unsafe for people and wildlife. These criteria are developed as
33 recommendations. State and tribal governments may adopt these criteria or use them as
34 guidance in developing their own. U.S. EPA bases aquatic life criteria on how much of a

1 chemical can be present in surface water before it is likely to harm plant and animal life.
2 WQC are determined to protect aquatic life, biology, human health, microbial/recreational,
3 and sediment condition. For aquatic life, the criteria are designed to protect both freshwater
4 and marine organisms from short-term and long-term exposure to pollutants. Biological
5 criteria indicate the health of water bodies based on how many and what kinds of organisms
6 are present. More details about the scientific basis for these criteria may be found at
7 <https://www.epa.gov/wqc/basic-information-water-quality-criteria>.

8 The U.S. EPA is working with the states to develop numeric nutrient criteria to better
9 define levels of N and P that affect U.S. waters. The numeric values include both causative
10 (N and P) and response (chlorophyll *a*, turbidity) variables. The U.S. EPA's National
11 Nutrient Program recommended nutrient criteria for rivers and streams in 14 ecoregions of
12 the U.S. (based on Omernik Level III ecoregions) to use as starting points for states to
13 develop their own criteria ([U.S. EPA, 1998b](#)).

14 WQC indicators related to N are available for 10 states to date ([Table 7-6](#)) including
15 Oregon, California, Arizona, Colorado, Montana, Utah, and Mississippi which have
16 numeric nutrient criteria. These criteria may include a variety of N species and chlorophyll
17 *a* ([Table 7-6](#)). For Washington and Louisiana, which lack explicit numeric nutrient criteria,
18 U.S. EPA aggregate Level III ecoregion nutrient criteria for rivers and streams were used
19 ([Table 7-6](#); <http://www2.epa.gov/nutrient-policy-data/ecoregional-criteria-documents>).
20 Florida has numeric nutrient criteria for TN for most of the state. The compiled state WQC
21 vary greatly in spatial resolution and N forms addressed. Mississippi applies only one
22 criterion for the entire state. By contrast, California has a patchwork of criteria designated
23 by regional water boards.

24 U.S. EPA Aggregate Level III Omernik Ecoregion Nutrient Criteria for Rivers and Streams
25 (from U.S. EPA Ecoregional Nutrient Criteria Documents for Rivers and Streams; available
26 at [http://www2.epa.gov/nutrient-policy-data/ecoregional-nutrient-criteria-documents-rivers-
27 and-streams](http://www2.epa.gov/nutrient-policy-data/ecoregional-nutrient-criteria-documents-rivers-and-streams)) were developed for states to provide a more spatially even set of standards for
28 TN and chlorophyll *a* ([Table 7-7](#)). The regionally based criteria are designed to reflect
29 characteristics such as soils, vegetation, climate, geology, and land cover, which are
30 relatively similar within each ecoregion. Pristine or minimally impacted waters from each
31 region are used as a basis for developing ecoregion-specific nutrient criteria. The aggregate
32 ecoregion criteria are mapped in [Figure 7-4](#) and [Figure 7-5](#).

33 The ambient water quality criteria for NH₃ was recently updated to reflect the sensitivity of
34 freshwater unionoid (order Unionoida) mussels to this nutrient ([U.S. EPA, 2013a](#)). The
35 acute criterion is 17 mg total NH₃⁻-N (TAN)/L, and the chronic criterion is 1.9 TAN/L at
36 pH 7 and temperature 20°C.

7.1.7. Freshwater Biogeochemistry Summary

1 In the 2008 ISA, the body of evidence was sufficient to infer a causal relationship
2 between N and S deposition and the alteration of biogeochemical cycling of N and C in
3 freshwater ecosystems, and between acidifying deposition and changes in
4 biogeochemistry of fresh waters. The strongest evidence for a causal relationship between
5 acidifying deposition and aquatic biogeochemistry comes from studies of changes in
6 surface water chemistry, including concentrations of SO_4^{2-} , NO_3^- , inorganic Al, Ca, sum
7 and surplus of base cations, ANC, and surface water pH. Data from long-term
8 monitoring, experimental manipulations, and modeling studies provide consistent and
9 coherent evidence for biogeochemical changes associated with acidifying N and S
10 deposition. As reviewed in the 2008 ISA and newer studies, biogeochemical processes
11 and surface water chemistry are influenced by characteristics of the catchment and the
12 receiving waters. Atmospheric deposition affects the chemistry, and often also the
13 biology, of each type of freshwater environment. These waters may be chronically
14 acidified or subject to occasional episodes of decreased pH, decreased ANC, and
15 increased inorganic Al concentration. Increased N deposition to freshwater systems via
16 runoff or direct atmospheric deposition, especially to N limited and N and phosphorus (P)
17 colimited systems, can stimulate primary production. New information on
18 biogeochemical cycling of N and S, acidifying deposition effects on biogeochemical
19 processes and changes to chemical indicators of surface water chemistry associated with
20 acidification and N nutrient enrichment is consistent with the conclusions of the 2008
21 ISA, and **the body of evidence is sufficient to infer a causal relationship between N
22 and S deposition and the alteration of freshwater biogeochemistry.**

23 Indicators of altered N cycling include changes in the concentrations of NO_3^- in surface
24 waters. It was well known at the time of the 2008 ISA that key processes such as
25 nitrification and denitrification are quantitatively important portions of the N cycle and
26 that they can be influenced by atmospheric inputs of oxidized and reduced N. More
27 recent research has further substantiated these earlier findings and provided additional
28 quantitative context. Some new research suggests that denitrification may, in some
29 situations, produce more N_2O in relationship to surface water NO_3^- concentration than
30 was previously widely recognized. The quantity and timing of NO_3^- leaching into surface
31 waters is an indicator of terrestrial N cycling in the associated watershed. The
32 concentration of NO_3^- in drainage water provides an index of the balance between
33 removal and addition of N to terrestrial ecosystems. Studies of several types have been
34 conducted in recent years to elucidate these processes, including experimental studies,
35 isotopic analyses, monitoring, and observational studies.

1 As stated in the 2008 ISA, decreases in base cation concentrations in surface waters in the
2 eastern U.S. over the past two to three decades have been ubiquitous and closely tied to
3 trends in SO_4^{2-} concentrations in surface waters. As reported in the 2008 ISA, lake and
4 stream ANC values decreased throughout much of the 20th century in a large number of
5 acid-sensitive lakes and streams throughout the eastern U.S. This effect has been well
6 documented in monitoring programs, paleolimnological studies, and model simulations.
7 As stated in the 2008 ISA, the concentration of dissolved inorganic monomeric Al in
8 surface waters is an especially useful indicator of the adverse impacts of acidifying
9 deposition. Since the 2008 ISA, several monitoring studies have reported decreases in
10 inorganic Al suggestive of chemical recovery of surface waters [([Baldigo et al., 2016](#);
11 [Driscoll et al., 2016](#); [Strock et al., 2014](#); [Warby et al., 2008](#)); [Appendix 7.1.5.1](#)].

12 Monitoring data have proven to constitute a reliable means with which to confirm
13 environmental models and evaluate damage/recovery of ecosystems in response to
14 changes in acidic atmospheric deposition. A number of freshwater monitoring studies
15 have documented ecosystem damage and recovery caused by acidifying deposition of S
16 and/or N. Many of these studies have been conducted in the U.S., especially in the
17 northeast and the Appalachian Mountains. Since 2008, TIME, LTM, and other long-term
18 studies have documented and quantified the responses of surface waters to changes in
19 acidic deposition and other ecosystem drivers. Although many of these monitoring
20 programs were in existence at the time of the 2008 ISA and were considered in that
21 analysis, more recent publications reflect the longer period of monitoring record and
22 strengthen previous conclusions.

23 With long-term decreases in atmospheric S deposition, the effects of future increases in
24 precipitation that may occur in some areas in response to climate change will likely
25 become increasingly important in regulating the amount of SO_4^{2-} mobilized from internal
26 watershed sources. A number of S cycling studies ([Rice et al., 2014](#); [Mitchell et al., 2013](#))
27 have emphasized the importance of S adsorption and desorption and their interactions
28 with soil pH. In addition, internal watershed sources of S, which were earlier believed to
29 be relatively minor in the northeastern U.S., have and will likely continue to become
30 proportionately more important as S deposition continues to decline.

31 Reductions in SO_x deposition have not consistently resulted in increases of ANC in
32 surface water. The quantitatively most important component of the overall surface water
33 acidification and chemical recovery responses has been change in base cation supply.
34 This was highlighted in the assessment of [Charles and Christie \(1991\)](#) and in the 2008
35 ISA. Base cations are added to watershed soils by weathering of minerals and
36 atmospheric deposition, and are removed by uptake into growing vegetation or by
37 leaching. Acidic deposition increased leaching of base cations, as SO_4^{2-} anions in soil

1 solution carried along base cations to maintain the charge balance. In watersheds that
2 have received high levels of historical acidic deposition, current exchangeable
3 concentrations of Ca^{2+} and other base cations are substantially reduced from likely
4 preindustrial levels, having been depleted by many years of acidic deposition. This base
5 cation depletion constrains ANC and pH recovery of surface waters, as described in the
6 2008 ISA. Recent results have further corroborated earlier findings and have included
7 experiments, modeling, and gradient studies.

8 Recent research has described an ecosystem recovery response to decreasing SO_4^{2-}
9 deposition that was not a major focus of the 2008 ISA: DOC increases in surface water.
10 Such changes have been attributed to increased atmospheric CO_2 concentration, climate
11 warming, decreased S deposition with associated changes in water pH and ionic strength,
12 and hydrologic changes associated with drought and precipitation. Although not all
13 increases in DOC are directly caused by decreases in acidifying deposition, any changes
14 in DOC concentration or properties can impact the acid-base chemistry of surface waters
15 and perhaps the composition of aquatic biota. It has been recognized that surface water
16 DOC concentrations had decreased to some extent as a result of acidification, and that
17 DOC would likely increase with recovery. However, the strength of this response and the
18 magnitude of DOC changes have exceeded scientific predictions. Recent research on this
19 topic has been diverse and has included experiments, observation, isotope studies, and
20 synthesis and integration work. Overall, these studies illustrate large increases in DOC
21 with acidification recovery in some aquatic systems. Increases in DOC constrain the
22 extent of ANC and pH recovery, but decrease the toxicity of dissolved Al by converting
23 some of it from inorganic to organic forms ([Lawrence et al., 2013](#)). However, DOC is not
24 an indicator of recovery everywhere; some recovering sites have not shown increasing
25 trends in DOC.

26 Taken together, results of recent acid-base chemistry studies in the northeastern U.S.
27 confirmed the previously observed pattern of gradual surface water ANC and pH
28 recovery, in some cases more marked decrease in inorganic Al concentrations, and
29 important interactions with DOC. It is important to recognize that recent changes in
30 atmospheric S and N deposition, although substantial in many areas of the U.S., have not
31 occurred in a vacuum. Other important ecosystem drivers have also changed, including
32 various kinds of disturbance, and these changes have varied by region. The potential
33 importance of such factors was known at the time of preparation of the 2008 ISA. More
34 recent work has further confirmed the importance of these linkages, especially those
35 related to climate ([Appendix 13](#)).

7.2. Biogeochemistry of Nitrogen in Estuarine and Near-Coastal Systems

1 In the 2008 ISA, the evidence was sufficient to infer a causal relationship between N
2 deposition and alterations in the biogeochemical cycling of N and carbon (C) in estuarine
3 and near-coastal marine systems. Since the 2008 ISA, additional studies have quantified
4 atmospheric N deposition to estuaries, especially along the Atlantic coast. New evidence
5 shows that a trend from dominantly oxidized N inputs to dominantly reduced forms of N
6 input have ramifications for N cycling and biological response in some estuaries. There is
7 additional evidence that N alters biogeochemistry of coastal ecosystems, especially in
8 regard to microbial-mediated N transformations, which play large roles in N within
9 estuaries. Research and modeling since the 2008 ISA have shown that many of these N
10 processes such as dissimilatory NO_3^- reduction to NH_4^+ (DNRA) are more important in
11 the estuarine environment than previously thought, and that rates of N cycling can be
12 highly variable. Key processes affected by N loading include nitrification and
13 denitrification. Monitoring of coastal areas shows that excess nutrient inputs continues to
14 be a widespread problem in many parts of the U.S. **The body of evidence is sufficient to**
15 **infer a causal relationship between N deposition and the alteration of**
16 **biogeochemistry in estuarine and near-coastal marine systems**, which is consistent
17 with the findings of the 2008 ISA.

18 Recently, elevated nutrient loading to coastal areas has been hypothesized to contribute to
19 coastal acidification. Ocean acidification is already occurring from dissolution of rising
20 atmospheric CO_2 . Nitrogen enrichment is expected to worsen this acidification when
21 algal biomass and excess organic matter from increased primary production and
22 allochthonous inputs decomposes, and the CO_2 produced by decomposition undergoes
23 dissociation and production of hydrogen ions, making the water more acidic
24 ([Appendix 7.2.4](#)). Respiration of living algae and seagrasses during the night can also
25 contribute to acidification. Nutrient-enhanced coastal acidification was not discussed in
26 the 2008 ISA. **The body of evidence is sufficient to infer a likely causal relationship**
27 **between N deposition and increased nutrient-enhanced coastal acidification.**

28 Atmospherically deposited N to watersheds, along with other nonatmospheric sources of
29 N, influence processes that operate along the headwater to ocean continuum. Total N
30 loading to estuaries includes riverine transport of N and direct deposition of N to the
31 estuary itself. This influx of N alters N and C cycling and leads to estuary eutrophication,
32 the process of nutrient over-enrichment. Eutrophic systems are characterized by an
33 increase in the rate of supply of organic matter (primary production and organic C
34 accumulation) in excess of what an ecosystem is normally adapted to processing ([Diaz et](#)
35 [al., 2013](#); [Nixon, 1995](#)). Estuary eutrophication is indicated by water quality

deterioration, including development of hypoxic zones, species mortality, and formation of harmful algal blooms (HABs). Biological indicators of estuarine condition (e.g., chlorophyll *a*, HABs, macroalgae, submerged aquatic vegetation [SAV]) are described in [Appendix 10](#). [Andersen et al. \(2006\)](#) suggested eutrophication be defined as “the enrichment of water by nutrients, especially N and P and organic matter, causing increased growth of algae and higher forms of plant life to produce an unacceptable deviation in structure function and stability of organisms present in the water and to the quality of water concerned, compared to reference conditions.” This appendix considers biogeochemical processes affected by N loading, a topic not covered in detail in the 2008 ISA. Although this ISA includes both N and S deposition, seawater contains high concentrations of SO_4^{2-} so atmospheric inputs of S are unlikely to contribute substantially to biogeochemistry in coastal areas and will not be discussed further in the following sections.

Estuarine biogeochemistry is complicated because it directly controls more than just the N cycle; the response to N loading resulting in eutrophication impacts the chemical cycling of metals and DO ([Appendix 7.2.3](#)), redox conditions, pH ([Appendix 7.2.4](#)) and ultimately energy transfer (e.g., food webs from microbes to humans). The response to N loading is also tightly controlled by the availability of organic matter (C) and its lability and reactivity. Excess nutrient inputs are occurring within the context of other stressors such as climate change ([Appendix 7.2.6.12](#)) and rising atmospheric CO_2 , which further modify coastal biogeochemistry ([Doney, 2010](#)). In the complex environment of the freshwater-to-ocean continuum, there are many chemical and biological indicators of eutrophic condition. One approach is to measure total nutrient loading and concentrations; however, these data need to be interpreted in the context of the physical and hydrological characteristics that determine ecosystem response. Water quality measures such as pH and DO, along with key biological indicators such as chlorophyll *a*, phytoplankton abundance, harmful algal blooms (HABs), macroalgal abundance, and SAV, can all be used to assess responses to nutrient loading ([Table 7-8](#)). The following sections highlight post-2007 research focusing on N biogeochemistry in estuaries and near-coastal areas.

Table 7-8 Summary of key indicators of nitrogen enrichment and nutrient-enhanced coastal acidification.

Endpoint	N-Driven Nutrient Enrichment	Nutrient-Enhanced Coastal Acidification	Section of ISA That Discusses Endpoint
Chemical indicator			

Endpoint	N-Driven Nutrient Enrichment	Nutrient-Enhanced Coastal Acidification	Section of ISA That Discusses Endpoint
Dissolved oxygen	X	X	7.2.3 , 10.2.4
Water pH	X	X	7.2.4 , 10.5
Biological indicator			
Chlorophyll <i>a</i>	X		10.2.1
Harmful algal blooms	X		10.2.2
Macroalgal abundance	X		10.2.3
Submerged aquatic vegetation	X		10.2.5

1

7.2.1. Nitrogen Sources

2 In the 2008 ISA, it was well understood that the importance of atmospheric deposition as
3 a cause of estuarine eutrophication is determined by the relative contribution of the
4 atmospheric versus nonatmospheric sources of N input ([U.S. EPA, 2008a](#)).

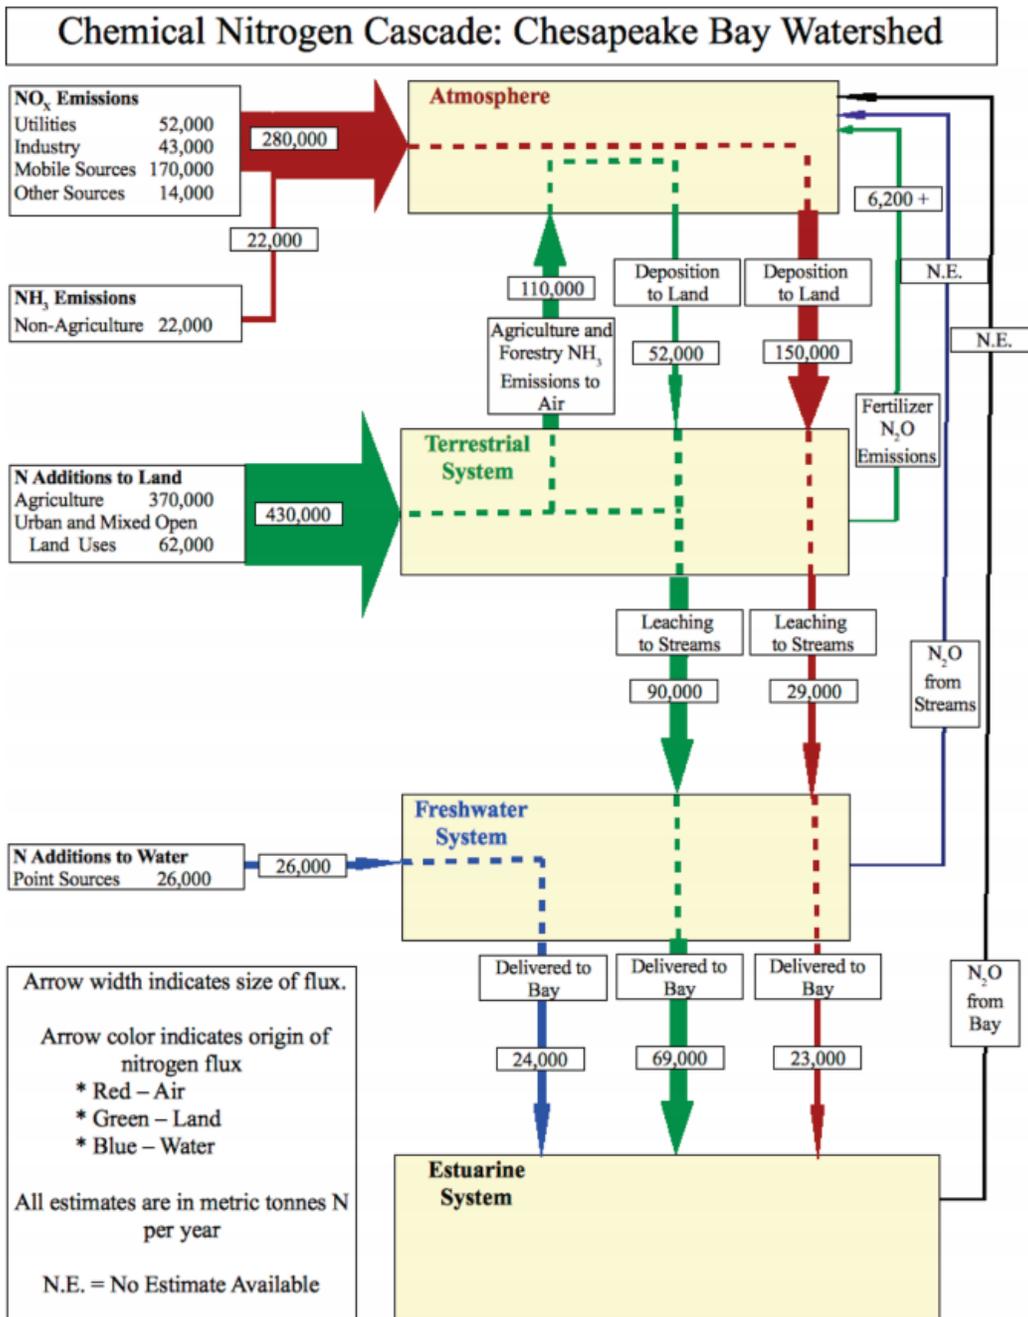

5 Atmospherically deposited N from combustion of fossil fuels (NO_x), agricultural sources
6 (NH₃, NH₄⁺) and organic N combine with N from other anthropogenic and natural
7 sources to contribute varying total N inputs in coastal regions. It is the cumulative effects
8 from multiple sources that contributes to ecosystem enrichment ([Paerl et al., 2002](#)).

9 Atmospheric deposition of reduced N has increased relative to oxidized N in parts of the
10 U.S. including the East and Midwest in the last few decades ([Appendix 2](#)), and this trend
11 is expected to continue in the future under existing emissions controls ([Pinder et al.,](#)
12 [2008](#); [U.S. EPA, 2008a](#)). Thus, the form of inorganic N input to coastal areas is changing
13 over time. This has ramifications for N cycling. The increase in highly bioreactive
14 reduced N from deposition and other sources is often a preferred form of N for
15 phytoplankton including unwanted or harmful species ([Appendix 10.3.3](#)). Deposition of
16 oxidized and reduced forms of N are detailed in [Appendix 2](#).

17 In many places throughout the U.S., nonpoint sources are now the dominant sources of N
18 to water bodies ([Howarth, 2008a, b](#); [Howarth et al., 2002](#)). Releases of N from
19 agricultural, urban, and mixed land uses comprise a significant portion of the nonpoint
20 sources in many watersheds ([Birch et al., 2011](#); [Alexander et al., 2008](#)). The Chesapeake
21 Bay is an example of a well-studied coastal system where N fluxes have been relatively
22 well characterized (atmospheric inputs represent approximately 25% of total N budget;
23 [Figure 7-6](#)). In management of coastal eutrophication, both point and nonpoint sources
24 have been identified as targets for control of N inputs ([Stephenson et al., 2010](#); [Paerl et](#)
25 [al., 2002](#)). Nonpoint sources include diffuse agricultural runoff and wet and dry

1 deposition from the atmosphere. Increased respiration caused by N enrichment may
2 exacerbate coastal ocean acidification through alteration of the C cycle. Nitrogen sources
3 also cause production of excess organic matter that feed respiration by microbial
4 decomposers. In estuaries adjacent to areas of coastal upwelling, such as some locations
5 along the Pacific coast of the U.S., oceanic inputs of nutrients can also represent an
6 important source of N to estuarine waters ([Brown and Ozretich, 2009](#)).

7 Estimates of the contribution of atmospheric deposition to the overall estuary N load
8 exhibit wide variability due in part to the difficulty associated with quantifying multiple
9 agricultural and mobile and stationary fuel combustion emissions sources and N
10 transformations and losses as the N moves from the terrestrial watershed to and within
11 the estuary ([U.S. EPA, 2008a](#); [NRC, 2000](#)). Despite high variability, it appears that
12 atmospheric sources of N loading to estuaries can be quantitatively important, based on
13 studies reviewed in the 2008 ISA and newer studies ([Table 7-9](#)). For example,
14 atmospheric N loads to estuaries in the U.S. were estimated to be as high as 72% for St.
15 Catherine's-Sapelo estuary, Georgia ([Castro et al., 2003](#)). In another study considering
16 atmospheric deposition of N to the East Coast and Gulf of Mexico, direct deposition of N
17 was estimated to contribute from 10 to over 40% of N loading to estuarine, coastal, and
18 open marine waters ([Paerl et al., 2002](#)). In Chesapeake Bay, studies reviewed in the 2008
19 ISA indicated that atmospheric deposition makes a substantial contribution (up to 50%)
20 to the overall N budget ([Howarth, 2008b](#); [Boyer et al., 2002](#)).

Source: [Birch et al. \(2011\)](#).

Figure 7-6 Chemical nitrogen cascade in the Chesapeake Bay watershed (metric tons/year).

Table 7-9 Summary of studies quantifying atmospheric nitrogen contribution to total nitrogen in coastal areas via watersheds and/or direct deposition to estuary surface waters.

Region	Total N Loading Due to Atmospheric Deposition	Model	Reference
U.S. coastal areas	N deposition to land surfaces that is subsequently exported from watersheds to the coastal zone is responsible for 17 to 21% of the total N input.	NEWS SPARROW	McCrackin et al. (2013)
Gulf of Mexico in the Mississippi/Atchafalaya River basin	Atmospheric deposition contribution, which may include volatilized losses from natural, urban, and agricultural sources, was estimated to be 26% of total N transported to the Gulf of Mexico.	SPARROW using CMAQ total deposition	Robertson and Saad (2013)
Northeast and mid-Atlantic coastal region	Identified wet deposition to the watershed as the dominant source of N to the estuaries of the Connecticut, Kennebec, and Penobscot rivers, but the third largest source (20%) for the region as a whole, after agriculture (37%) and sewage and population-related sources (28%).	SPARROW	Moore et al. (2011)
Narragansett Bay	Combined direct atmospheric deposition to the estuary and atmospheric deposition to the watershed were responsible for 20% of N loading to the bay.		Vadeboncoeur et al. (2010)
Waquoit Bay Estuaries in Cape Cod	Since 1990 wastewater N loads have increased about 80% while loads from atmospheric deposition have decreased by about 41% with no change in total loading on a decadal scale.	NLM	Valiela et al. (2016)
Small-to-medium sized estuaries of southern New England	Direct atmospheric deposition to estuary surface averaged 37%, and indirect atmospheric deposition via the watershed averaged 16% of total N loading, although the percentage varied widely for each individual estuary.	NLM	Latimer and Charpentier (2010)
Tampa Bay	Direct and indirect atmospheric loading were estimated to be 30 and 41%, respectively, of total N loading to the bay.	WDT	Poor et al. (2013b)
	Direct and indirect atmospheric loading were estimated to be 17 and 40%, respectively, of total N loading to the bay.	CMAQ modified with University of California Davis aerosol module	Poor et al. (2013a)
Chesapeake Bay	Atmospheric loading is 24% of total N loading.		Birch et al. (2011)
	Half of the atmospheric source of N to the watershed originates outside of the watershed; indirect loading of atmospheric N via watershed inputs are larger than direct loading to tidal waters.	Chesapeake Airshed Model, combining CMAQ and regression model for wet deposition	Linker et al. (2013)

Table 7-9 (Continued): Summary of studies quantifying atmospheric nitrogen contribution to total nitrogen in coastal areas via watersheds and/or direct deposition to estuary surface waters.

Region	Total N Loading Due to Atmospheric Deposition	Model	Reference
Gulf of Mexico in the Mississippi/Atchafalaya River basin	Atmospheric deposition to watersheds in the basin contributed about 16% of the total N load, second to N from corn and soybean production (52%).	SPARROW	Alexander et al. (2008)
Pacific Northwest, Yaquina Bay	Direct deposition represented only 0.03% of N inputs and watershed inputs of N fixing red alder (<i>Alnus rubra</i>) was a greater source of N to the watershed than atmospheric deposition (8%).		Brown and Ozretich (2009)
Key pre-2008 literature			
34 Atlantic and Gulf coast estuaries	The contribution of atmospheric deposition (including directly onto the water surface and onto the watershed) was 7–72% of the total N.	WATERS-N	Castro et al. (2001); Castro et al. (2003)
10 estuaries along the U.S. east coast	Total atmospheric inputs (watershed runoff plus direct deposition to the surface of the estuary) accounted for 15 to 42% of total N inputs. In four of the estuaries direct deposition was 35 to 50% of the total atmospheric N inputs.		Castro and Driscoll (2002)
Chesapeake Bay	Atmospheric deposition makes a substantial contribution (about 25%) to the overall N budget.		Howarth (2007)
16 northeastern river basins	Atmospheric deposition averaged 31% of total N inputs; values for watersheds in northern New England were substantially higher and atmospheric deposition dominated. Estimated riverine export of N amounted to 25% of total N inputs.		Boyer et al. (2002)
Based on 34 Atlantic and Gulf coast estuaries	In systems with watershed area to estuarine surface area ratios greater than 15, N deposition is not as important (comprising less than 25% total N input) as in estuaries that are large relative to their watershed.		Castro et al. (2001)

CMAQ = Community Multiscale Air Quality; N = nitrogen; NEWS = Nutrient Export from Watersheds; NLM = Nitrogen Loading model; SPARROW = Spatially Referenced Regressions on Watershed Attributes; WATERS-N = Watershed Assessment Tool for Evaluating Reduction Scenarios for Nitrogen; WDT = Water Deposition Tool.

1 In a series of studies reviewed in the 2008 ISA, the model Watershed Assessment Tool
2 for Evaluating Reduction Scenarios for Nitrogen (WATERS-N) estimated that the
3 contribution of atmospheric deposition (including directly onto the water surface and
4 indirectly onto the watershed) was 7–60% of the total N input to 34 Atlantic and Gulf
5 coast estuaries ([Castro et al., 2003](#); [Castro et al., 2001](#)). Nitrogen deposition contributed
6 20–86% (average = 48%) of the total N input to 22 watersheds having watershed area to
7 estuarine surface area ratio less than 15. In systems with a ratio greater than 15, N
8 deposition is not as important, comprising less than 25% of total N input across
9 12 systems ([Castro et al., 2001](#)).

10 Since the 2008 ISA, additional modeling studies have estimated the amount and
11 proportion of current and future N loading expected to result from atmospheric deposition
12 ([Table 7-1](#)). The Nutrient Export from Watersheds (NEWS) and SPARROW models
13 agreed that 62–81% of N delivered to the coastal zone in the continental U.S. is
14 anthropogenic in source ([McCrackin et al., 2013](#)). Model results showed that atmospheric
15 N deposition that is subsequently transported to estuaries represents 17–21% of the total
16 N exported to the coastal zone ([McCrackin et al., 2013](#); [Moore et al., 2011](#)). Using
17 SPARROW atmospheric N deposition was identified as the dominant source of delivered
18 N to estuaries along the Atlantic Coast and the Gulf of Mexico ([McCrackin et al., 2013](#)).
19 Using SPARROW, the atmospheric deposition contribution (which may include
20 volatilized losses from natural, urban, and agricultural sources) was estimated to be 26%
21 of total N transported to the Gulf of Mexico in the Mississippi/Atchafalaya River basin
22 ([Robertson and Saad, 2013](#)). [Moore et al. \(2011\)](#) found that SPARROW identified
23 atmospheric deposition to watersheds as the dominant source of N to the estuaries of the
24 Connecticut, Kennebec, and Penobscot rivers, but the third largest source (20%) for the
25 Northeast and mid-Atlantic coastal region as a whole, after agriculture (37%) and sewage
26 and population-related sources (28%). In contrast, atmospheric deposition is a less
27 substantial source of N to some estuaries, especially in the Pacific Northwest. In Yaquina
28 Bay estuary, OR, direct deposition represented only 0.03% of N inputs and watershed
29 inputs of N fixing red alder (*Alnus rubra*) trees was a larger (8%) source of N to the
30 watershed than atmospheric deposition ([Brown and Ozretich, 2009](#)). In Yaquina Bay
31 estuary, the ocean is the primary source of N during the dry season and the river is the
32 primary source during the wet season.

33 A modeling study conducted by [Vadeboncoeur et al. \(2010\)](#) estimated that the third
34 largest source of N loading (via the watershed and directly to the water body) to
35 Narragansett Bay in the year 2000 was atmospheric deposition (20%). Future scenarios
36 suggested that very aggressive reductions in both fertilizer use and atmospheric
37 deposition would be needed for Narragansett Bay to return to early twentieth century
38 levels of N loading ([Vadeboncoeur et al., 2010](#)). [Latimer and Charpentier \(2010\)](#) applied

1 the Watershed N Loading Model (NLM) to small- to medium-sized estuaries of southern
2 New England. Direct atmospheric deposition to the water surface made up an average of
3 37% of the N input, although the percentage varied widely for individual estuaries
4 ([Latimer and Charpentier, 2010](#)). In the same study, wastewater represented 36% of the
5 total N inputs. Indirect atmospheric deposition within the watershed was estimated to be
6 16% and the fertilizer component was 12%. The relative magnitudes of these source
7 types varied across estuaries. In another modeling study with NLM using data going back
8 to 1990, atmospheric deposition decreased by about 41% while wastewater inputs have
9 increased 80% with a net result that total loads have not changed on a decadal scale in the
10 Waquoit Bay estuaries in Cape Cod, MA ([Valiela et al., 2016](#)). Using the Watershed
11 Deposition Tool (WDT), [Poor et al. \(2013b\)](#) estimated direct atmospheric loading of
12 1,080 metric tons of N and 1,490 metric tons of N from indirect atmospheric loading
13 (assuming a watershed-to-bay transfer rate of 18%) for Tampa Bay using data from 2002.
14 Thus, atmospheric sources were an estimated 71% of the total N loading. Key studies
15 from the 2008 ISA on atmospheric N loading to estuaries are summarized in [Table 7-9](#),
16 along with newer estimates.

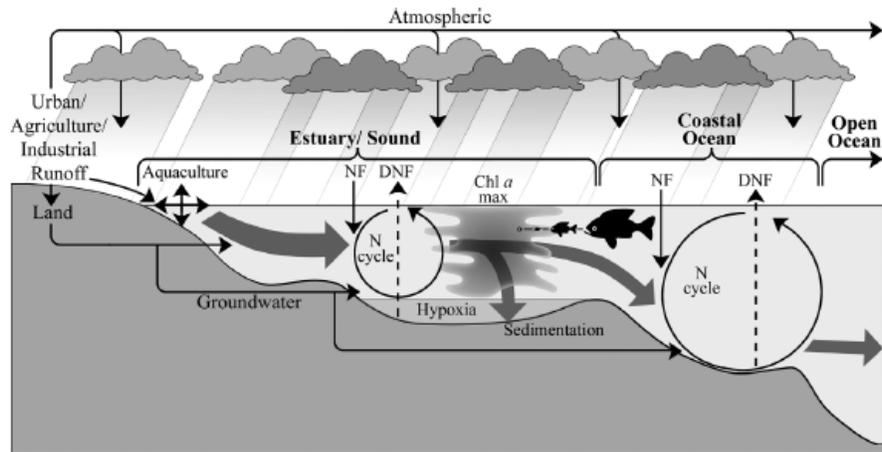

17 Near NH₃ emission sources, such as large mammal and poultry livestock operations, N
18 deposition is expected to increase 10–40% by 2020 according to different regulation and
19 reduction scenarios ([Pinder et al., 2008](#)). Many of the agricultural emission sources are
20 located in sensitive watersheds such as the Chesapeake Bay and Pamlico Sound, NC
21 ([Pinder et al., 2008](#)). [Birch et al. \(2011\)](#) estimated that 24% of the reactive N that reached
22 Chesapeake Bay originated as emissions to the atmosphere that were then deposited in
23 the watershed to land and water, 57% came from terrestrial N additions from nonpoint
24 source runoff, and the remaining 19% was estimated to come from direct discharges of N
25 to freshwater ecosystems. The results of a modeling study that integrated the airshed,
26 watershed, and estuary indicated that atmospheric deposition represented one of the
27 largest inputs of N to the Chesapeake Bay watershed, and about half of it originated
28 outside the watershed ([Linker et al., 2013](#)). Atmospheric N loading to tidal waters was
29 included in the Chesapeake Bay 2010 TMDL, the first time that atmospheric deposition
30 has been included in a plan for nutrient load reduction ([U.S. EPA, 2010](#)). The explicit
31 TMDL N allocation was determined to be 7.1 million kg per year of total N atmospheric
32 deposition loads directly to Chesapeake Bay and tidal tributary surface waters. It was
33 based on the 2020 CMAQ N deposition scenario described by [Linker et al. \(2013\)](#).
34 [Appendix 2](#) provides more detailed discussion of N source apportionment.

35 Although the geographic scope of this ISA is limited to estuaries and near-coastal areas
36 of the U.S., some evidence indicates that the open ocean may be affected by atmospheric
37 deposition of N ([Ren et al., 2017](#); [Kim et al., 2011](#)). [Ren et al. \(2017\)](#) provided ¹⁵N stable
38 isotope evidence that N emissions have changed the biogeochemical cycling of N in the

1 open ocean in nutrient-limited low-latitude regions such as the northwestern Pacific
2 Ocean. Changes in ¹⁵N over time were documented in coral skeletons over a period of
3 45 years at Dongsha Atoll in the northern South China Sea. The proximity of this water
4 body to anthropogenic N emissions sources in Asia and its depth (1,300 m) both
5 contribute to its sensitivity to N deposition and changes in nutrient cycling.

7.2.2. The Estuary Environment

6 Atmospherically deposited N, along with other sources of N to coastal systems,
7 influences uptake and conversion processes that operate along the freshwater-to-ocean
8 continuum [([Paerl and Piehler, 2008](#); [Seitzinger et al., 2006](#)); [Figure 7-7](#)]. Conditions in
9 upstream terrestrial systems, such as nutrient loading or land use, can exert strong
10 influences on coastal habitats and processes ([Ruttenberg and Granek, 2011](#)) [Appendix 4](#).
11 In addition to inputs of N from outside sources, the varying rates of different N cycling
12 processes, as well as C availability and reactivity within estuaries themselves, can also
13 affect the magnitude of eutrophication experienced as a result of external N enrichment
14 ([Newell et al., 2016](#); [Anderson et al., 2014b](#); [Smyth et al., 2013](#); [Crowe et al., 2012](#)).
15 Estuaries are heterogeneous environments characterized by physicochemical gradients of
16 salinity and both naturally and anthropogenically derived nutrients. Water quality in
17 estuaries is highly variable due to physical and chemical aspects of each estuary
18 ([Appendix 10.1.4](#)) and factors such as temperature and precipitation ([Rheuban et al.,](#)
19 [2016](#)). At the upstream end of an estuary, the water is primarily fresh much of the time.
20 Nonpoint source runoff of N from the land surface, only a part of which is of atmospheric
21 origin (mainly deposition to land and subsequently leached to the river water), dominates
22 new N inputs. Downstream, freshwater inflows gradually mix with salt water to form
23 mesohaline segments of the estuary. These changes in salinity impact the ionic strength
24 of the water. Further along the salinity gradient, a significant fraction of the terrestrial
25 biologically available N load is assimilated by phytoplankton and benthic flora, removed
26 by microbes in the process of denitrification or advected to the ocean ([Paerl et al., 2002](#)).
27 Direct atmospheric N inputs also impact the lower estuary, although the relative
28 importance of N deposition in this zone is uncertain and variable ([Paerl et al., 2002](#)). In
29 many estuary and sound ecosystems, primary production and phytoplankton biomass are
30 highest at mid-estuary locations, where N loads and decreasing rates of flushing
31 (increasing residence times) overlap.

Chl *a* = chlorophyll *a*; DNF = denitrified; N = nitrogen; N₂ = nitrogen; NF = nitrogen (N₂) fixation.
 Source: From [Paerl and Piehler \(2008\)](#).

Figure 7-7 Schematic diagram illustrating sources, transformations, and fate of nitrogen along the estuary-to-ocean continuum. Surface, subsurface, and atmospheric pathways of externally supplied or new nitrogen inputs attributable to anthropogenic activities are shown as internal nitrogen cycling. The combined anthropogenic nitrogen inputs are shown as a thick arrow (upstream), which decreases in thickness downstream as a portion of the nitrogen inputs settles to the bottom sediments and is buried and/or denitrified. Nitrogen (N₂) fixation is a biologically mediated new nitrogen input. The linkage of anthropogenically enhanced nitrogen inputs to accelerated primary production or eutrophication and its trophic and biogeochemical fate are also shown.

7.2.3. Dissolved Oxygen and Hypoxia

1 Low oxygen (hypoxia) or the absence of oxygen (anoxia) in coastal waters have
 2 implications for N cycling. Oxygen depletion mainly occurs in bottom waters under
 3 stratified conditions. The extent of hypoxia in U.S. waters and effects of low DO on biota
 4 are discussed in [Appendix 10.2.4](#). Biogeochemical processes that occur in the sediment
 5 of estuarine and near-coastal ecosystems are important to the cycling of N that is
 6 deposited or transported to estuarine ecosystems. Inputs of C and a stratified water
 7 column that separates well-oxygenated surface water from bottom water and sediments is
 8 generally required for formation of hypoxic zones ([Jewett et al., 2010](#)).
 9 Eutrophication-induced hypoxia, which has been documented globally, can be

1 characterized by both the duration of the hypoxic event and the ecosystem response ([Diaz](#)
2 [et al., 2013](#); [Diaz and Rosenberg, 2008](#)). Summer hypoxia is most common, followed by
3 systems that experience periodic O₂ depletion that may occur more often than seasonally.
4 Development of seasonal hypoxia is common in shallow coastal regions that receive high
5 inputs of nutrients, including N, from coastal rivers. Development of hypoxia is
6 increasingly becoming a concern throughout the U.S. and internationally ([Jewett et al.,](#)
7 [2010](#); [Diaz and Rosenberg, 2008](#)). [Middelburg and Levin \(2009\)](#) provided a review of
8 coastal hypoxia and linkages with biogeochemistry. Changes in bottom water O₂
9 concentrations influence chemical exchange between sediment and bottom water.
10 [Rabalais et al. \(2010\)](#) provided a synthesis of knowledge regarding hypoxia in coastal
11 waters. Hypoxic water masses (less than approximately 30% saturation) are more likely
12 to occur in marine waters where and when water residence time is long, water exchange
13 is limited, the water column stratifies, and the production and movement of C to bottom
14 waters are relatively high. [Howarth et al. \(2011\)](#) reviewed the complex interactions
15 between biogeochemical cycling, eutrophication, and hypoxia in coastal marine systems.
16 Biochemical feedbacks under eutrophic conditions accelerate further eutrophication and
17 hypoxia. In locations where coastal upwelling can be a large source of nutrient loads such
18 as the Pacific Northwest, advection of upwelled water can introduce hypoxic water into
19 estuaries that is not or poorly related to anthropogenic eutrophication ([Brown and Power,](#)
20 [2011](#); [Brown and Ozretich, 2009](#)).

7.2.4. Estuarine and Near-Coastal pH

21 The pH of estuarine waters can affect N cycling processes and reflect coastal
22 acidification. Since the 2008 ISA, a number of papers have identified links between
23 nutrient enrichment and coastal acidification, and several mechanisms have been
24 identified. One of the initial studies found that CO₂ production during decomposition of
25 organic matter delivered to coastal zones from rivers experiencing eutrophication has
26 enhanced the acidification of coastal subsurface waters in the Gulf of Mexico and the
27 East China Sea ([Cai et al., 2011c](#)). Coupled with dissolution of atmospheric
28 anthropogenic CO₂ into the ocean which has led to long-term decreases in pH, CO₂
29 produced from decomposition of excess organic matter associated with eutrophication
30 can also lower pH. Production of CO₂ by living algae and seagrasses during the night can
31 also drive acidification. In a eutrophic seagrass ecosystem in Cape Cod, MA, there was a
32 very pronounced diel pattern of pH, with moderate pH during the day, but by dawn very
33 acidic waters resulted from overnight respiration of living algae and seagrasses ([Howarth](#)
34 [et al., 2014](#)). During the daytime, CO₂ was drawn down through primary production, and
35 as a consequence the pH steadily climbed. The net effect was to increase acidification,

1 due to slow exchange of CO₂ with the atmosphere. This additional CO₂ further acidifies
2 marine waters as it dissociates into carbonate ions and hydrogen ions ([Sunda and Cai,](#)
3 [2012](#); [Cai et al., 2011c](#); [Howarth et al., 2011](#)). An important additional source of organic
4 matter leading to overall declines in pH is potentially allochthonous organic matter inputs
5 that have been increasing in many coastal watersheds from changing land use ([Wilson et](#)
6 [al., 2016](#); [Wetz and Yoskowitz, 2013](#)). Nitrogen-driven eutrophication and
7 anthropogenically enhanced allochthonous organic matter loading operate
8 simultaneously.

9 Biogeochemical modeling of eutrophically driven ocean acidification coupled to data
10 collected from the Gulf of Mexico, the Baltic Sea, and the East China Sea predicted that
11 eutrophication would cause a 0.24 to 1.1 unit decrease in pH of bottom waters, and also
12 that increasing atmospheric CO₂ will synergistically amplify eutrophically driven
13 acidification ([Sunda and Cai, 2012](#); [Cai et al., 2011c](#)). The increase in atmospheric CO₂
14 dissolution is also expected to alter the N cycle in the ocean, with implications for the
15 entire ecosystem. Acidification will result in decreased rates of nitrification, which,
16 combined with expected increasing N deposition, will likely cause the NH₄⁺
17 concentration of the water to rise ([Lefebvre et al., 2012](#)). Models show that while the
18 impact of each acidification pathway (N enrichment and atmospheric CO₂ dissolution)
19 may be moderate, the combined effect of the two may be much larger than would be
20 expected by just adding the effects of each pathway together ([Sunda and Cai, 2012](#); [Cai et](#)
21 [al., 2011c](#)).

22 More recent work has identified some similar dynamics in Chesapeake Bay, where
23 anoxia related to eutrophication is driving acidification and carbonate mineral dissolution
24 ([Cai et al., 2017b](#)). Ocean acidification has detrimental effects on marine calcifiers and is
25 projected to alter marine habitat and food webs affecting a wide range of marine
26 ecosystem processes [([Marshall et al., 2017](#); [Mostofa et al., 2016](#); [Andersson et al., 2015](#);
27 [Sunda and Cai, 2012](#); [Doney et al., 2009](#)) Appendix 10.5].

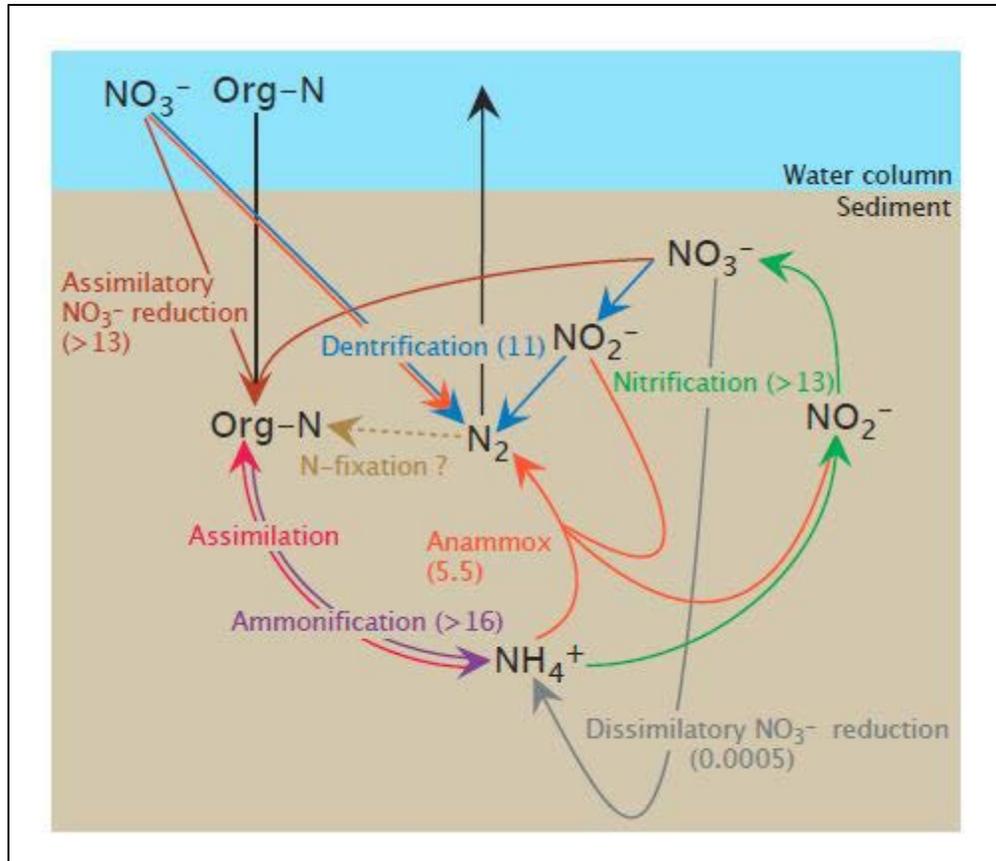

7.2.5. Nitrogen in Surface Waters

28 In most estuaries, N inputs from atmospheric deposition, wastewater and agricultural
29 runoff control eutrophication ([Valiela et al., 2016](#); [Howarth et al., 1996a](#); [Vitousek and](#)
30 [Howarth, 1991](#)) and can be linked to changes in biological indicators of nutrient
31 enrichment known to be sensitive to shifts in N loading ([Appendix 10](#)). In many
32 estuaries, this occurs with a simultaneous increase in P as N, and P runoff loads are often
33 coupled, especially where agricultural or human waste sources dominate. In general,
34 estuaries tend to be N limited ([Howarth et al., 2011](#); [Paerl and Piehler, 2008](#); [Elser et al.,](#)

1 [2007](#); [Howarth and Marino, 2006](#); [NRC, 2000](#); [Nixon, 1995](#); [Howarth, 1988](#)). However,
2 more recent studies show that some estuaries are P limited, or colimited by N and P, or
3 switch seasonally between N and P limitation ([Howarth et al., 2011](#); [Paerl and Piehler,](#)
4 [2008](#); [Howarth and Marino, 2006](#)). To date, several states have developed site-specific or
5 state-wide numeric nutrient criteria to address nutrient pollution problems
6 ([Appendix 7.2.9](#)). Adopted criteria include TN, NO₃⁻ as N, DIN as N, or TMDLs. In
7 some estuaries, especially in the Pacific Northwest, nutrients from upwelling and oceanic
8 exchange caused by regional wind patterns likely control primary production rather than
9 anthropogenic nutrient loading ([Brown and Ozretich, 2009](#); [Hickey and Banas, 2003](#)).
10 Quantification of N in the estuarine environment can be highly variable both spatially and
11 temporally due to the physiochemical gradients within estuaries ([Appendix 10.1.4](#)), the
12 influence of natural and anthropogenic stressors, and factors such as precipitation and
13 warming ([Appendix 10.1.4.1](#)). For example, analysis of 22 years of water quality data
14 from Buzzards Bay, MA by [Rheuban et al. \(2016\)](#) indicated that climate related stressors
15 of warming and precipitation appeared to influence ecosystem response to TN over time.
16 Since the 2008 ISA, additional thresholds of response to N have been identified for
17 biological indicators ([Appendix 10.6](#)).

7.2.6. Nitrogen Cycling

18 Some of the key processes involved in N cycling in estuarine and near coastal
19 environments include N sinks such as denitrification and N₂ production via anaerobic
20 ammonium oxidation (anammox), bioavailable N sources such as N fixation and DNRA,
21 and other N cycling processes including nitrification ([Figure 7-8](#)). A major control on
22 these processes is C availability and reactivity ([Plummer et al., 2015](#)). Benthic DO
23 concentrations (hypoxia) and S cycling may also affect the occurrence and rates of many
24 of these N cycling processes. Recent research has shown that many of these N cycling
25 processes are more important in the estuarine environment than previously thought, and
26 that the rates of different N cycling processes can be highly variable, depending on
27 environmental factors such as N availability, organic C source, temperature, seasonality,
28 oxygen levels, microbial community structure, aquatic habitat type, and others ([Newell et](#)
29 [al., 2016](#); [Plummer et al., 2015](#)). Some processes were relatively well understood at the
30 time of the 2008 ISA while the role of others such as DNRA has been characterized only
31 recently as an important pathway in which N is conserved in coastal ecosystems.

Notes: numbers in parentheses are rates of the reactions in $\mu\text{mol}/\text{m}^2/\text{h}$ as measured by [Crowe et al. \(2012\)](#).

Figure 7-8 New complexities in nitrogen cycling have been detailed since the 2008 ISA as shown in this illustration of the sedimentary N cycle in the Lower St. Lawrence estuary.

7.2.6.1. Nitrogen Fixation

1 Nitrogen fixation is the microbially mediated conversion of atmospheric nitrogen gas
 2 (N_2) to a bioavailable form of N, (i.e., ammonia [NH_3]). The community of N fixing
 3 microorganisms is more diverse in estuarine and coastal waters than previously thought,
 4 and N fixation occurs more widely than previously assumed. Advances in research
 5 methods for measuring heterotrophic N fixation have led to the discovery that rates of N
 6 fixation in coastal sediments can cause the sediments to be a significant source of N to
 7 the ecosystem ([Newell et al., 2016](#)). [Newell et al. \(2016\)](#) reported on several studies of N
 8 fixation rates in coastal sediments (measured as sediment N_2 uptake) with rates ranging
 9 from -12 to $-250 \mu\text{mol N}/\text{m}^2/\text{h}$. In some cases, these higher rates of N fixation can

1 potentially exacerbate the eutrophic conditions already experienced in an estuary, as was
2 the case in Narragansett Bay, RI, where up to 30% of the N added to the system came
3 from N fixation in some years ([Newell et al., 2016](#); [Fulweiler and Heiss, 2014](#)).

4 Research in the past decade has also sought to determine what environmental factors may
5 cause sediments to switch from acting as a sink to acting as a net source of N due to
6 increased N fixation. Organic matter enrichment appears to be one factor. [Fulweiler et al.](#)
7 [\(2008\)](#) noted a “threshold” of organic enrichment at 0.3 g C/m²/day, below which N
8 fixation took place at high rates but above which the rates of N fixation declined and the
9 sediments became a net sink of N due to denitrification ([Fulweiler et al., 2008](#)).

10 In Copano Bay, a shallow bay on the Gulf of Mexico in Texas, periods of drought
11 coincided with higher rates of N fixation ([Bruesewitz et al., 2013](#)). Thus, base flow
12 conditions allowed primary production to continue, even when external sources of N via
13 riverine transport and runoff were very low.

7.2.6.2. Role of Dissolved Organic Nitrogen

14 Recent research has shown the importance of measuring DON fluxes, as they can be a
15 more significant internal source of N from the sediments than previously assumed.
16 Terrestrial inputs of DON are poorly characterized, and these fluxes are not routinely
17 included in estuarine nutrient budgets. [Alkhatib et al. \(2013\)](#) found that DON fluxes out
18 of the sediments, at rates of 110 to 430 μmol/m²/day, were at times greater than NO₃⁻
19 flux into the sediments in the St. Lawrence estuary and Gulf of St. Lawrence. Many
20 species of algae and bacteria will take up DON; thus, this flux of DON out of the
21 sediments leads to an important sink for N within the system ([Alkhatib et al., 2013](#)).
22 Reactivity of organic matter is another key factor in DON availability.

7.2.6.3. Dissolved Inorganic Nitrogen

23 Dissolved inorganic nitrogen (NH₄⁺ plus [NO₂⁻ + NO₃⁻]) plays an important role in N
24 cycling and primary productivity. N laden organic matter may be transported to estuaries
25 and coastal waters from river basins. Estuarine benthic communities degrade this
26 allochthonous organic matter, releasing NH₄⁺ at the aerobic sediment-water interface, and
27 NH₄⁺ further enhances estuarine productivity via oxidation to NO₃⁻. Generally, NH₄⁺ is
28 considered the preferred form for some phytoplankton, including harmful species, due to
29 lower energy requirements for uptake ([Glibert et al., 2016](#)) ([Appendix 10.2.2](#) and
30 [Figure 10-7](#)). Remineralization of organic matter is sensitive to redox conditions ([Reddy](#)
31 [and Patrick, 1984](#)), sediment grain size ([Nowicki and Nixon, 1985](#)), and temperature

1 ([Kemp and Boynton, 1984](#)). If NH_4^+ has to compete with saltwater cations for adsorption
2 sites, then excess NH_4^+ becomes free in these saline waters ([Gardner et al., 1991](#)).

3 The understanding of DIN's role in estuarine and near-coastal nutrient enrichment is an
4 active field of research. [Cornwell et al. \(2014\)](#) measured September 2011 versus March
5 2012 benthic nutrient fluxes in the San Francisco Bay and delta and ascertained that
6 sediment DIN is an important source of N to the water column and system productivity.
7 [Paudel et al. \(2017\)](#) examined the effect of flow regimes on DIN release at the
8 sediment-water interface. They compared two south Texas estuaries: the Nueces and the
9 Guadalupe. The Guadalupe has eight times the inflow of the Nueces. They observed
10 significantly different NH_4^+ concentrations between the estuaries; however, the
11 $\text{NO}_2^- + \text{NO}_3^-$ concentration did not differ significantly. Using the coastal water
12 phytoplankton Redfield ratio (ratio of N:P in phytoplankton) of 16:1, they found the
13 Nueces N:P ratio below the Redfield but the Guadalupe above, suggesting that the
14 Nueces was N limited. NH_4^+ releases were greater in the Nueces estuary due to its higher
15 organic content in sediment. In the Guadalupe estuary, finer sediment particles may retain
16 N.

17 [Buzzelli et al. \(2013b\)](#) applied the Land-Ocean Interactions in the Coastal Zone (LOICA)
18 approach to gain understanding about the seasonal budgets for DIN in two south Florida
19 estuaries—Caloosahatchee River estuary (CRE) and the St. Lucie estuary (SLE)—during
20 the years 2002 to 2008. The analysis included the contribution of direct wet atmospheric
21 N deposition to estuarine loading. They compared the production of C, N, and P in the
22 two estuaries and source attribution. These two watersheds are highly disturbed due to
23 urban growth and agriculture and flush at substantially different rates. They sought to
24 understand the optimum metabolism of each estuary from a C, N, and P production and
25 consumption perspective to better inform coastal watershed management planning. Both
26 estuaries have similar agricultural and urban land use; however, study authors observed
27 increased DIN in the CRE during the wet season but not in the SLE. The SLE's
28 “muck-like” sediment reduces light penetration and isolates the water column from the
29 benthic zone. ([Buzzelli et al., 2013a](#); [Sime, 2005](#)). External loading influenced the SLE's
30 production of C, N, and P more than the CRE. Even though the CRE is 2.5 times larger
31 (and receives double the freshwater inflow) as compared with the SLE, the CRE's DIP
32 and DIN loadings are only 60–70% of SLE's loadings when spatially normalized.

7.2.6.4. Nitrification

33 Nitrification is the microbially mediated conversion of NH_4^+ to NO_3^- ; thus, exchanging
34 one bioavailable N form for another. The process includes NH_3 oxidation to NO_2^- ,

1 followed by NO_2^- oxidation to NO_3^- . This importance was well known at the time of
2 preparation of the 2008 ISA. More recent research has provided additional quantitative
3 context, including new studies in North America and Europe. Where DIN loading is not
4 dominated by NO_3^- , the oxidation of NH_4^+ to form NO_3^- largely controls the relative
5 abundance of oxidized and reduced DIN in estuaries. Nitrification rates are often
6 correlated with suspended particulate matter and NH_4^+ concentration in water ([Damashek
7 et al., 2016](#)).

8 There have been new findings about the process of nitrification since the 2008 ISA. It has
9 generally been assumed that the first step of nitrification (NH_4^+ oxidation to NO_2^-) is the
10 rate-limiting step ([Damashek et al., 2015](#)). However, recent research indicates that
11 physical factors such as salinity, temperature, pH, DO concentration, and light can affect
12 the rates to the extent that the two steps of nitrification may not always be “coupled” as is
13 often assumed ([Heiss and Fulweiler, 2016](#); [Bristow et al., 2015](#)). In some cases, the rate
14 for the second step of the nitrification process may be higher than for the first step. For
15 example, results showed that rates of NO_2^- oxidation to NO_3^- were negatively correlated
16 with light and pH, indicating in part that NO_2^- oxidation rates are higher when the pH is
17 lower ([Heiss and Fulweiler, 2016](#)). Decoupling of the two nitrification steps was also
18 observed in the Gulf of Mexico hypoxic zone, where the first step occurred at rates of up
19 to 30 times higher than the second step, a result the authors concluded was due to
20 environmental factors such as temperature, substrate availability, and hypoxic conditions
21 ([Bristow et al., 2015](#)). These results add complexity to the understanding of nitrification
22 rate and the degree to which that process is affected by environmental factors, and
23 support the need to measure the two steps of nitrification separately to better predict the
24 effects of perturbations to the N cycle in coastal waters.

25 Nitrification makes denitrification possible to some degree, and the reactions are often
26 assumed to be coupled, as nitrification provides the NO_3^- starting point for the N
27 reduction process of denitrification. Since the 2008 ISA, the degree of coupling (and
28 “decoupling”) between nitrification and denitrification reactions has been the subject of
29 much research (see discussion in [Appendix 7.2.6.8](#)).

7.2.6.5. Dissimilatory Nitrate Reduction to Ammonium

30 DNRA has been characterized as an important pathway in which N is conserved in
31 coastal ecosystems ([Giblin et al., 2013](#)). Although DNRA was not discussed in the 2008
32 ISA, more recent research has established DNRA as a potentially important N reduction
33 pathway, and one that varies in magnitude depending on a range of environmental
34 factors. Ammonium produced via DNRA can enhance productivity and respiration,

1 which in turn may exacerbate hypoxia ([Mccarthy et al., 2015](#)). Rates of DNRA usually
2 vary seasonally and peak in the warmer summer months. [Bernard et al. \(2015\)](#) found that
3 in Little Lagoon, AL, DNRA accounted for up to 30–40% of the annual NH_4^+ flux, and
4 up to 80% of the seasonal NH_4^+ flux during summer months. Also in the summer, DNRA
5 rates (study average: $52.1 \mu\text{mol N/m}^2/\text{h}$) outpaced the removal of NO_3^- via conversion to
6 N_2 (denitrification) (study average $7.7 \mu\text{mol N/m}^2/\text{h}$), resulting in more bioavailable N
7 retained in the system. This could help promote eutrophic conditions ([Bernard et al.,](#)
8 [2015](#)).

9 Several reasons have been proposed for observed seasonal peaks in DNRA rates. These
10 include warmer temperatures, higher sulfide (HS^-) and oxygen concentrations, and more
11 NO_3^- availability. Higher HS^- concentrations are shown to favor DNRA rather than
12 denitrification ([Kraft et al., 2014](#); [Howarth et al., 2011](#)). In the Niantic River estuary, CT,
13 one study area with the highest rates of DNRA was also found to have high HS^-
14 concentrations and reaction rates of sediment denitrification, anaerobic oxidation of
15 ammonium ([Appendix 7.2.6.7](#)), and DNRA varied considerably within the estuary.
16 Approximately one-third of the total area of the estuary exhibited rates of DNRA that
17 exceeded denitrification by at least 20%, although denitrification accounted for about
18 90% of NO_3^- reduction across the entire estuary ([Plummer et al., 2015](#)). Sulfide was
19 found to predict 44% of the variability in a DNRA ratio metric, while organic carbon
20 abundance and organic carbon source were less strongly correlated with DNRA
21 ([Plummer et al., 2015](#)). [Decleyre et al. \(2015\)](#) observed wide variations in N removal
22 pathway rates over small distances in the Paulina polder mudflat (Westerschelde estuary,
23 Netherlands). Rates of DNRA varied significantly on a small scale of less than 2 m and
24 were significantly related to HS^- production.

25 [Jäntti and Hietanen \(2012\)](#) demonstrated that DNRA controlled the overall NO_3^-
26 reduction under conditions of low oxygen. DNRA is thought to provide energy to
27 diatoms in dark and/or hypoxic conditions ([Glibert et al., 2016](#); [Kamp et al., 2011](#)). A
28 study from Australia's Yarra River estuary found that DNRA rates were increased under
29 oxygen saturation and depressed under hypoxic conditions ([Roberts et al., 2014](#)). This
30 result may be explained by increased iron availability and the binding of Fe^{2+} with free
31 sulfides. Increased iron availability in sediments has been linked with increased rates of
32 DNRA ([Robertson et al., 2016](#)).

7.2.6.6. Denitrification

33 Bioavailable N removal from estuarine and near-coastal ecosystems occurs via several
34 different pathways in the N cycle. These pathways include sediment burial, uptake by

1 plants, denitrification (NO_3^- reduction to N_2) and anaerobic NH_4^+ oxidation to N_2 (termed
2 anammox; [Appendix 7.2.6.7](#)). In some areas, uptake by vegetation such as SAV can
3 represent a significant N sink ([Zarnoch et al., 2017](#); [Boynton et al., 2014](#); [Hayn et al.,](#)
4 [2014](#)). However, much of the N contributed to riverine estuaries by atmospheric
5 deposition and other nonpoint and point sources of N is removed from the aquatic
6 ecosystem by either denitrification or anammox ([Damashek et al., 2015](#); [Ward, 2013](#);
7 [Boynton and Kemp, 2008](#)). These processes predominate in the anoxic sediments if the
8 water body is well mixed and occur in the water column of stratified hypoxic systems.
9 Since the 2008 ISA, there have been additional insights into factors that affect
10 abundance, biodiversity, and biological activity of denitrifying microbial communities
11 ([Appendix 7.2.6.9](#)).

12 Denitrification can occur in both the hypoxic water column and hypoxic sediments,
13 although in most estuaries sediment processing probably exceeds water column
14 processing ([Seitzinger et al., 2006](#)). Denitrification is a very important sink for N in most
15 estuaries ([Hayn et al., 2014](#); [Nixon et al., 1996](#)). Because N is such an important limiting
16 factor for primary production in estuaries, the removal of N through denitrification is a
17 valuable ecosystem service in terms of constraining the extent and magnitude of
18 eutrophication ([Piehler and Smyth, 2011](#) [Smyth, 2013, 2481620](#)). In the eutrophic Baltic
19 Sea, denitrification in sediments is important for partially mitigating the adverse effects
20 of eutrophication ([Jäntti and Hietanen, 2012](#)). However, denitrification rates are not
21 always high enough to result in a net sink of N within an estuary or embayment. [Barnes](#)
22 [and Upstill-Goddard \(2011\)](#) reported measurements of dissolved nitrous oxide (N_2O),
23 inorganic N, O_2 , and turbidity in six estuaries in the U.K. and results suggested that the
24 main source of N_2O was nitrification; denitrification did not appear to be a significant
25 NO_3^- sink in that ecosystem.

26 Denitrification was found to be the primary pathway for N reduction in the Niantic River
27 estuary in Connecticut, accounting for an average of 90% of total N reduction, a result
28 that is in line with measurements from other temperate estuaries ([Plummer et al., 2015](#)).
29 Estuaries and coastal embayments with longer water residence times and shallower water
30 depths have also been found to exhibit greater rates of denitrification ([Hayn et al., 2014](#)).
31 Shallow waters enhance denitrification because they lead to a greater level of interaction
32 between N in the water and sediments ([Hayn et al., 2014](#); [Nixon et al., 1996](#)). An analysis
33 of estuary nutrient budgets for North Atlantic estuaries by [Nixon et al. \(1996\)](#) suggested
34 that the fractional transport of nutrients through estuaries to the continental shelf is
35 inversely correlated with water residence time; specifically, the fraction of the total
36 export of N from the estuary is roughly proportional to the log mean residence time of the
37 water in the estuary. [Hayn et al. \(2014\)](#) studied the nutrient dynamics of West Falmouth
38 Harbor on Cape Cod, MA, a shallow estuary that experienced a large increase in N load

1 from human activities without a substantial change in P load. Since the 1990s, this
2 estuary received a threefold increase in N inputs caused by groundwater contamination
3 by a municipal wastewater treatment plant. During summer, the Falmouth Harbor
4 retained most of the N load contribution and also imported some additional N from the
5 adjacent Buzzards Bay; during spring and fall, N was exported from the Harbor to the
6 Bay.

7 Inhibition of denitrification rates by HS^- has been widely observed. [Plummer et al.](#)
8 [\(2015\)](#) found that denitrification rates were inversely related to pore water HS^- (as a
9 measure of SO_4^{2-} reduction), consistent with previous studies. Organic carbon abundance
10 and organic carbon source were also shown to be related to denitrification rates in that
11 study ([Plummer et al., 2015](#)).

12 [Smyth et al. \(2013\)](#) measured the N_2 fluxes in five major estuarine habitat types in Bogue
13 Sound, southeastern North Carolina: salt marshes, seagrass beds, oyster reefs, and inter
14 tidal and subtidal flats. Based on the distribution of habitats across the study estuary, it
15 was estimated that about 76% of the watershed N load was removed by denitrification in
16 the estuary each year. Results suggested that the amount of N removed by denitrification
17 from an estuary depends on the amount and type of habitats located in that estuary. Each
18 habitat had a characteristic impact on N cycling in the sediment ([Smith et al.,](#)
19 [2013](#)). [Smyth et al. \(2013\)](#); [Piehler and Smyth \(2011\)](#) concluded that more structured
20 habitats such as oyster reefs and seagrass beds provided especially high N removal per
21 unit estuary area. Calculations showed that the SAV habitat produced the highest value of
22 N removal in terms of an ecosystem service valued at \$3,000/ac/year, compared to
23 \$400/ac/year value provided by a subtidal flat habitat ([Piehler and Smyth, 2011](#)).

7.2.6.7. Anammox

24 Anammox removes N from estuaries by producing N_2 gas. This process can in some
25 cases be a significant pathway for N removal, depending on environmental factors,
26 although it is typically secondary to denitrification in N removal. Anammox and
27 denitrification are usually highly correlated ([Plummer et al., 2015](#); [Lisa et al., 2014](#)). A
28 review of several studies revealed that anammox rates in coastal sediments can
29 potentially range up to $52 \mu\text{mol N/m}^2/\text{h}$ ([Plummer et al., 2015](#)). [Mccarthy et al. \(2015\)](#)
30 found that up to 29% of the N removal (mean = $11.8 \pm 1.7\%$) from the Mississippi River
31 TN load to the Louisiana-Texas continental shelf may be due to anammox under hypoxic
32 conditions. The median denitrification rate measured in that study, which includes
33 anammox, of $88.1 \mu\text{mol N/m}^2/\text{h}$ was found to be comparable to other studies ([Mccarthy](#)
34 [et al., 2015](#)). In the Niantic River estuary, CT, anammox rates ranged from 0 to $3.1 \mu\text{mol}$

1 N/m²/h, accounting for 3.5% of total N reduction, while denitrification accounted for
2 91% of total N reduction ([Plummer et al., 2015](#)). Anammox was also found to be a
3 significant N sink in the lower St. Lawrence estuary, where it was measured at a rate of
4 5.5 ± 1.7 $\mu\text{mol N/m}^2/\text{h}$ ([Crowe et al., 2012](#)). In the Cape Fear estuary, NC, anammox
5 rates ranged from 0.17 to 4.77 nmol N/g wet sediment/h, with the highest rates measured
6 during the winter ([Lisa et al., 2015](#)). Anammox rates in this study were also found to be
7 inversely related to temperature.

8 Several studies have linked anammox activity to N loading. In the Chesapeake Bay,
9 higher anammox activity was associated with higher concentrations of NO₃⁻ in the tidal
10 freshwater segment and was not observed in the lower saline part of the estuary ([Rich et
11 al., 2008](#)).

7.2.6.8. Nitrification/Denitrification Uncoupling

12 Sediment N cycling is dynamic, and rates of various processes fluctuate over time.
13 Recent research has highlighted the importance of quantifying each process, the resulting
14 N fluxes, and environmental controls on these reactions. Denitrification has long been
15 assumed to be coupled with nitrification; however, the extent of that coupling is
16 increasingly understood to be dependent on environmental factors. [Hines et al. \(2012\)](#)
17 found that 43% of denitrification was coupled to nitrification in the upper Cape Fear
18 River estuary, NC. [Lisa et al. \(2015\)](#) found that nitrification and denitrification rates were
19 significantly coupled (correlated) in the Cape Fear River estuary, and that this coupling
20 was driven by organic carbon mineralization. The study found that tidal changes and
21 salinity fluctuations did not affect the coupling of nitrification/denitrification on the same
22 scale ([Lisa et al., 2015](#)). Under some conditions, such as warmer summer conditions,
23 DNRA may be the favored N reduction pathway over denitrification, which can also lead
24 to uncoupling of nitrification/denitrification rates. In Little Lagoon, AL, DNRA rates can
25 be much higher in the summer and are correlated with higher concentrations of HS⁻
26 ([Bernard et al., 2015](#)). Seasonality was also a factor in the San Francisco Bay, where
27 coupling of nitrification/denitrification was more prominent in the late summer; in the
28 spring, high NO₃⁻ concentrations in the water drove denitrification ([Cornwell et al.,
29 2014](#)).

7.2.6.9. New Insights Regarding the Abundance, Biodiversity, and Biological Activity of Estuarine Microbial Communities

1 Since the 2008 ISA, there is new information on the abundance, diversity
2 ([Appendix 10.3.4](#)) and biological activity of microbial communities and their role in N
3 cycling. Quantification of functional genes reflect changes in microbial function and have
4 been linked to forms of N. For example, in seasonally anoxic bottom waters in
5 Chesapeake Bay, [Eggleston et al. \(2015\)](#) observed that relative expression of genes
6 involved in denitrification and DNRA were coincident with changes in concentrations of
7 NO_3^- , NO_2^- , and NH_4^+ . In an analysis of denitrifiers in San Francisco Bay estuary, N was
8 identified as one of the key factors (along with salinity, organic C and several metals)
9 affecting community structure and function and denitrification rates ([Mosier and Francis,](#)
10 [2010](#)). Seasonal inputs of N loading from the watershed affect microbial community
11 structure and biodiversity, which in turn affect rates of processes involved in N cycling
12 ([Lisa et al., 2015](#); [Lisa et al., 2014](#)).

7.2.6.10. Archaea and Nitrogen Cycling

13 Prior to the 2000s, it was generally believed that NH_3 oxidation was accomplished only
14 by Proteobacteria ([Damashek et al., 2015](#); [Kowalchuk and Stephen, 2001](#)). Complexity
15 increased with the discovery that some Archaea (also called Thaumarchaeota), a
16 primitive life form separate from bacteria, can also oxidize NH_3 ([Brochier-Armanet et al.,](#)
17 [2008](#); [Könneke et al., 2005](#)). These ammonia-oxidizing Archaea (AOA) are dominant in
18 some estuaries ([Moin et al., 2009](#)). Ammonia-oxidizing bacteria (AOB) are important in
19 others ([Abell et al., 2010](#)). These two life forms can vary spatially and seasonally in
20 importance in still other estuaries ([Damashek et al., 2015](#); [Urakawa et al., 2014](#); [Zheng et](#)
21 [al., 2014](#)). Benthic NH_3 oxidizers may be able to oxidize a significant quantity of NH_4^+ in
22 NH_4^+ rich systems, such as the Sacramento River ([Damashek et al., 2015](#)). Several
23 studies that have examined changes in AOA and AOB relative abundance and
24 community structure associated with N loading are reviewed in [Appendix 10.3.4](#).

7.2.6.11. Role of Benthic Macrofauna in Nitrogen Cycling

25 The role of benthic macrofauna (including crustaceans and molluscs) in N and C cycling
26 and their ability to modulate water quality have significant implications for estuarine
27 functioning ([Rose et al., 2015a](#); [Bricker et al., 2014](#); [Petersen et al., 2014](#); [Rose et al.,](#)
28 [2014](#); [STAC, 2013](#); [Carmichael et al., 2012](#); [Volkenborn et al., 2012](#); [D'Andrea and](#)
29 [DeWitt, 2009](#); [Cerco and Noel, 2007](#)). Activities of burrowing macrofauna can create

1 areas of oxic-anoxic oscillations, which vary on the order of minutes to hours and affect
2 geochemical reactions and microbial activity in sediments ([Volkenborn et al., 2012](#)).
3 Burrowing mudshrimp (*Upogebia pugettensis*) were shown to increase the rate of N
4 cycling processes and DIN fluxes in an intertidal mud flat in the Yaquina River estuary in
5 Oregon ([D'Andrea and DeWitt, 2009](#)). [Stief \(2013\)](#) reviewed the contributions of benthic
6 macrofauna to the turnover of N and to emissions of greenhouse gasses such as nitrous
7 oxide from the estuary to the atmosphere. Sediment burrowing macrofauna stimulated
8 nitrification and denitrification in the sediment. Together these facilitate removal of N
9 from the estuary system. Benthic macrofauna intensify the coupling among water,
10 benthos, and atmosphere by enhancing turnover and transport of N.

11 The use of shellfish for remediation of coastal N enrichment has been explored due to the
12 ability of these organisms to modulate nutrient dynamics and water quality ([Reitsma et
13 al., 2017](#); [Ferreira and Bricker, 2016](#); [Petersen et al., 2016](#); [Bricker et al., 2014](#); [STAC,
14 2013](#); [Cercó and Noel, 2007](#); [Carmichael et al., 2004](#)). These filter feeders store nutrients
15 in shell and tissue that are permanently removed from the estuary with shellfish harvest.
16 Biodeposits (partially digested phytoplankton expelled from suspension feeding bivalves)
17 may remove additional N through acceleration of denitrification processes in underlying
18 sediments ([Pollack et al., 2013](#); [STAC, 2013](#); [Stephenson et al., 2010](#)). For example, in
19 the Mission-Aransas estuary in Texas, oyster reefs were estimated to remove 502.5 kg
20 N/km² through denitrification of biodeposits and 251.3 kg N/km² in burial of biodeposits
21 to sediments ([Pollack et al., 2013](#)). Oyster harvest in the same estuary was calculated to
22 remove approximately 21,665 kg N/year.

23 Additional studies have reported N removal by shellfish in U.S. waters. [Carmichael et al.
24 \(2004\)](#) directly measured N removal in the oyster *C. virginica* in transplant studies to five
25 Cape Cod estuaries with different N loadings. Estimated N removal of different sources
26 was ≤15% of land-derived N loads and <1% of phytoplankton. Nitrogen removal by
27 oysters in the Great Wicomico River, which drains into the Chesapeake Bay, was
28 estimated to be 15.2 tons/year [total area 2.8 × 10⁵ m²; ([Cercó, 2015](#))]. Based on model
29 estimates for Chesapeake Bay harvesting 7.7 × 10⁶ harvest-sized oysters (76-mm)
30 removes 1 ton of N from the bay ([Higgins et al., 2011](#)). In the same study, an offset of
31 approximately 10 to 15% of total N load in some basins (cultivation of
32 200 × 10⁶ oysters/year) was calculated. [Holmer et al. \(2015\)](#) recommended harvest of
33 mussels within 1 year of the production cycle for the most efficient N removal.

34 Over time, shellfish excretion and subsequent sedimentation may contribute to
35 development of hypoxic conditions. A shellfish farming operation may shift from a net
36 sink to a net source of N. Oyster reef restoration projects in several locations throughout
37 the U.S. have been evaluated for effects on N cycling; however, this process appears to

1 be dependent on local habitat and growing conditions and may vary by orders of
2 magnitude ([Cercu, 2015](#); [Smyth et al., 2015](#); [Kellogg et al., 2014](#); [Plutchak et al., 2010](#)).
3 In Great Bay estuary, NH, eutrophication enhanced oyster feeding rates and enhanced
4 biodeposit quality. Thus, oyster-mediated ecosystem services may be expected to vary
5 with environmental conditions ([Hoellein et al., 2015](#)).

6 Recent evaluation of oysters in Chesapeake Bay for inclusion in TMDL nutrient
7 reductions reported enhanced denitrification in association with oyster reefs; however,
8 the effect was highly variable and not reliable unless direct measurements were
9 conducted on individual reefs ([STAC, 2013](#)). The potential for shellfish aquaculture to be
10 included in proposed nutrient trading markets for achieving pollution control under the
11 Clean Water Act is being evaluated in Chesapeake Bay ([Stephenson et al., 2010](#)). Some
12 recent modeling studies showed that mean N removal by shellfish aquaculture compares
13 favorably with reported N removal effectiveness of agricultural best management
14 practices and stormwater control measures ([Rose et al., 2015a](#); [Rose et al., 2014](#)).

7.2.6.12. Climate Modification of Ecosystem Response to Nitrogen

15 Altered biogeochemical processes due to N loading are occurring within the context of
16 climate change. Microbial diversity is affected by environmental gradients within
17 estuaries, a condition that may be exacerbated under climate change. For example,
18 freshwater and nutrient contributions to estuaries are expected to rise due to predicted
19 increases in surface water flow and runoff from watersheds ([Rabalais et al., 2010](#); [Adrian
20 et al., 2009](#); [Whitehead et al., 2009](#)). [Howarth et al. \(2012\)](#) demonstrated larger N fluxes
21 (larger percentage delivery of human N inputs) in wetter climates with more discharge,
22 across 154 different watersheds in the U.S. and Europe. Temperature modification
23 leading to sea level rise and inputs of fresh water will likely influence the delivery of
24 nutrients and organic matter, alter salinity gradients, and increase stratification within
25 estuaries ([Statham, 2012](#)). Eutrophic conditions and the extent and duration of hypoxia
26 are predicted to increase with anticipated changes in temperature and precipitation
27 ([Altieri and Gedan, 2015](#); [Rabalais et al., 2009](#); [Boesch et al., 2007](#)). High organic loads
28 and freshwater inputs associated with extreme weather events may further enhance
29 thermal stratification and contribute to hypoxia ([Wetz and Yoskowitz, 2013](#)). Increased
30 thermal stratification will worsen hypoxia where it already occurs and may facilitate its
31 formation at other locations ([Rabalais et al., 2010](#)).

32 The “benthic filter” is a term given to the benthic microbe and algal communities that
33 remove N via uptake and denitrification and bury N from shallow estuarine and coastal
34 waters. Nitrogen removal via the benthic filter is an important mediator of nutrient

1 enrichment in shallow estuaries along the Atlantic and Gulf coasts of the U.S. where this
2 feature is common ([Anderson et al., 2014b](#)). The filtering function of this top layer of
3 sediment is affected by nutrient delivery as well as light availability, temperature, and
4 resuspension caused by wind and storms. Thus, the benthic filter and the N removal
5 services it provides are expected to be highly susceptible to climate change impacts
6 ([Anderson et al., 2014b](#)).

7.2.7. Monitoring Data

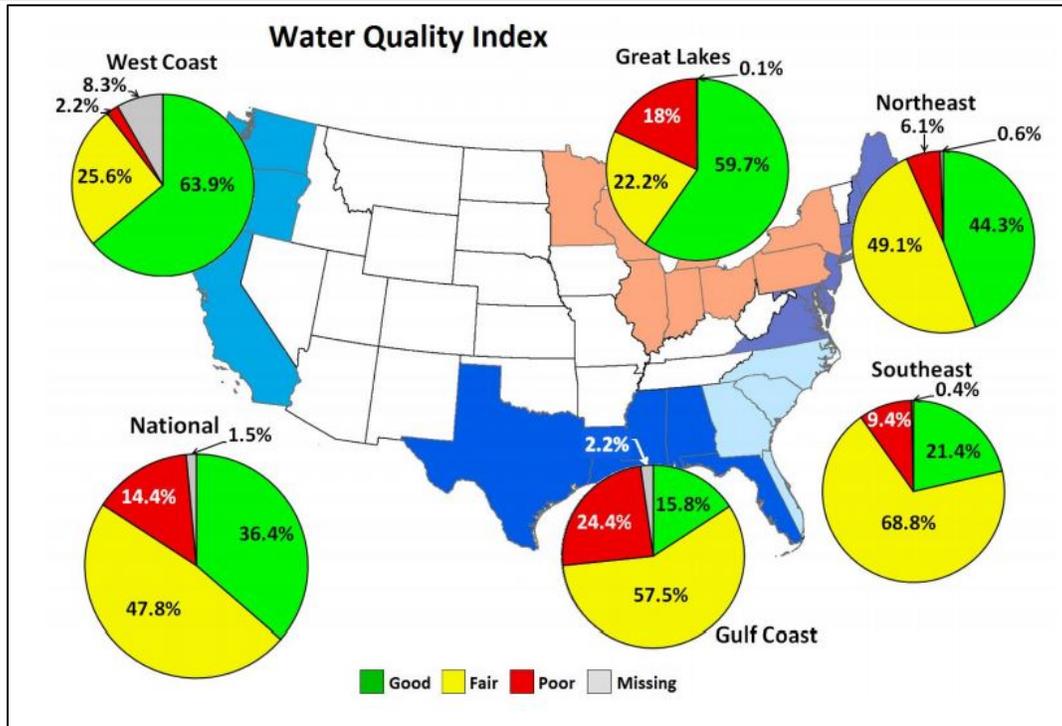

7 Monitoring data provide temporal trends of biogeochemical processes and indicators
8 associated with eutrophication and nutrient-enhanced coastal acidification in estuaries
9 and coastal ecosystems. These data document and quantify changes that occur in
10 response to environmental stressors, including N deposition. Many monitoring studies for
11 eutrophication have been ongoing for one or two decades, in some cases longer.
12 Monitoring for coastal acidification is more recent. Analysis of historical data suggest
13 that some coastal areas have been experiencing long-term acidification.

7.2.7.1. Eutrophication

14 Since the 2008 ISA, nearly a decade's worth of additional data have been added to some
15 of the monitoring programs described below. The availability of these additional data
16 facilitates trend detection now, compared to 2008. The U.S. EPA Estuary Data Mapper
17 tool accessed at <https://www.epa.gov/hesc/about-estuary-data-mapper-edm> allows users
18 to retrieve and visualize estuary data from several federal agencies to access water and
19 sediment quality, freshwater discharge, tides, N deposition, and other parameters.

20 The NARS include a survey of coastal waters called the National Coastal Condition
21 Assessment (NCCA). U.S. EPA, together with the states, tribes, other entities, and
22 individuals, have collaborated on these statistically representative surveys since the early
23 2000s. The NCCA survey uses standardized field protocols and indicators of coastal
24 condition including N, water clarity, chlorophyll *a*, and DO concentrations. The NCCA
25 2010 used a consistent set of data from three periods (1999–2001, 2005–2006, and 2010)
26 to evaluate change in coastal conditions over time ([U.S. EPA, 2016g](#)). This analysis
27 included only the Northeast, Southeast, Gulf, and West Coast regions. (The change
28 analysis does not include the Great Lakes because they were not part of this survey until
29 2010.) The change analysis showed that scores on the water quality index remained
30 relatively similar between 2005–2006 and 2010, after a significant decrease in the
31 percentage of area rated good from 1999–2000 to 2005–2006. The Gulf Coast had the

1 greatest proportion of waters (24.4%) rated poor for water quality compared to the other
2 regions surveyed for the NCCA in 2010 (Figure 7-9). The NCCA report noted that these
3 findings support the need for continued attention to coastal stressors at national, regional,
4 state, and watershed scales to identify and mitigate challenges where they exist and
5 protect areas that are still in good condition (U.S. EPA, 2016g).

Source: U.S. EPA (2016g).

Figure 7-9 Percentage of area in each coastal region scoring good, fair, and poor based on the Water Quality Index for the NCCA 2010.

6 Additional long-term monitoring surveys conducted with help from the U.S. EPA include
7 those undertaken by individual National Estuary Programs (NEP) around the U.S. The
8 NEP is a nonregulatory program designed to protect and restore the water quality and
9 ecological integrity of estuaries of national significance, of which there are currently 28.
10 The NEPs develop and implement long-term management plans that contain actions to
11 address water quality priorities, which are defined by local, city, state, federal, private,
12 and nonprofit stakeholders. In many cases these priorities include reducing and mitigating
13 the occurrence of eutrophic conditions in large estuaries, goals often accompanied by
14 long-term monitoring of nutrients and eutrophication indicators. For instance, the Tampa
15 Bay Estuary Program works with the Southwest Florida Water Management District's

1 Surface Water Improvement and Management Program to collect monitoring data on
2 trends in seagrass coverage, which is greatly affected by water clarity (often an indicator
3 of excessive N loads to the bay) ([Sherwood, 2017](#)). The most recent analysis of
4 monitoring data showed that Tampa Bay’s seagrass area continues to recover, with the
5 addition of 1,360 acres of seagrass coverage reported from 2014 to 2016. Tampa Bay’s
6 total seagrass coverage is now estimated to be 41,655 acres as of 2016, which now
7 exceeds the total estimated seagrass coverage in the 1950s period (40,420 acres) for the
8 first time since monitoring began ([Sherwood, 2017](#)). See the Tampa Bay Case Study
9 ([Appendix 16](#)) for additional information on this coastal system.

10 The NEP’s Long Island Sound Study has conducted two decades of monitoring to
11 identify N sources and track water quality conditions and eutrophic indicators over time.
12 The Long Island Sound Study uses several indicators, including the NCCA’s Water
13 Quality Index, to evaluate changes from year to year. Data from 1991–2011 show a
14 gradient in improving water quality from the eastern part of the sound, where population
15 and anthropogenic stressors are lower and water quality was most often rated “good,” to
16 the western side where population and development pressure are both higher and water
17 quality was consistently rated “fair” ([LISS, 2017](#)).

18 The Chesapeake Bay Monitoring Program established in 1984 is a regional partnership
19 that monitors 19 physical, chemical, and biological characteristics, including nutrients
20 and DO, enabling the study of the bay and long-term trends ([Testa et al., 2017](#)). The
21 original Chesapeake Bay Program agreement of 1983 included Maryland, Virginia,
22 Pennsylvania, Washington, D.C., the U.S. EPA, and regional partners. In 2014, the
23 Chesapeake Watershed Agreement was signed to include representatives from the entire
24 watershed and accelerate restoration of the bay.

25 The NPS also conducts estuarine water quality monitoring to monitor “Park Vital Signs,”
26 which are elements and processes of park ecosystems that can serve as indicators of the
27 overall health of the park. The Estuarine Nutrient Enrichment Monitoring (ENEM)
28 program monitors nitrogen loading inputs as well as overall water quality and seagrass
29 distribution in park estuaries within the Northeast Coastal and Barrier Network (NCBN)
30 region (covering Massachusetts to Virginia) of the NPS. In this region, the Park Vital
31 Signs are all related to nutrient enrichment, which is considered the stressor with the
32 ability to cause the greatest potential impacts on park health ([USGS US Department of
33 the Interior, 2015](#)). Water quality indicators are defined with the same criteria as U.S.
34 EPA’s NCCA methods, and data are available on the program’s website for each park in
35 the NCBN region of the NPS at
36 <https://science.nature.nps.gov/im/units/ncbn/monitor/estuaries.cfm>.

1 The National Oceanic and Atmospheric Administration (NOAA) conducts several
2 monitoring programs in estuaries and coastal waters. The National Estuarine Research
3 Reserves System (NERRS) is a federal-state partnership network of 29 coastal sites
4 encompassing 1.3 million acres designated to protect and study estuarine systems.
5 Estuarine water quality monitoring data are collected by the NERRS System-Wide
6 Monitoring Program (SWMP), which identifies and tracks short-term variability and
7 long-term changes in estuarine ecosystems and coastal watersheds. Data are housed in a
8 central online database available at <http://cdmo.baruch.sc.edu/>.

9 Many NERRS sites work with other groups to analyze and report their overall findings
10 about water quality indicators. In the Great Bay estuary in New Hampshire and Maine,
11 NERR's SWMP collects nitrogen, DO, and temperature data, which is used by the
12 Piscataqua Region Estuaries Partnership (an NEP site) to assess the environmental status
13 and trends in the Bay. The most recent State of the Estuaries report found that total N
14 load to the estuary in 2009–2011 was 1,225 tons per year, which appeared to be strongly
15 influenced by rainfall amounts ([PREP, 2013](#)).

16 NOAA's Gulf of Mexico Ecosystems and Hypoxia Assessment (NGOMEX) is a large
17 study focusing on a single geographic region in the Gulf of Mexico. NGOMEX has been
18 collecting data and conducting research for more than 30 years to investigate the spatial
19 and temporal dynamics of the hypoxia zone in the Gulf of Mexico, especially with
20 regards to the link between the hypoxia zone size and the amount of nutrient loading,
21 primarily from the Mississippi River watershed ([Appendix 10.2.4](#)). In 2017, work funded
22 by NGOMEX measured the largest Gulf of Mexico hypoxia zone since mapping of the
23 area began in 1985 ([U.S. EPA, 2017e](#)). The size of the 2017 hypoxia zone was accurately
24 forecasted by Mississippi River spring discharge levels and nutrient data, gathered by the
25 USGS and analyzed with NOAA-sponsored models, and clearly indicates that nutrient
26 pollution from the Mississippi River watershed is affecting the health of the coastal Gulf
27 ecosystem.

28 NOAA also conducts the Monitoring and Event Response for Harmful Algal Blooms
29 (MERHAB) program which helps identify when beaches, shellfisheries, and marine
30 animals are at risk from harmful algae and cyanobacteria. It allows local stakeholders to
31 react as quickly as possible to any human health risk. MERHAB largely funds research
32 projects, but also aims to help routine water quality and shellfish monitoring studies
33 upgrade to better HAB detection methods and technologies. NOAA's Center for
34 Operational Oceanographic Products and Services (CO-OPS) produces HAB forecasts
35 for the Gulf of Mexico to help communities plan for and mitigate the effects of
36 potentially harmful algal blooms. Data for these forecasts come from many sources. The
37 National Aeronautics and Space Administration (NASA) Moderate Resolution Imaging

1 Spectroradiometer (MODIS) satellite collects ocean color data which are processed by
2 NOAA CoastWatch ([NOAA, 2017a](#)). The satellite sensors measure visible light at
3 specific wavelengths to determine the color of the ocean. These color data can be used to
4 estimate chlorophyll concentrations; however, in coastal areas, interpretation can be
5 complicated by the presence of other biota, compounds, and minerals ([NOAA, 2017b](#)).
6 The HAB forecasts prepared by CO-OPS also integrate other data about factors that may
7 affect algal and cyanobacterial bloom formation and intensity such as water temperature,
8 ocean currents, and weather conditions ([NOAA, 2017b](#)). The forecasts also note cell
9 counts of the toxic dinoflagellate *Karenia brevis* (commonly called a “red tide” species)
10 taken from specific locations along the coast. Another NOAA product called the Harmful
11 Algal Bloom Observing System (HABSOS) integrates these data sources, including cell
12 counts and other environmental information into an interactive mapping application
13 available online at <https://habsos.noaa.gov/> ([NOAA, 2017c](#)). HABSOS can map recent
14 satellite data and cell counts to depict areas that may be at risk of HABs in the near
15 future. Trends in HABs and responses to N are discussed further in [Appendix 10.2.2](#) and
16 [Appendix 10.3.3](#).

7.2.7.2. Coastal Acidification

17 Coastal acidification programs are developing around the world. In the U.S., ocean
18 acidification has been documented from the New England region, California, Oregon,
19 Washington, and the northern Gulf of Mexico ([Laurent et al., 2017](#); [Gledhill et al., 2015](#);
20 [Gruber et al., 2012](#); [Hauri et al., 2009](#); [Feely et al., 2008](#); [Yang, 1998](#)). In a series of
21 sampling cruises and analysis of water sampling data, [Wallace et al. \(2014\)](#) identified
22 concurrent low pH conditions and declining DO in four Northeast estuaries (Long Island
23 Sound, NY; Jamaica Bay, NY; Narragansett Bay, RI; Hempstead Bay, NY). Observed
24 conditions in eutrophic estuaries during late summer were such that marine biota,
25 especially calcifying organisms, may be affected ([Appendix 10.5](#)). Analysis of historical
26 (from the late 1960s to 2010) alkalinity and pH data from bays along the northwestern
27 coast of Texas indicated that most of the bays in this region have experienced long-term
28 acidification ([Hu et al., 2015a](#)).

7.2.8. Modeling Estuaries and Near-Coastal Areas

29 Since the 2008 ISA, several new applications of existing models have quantified
30 eutrophication processes in estuaries and near-coastal marine ecosystems. These have
31 included studies that focused primarily on N cycling or hypoxia.

7.2.8.1. Models

1 There are several models that track the sources and movement of N through the landscape
2 and stream network to estuary and near-coastal marine ecosystems. These models vary in
3 scope, level of spatial and temporal resolution, forms of N considered, complexity, and
4 empirical versus deterministic construction ([Alexander et al., 2008](#)). They can be
5 structured as statistical models ([Howarth et al., 2012](#); [Peierls et al., 1991](#)), empirical
6 models ([Caraco and Cole, 1999](#)), export coefficient models ([Johnes, 1996](#)), deterministic
7 models such as SWAT ([Gassman et al., 2007](#); [Nietsch et al., 2002](#)), Generalized
8 Watershed Loading Function [GWLF; ([Haith and Shoemaker, 1987](#))], and hybrid
9 approaches (SPARROW, NEWS). The principal ecosystem models applied to U.S.
10 waters to assess N enrichment were reviewed in the 2008 ISA and are briefly summarized
11 here ([U.S. EPA, 2008a](#)).

12 Some of these models have been applied at national or large regional scales to examine N
13 loading to rivers and the coastal zone. SPARROW is a hybrid statistical-mechanistic
14 model that can attribute pollutant sources and contaminant transport to surface waters
15 ([Smith et al., 1997](#)). SWAT is a mechanistic model developed by the U.S. Department of
16 Agriculture, Agricultural Research Service ([Gassman et al., 2007](#); [Nietsch et al., 2002](#)).
17 WATERS-N is a mass balance model that has been used to evaluate N inputs to estuaries
18 ([Castro et al., 2003](#); [Castro et al., 2001](#)).

19 Since the 2008 ISA, there have been new applications of SPARROW and SWAT, as well
20 as development and application of new models and approaches such as NEWS and Net
21 Anthropogenic Nitrogen Inputs (NANI). SPARROW has been used to estimate total N
22 loads within watersheds to estimate sources of N to streams and rivers. It has also been
23 applied at regional and national scales ([Schwarz et al., 2011](#); [Alexander et al., 2008](#)).
24 SPARROW operates on an annual time step, usually integrating several decades of data
25 to develop load relationships and then simulating conditions for 1 year. NEWS is a
26 similar hybrid model. It has been used to estimate the magnitudes and sources of different
27 forms of N (particulate, dissolved inorganic, and organic) to coastal waters ([Glibert et al.,](#)
28 [2010a](#)). Recent work with NEWS included a global, seasonal version ([McCrackin et al.,](#)
29 [2014](#)). It has been used for scenario comparisons, including predictions about reductions
30 in air deposition resulting from Clean Air Act regulations and other policy actions
31 ([McCrackin et al., 2015](#)). NANI is a simple mass balance model for calculating net
32 anthropogenic nitrogen inputs that takes information about inputs and outputs of nitrogen
33 within a basin and estimates the riverine flux from the landscape to the ocean ([Howarth et](#)
34 [al., 2012](#)). It was developed for watersheds across the contiguous U.S. at the county level
35 ([Hong et al., 2013, 2011](#)). Using NANI, [Howarth et al. \(2012\)](#) demonstrated larger N
36 fluxes (larger percentage delivery of human N inputs) in wetter climates with more

1 discharge, across 154 different watersheds in the U.S. and Europe. The NANI Calculator
2 Toolbox takes into consideration fertilizer N application, agricultural N fixation, net food
3 and feed imports, and atmospheric sources of N.

4 Deterministic models of N flux are based on mechanistic relationships that simulate N
5 transformations, transport, and removal, often at relatively fine temporal and spatial
6 resolution. SWAT has been recently applied at the regional scale of the Mississippi River
7 basin ([Santhi et al., 2014](#)). It allows examination of the effects of changes in cropland
8 management on delivery of N to coastal waters. Recent SWAT publications do not
9 explicitly include atmospheric deposition as a source of N, but have produced similar
10 overall results as SPARROW and NEWS in terms of load and attribution to agriculture in
11 the Mississippi River basin ($\approx 54\text{--}61\%$; [White et al., 2014](#); [McCrackin et al., 2013](#)).

12 The watershed models described above route N from the landscape to estuaries and the
13 coastal zone, but generally do not model the contribution of N directly to the estuary
14 surface from the atmosphere. These models also deal with the freshwater components of
15 watersheds and do not predict N fate within estuaries or N effects on estuarine processes
16 or functions. The following sections describe new applications of several models that
17 operate within estuaries.

18 Additional models and tools that have been applied to assess atmospheric contributions of
19 N to U.S. estuaries since the 2008 ISA included the watershed N Loading Model [NLM;
20 ([Latimer and Charpentier, 2010](#))] and the Watershed Deposition Tool [WDT; ([Poor et al.,
21 2013b](#))]. The latter was developed by the U.S. EPA to map atmospheric deposition
22 estimates to watersheds using wet and dry deposition data from the Community
23 Multiscale Air Quality Model [CMAQ; ([Schwede et al., 2009](#))]. This tool links air and
24 water quality modeling data for use in TMDL determinations and analysis of
25 nonpoint-source impacts. The NLM has been used for New England estuaries to estimate
26 total N loading and the relative contributions of the various N sources ([Table 7-9](#)) and
27 develop load response relationships among N inputs and seagrass extent ([Latimer and
28 Rego, 2010](#)).

7.2.8.2. Predicted Response to Nitrogen Loading

29 Many of the models that estimate N loads to the coastal zone from the landscape and
30 freshwater inflow have been compared, and there is a good deal of knowledge about their
31 limitations and uncertainties ([McCrackin et al., 2013](#); [Alexander et al., 2008](#)). In a 2000
32 National Research Council review, it was determined that these models are
33 hydrodynamically complex and tend to be specific to particular sites. Thus, they are
34 difficult to apply broadly ([NRC, 2000](#)).

1 The range of coastal ecosystem responses to changing N loads reflect changes in DO,
2 productivity, SAV cover, and impacts on other organisms. Water residence time can
3 influence the response of estuaries to nutrient loading because of the effects of flushing
4 on nutrients, water temperature, plankton, and light penetration. Capturing these
5 dynamics in a model is challenging ([Swaney et al., 2008](#)).

6 A recent review of hypoxia modeling described trade-offs between details of complex
7 models and the need for simpler, more broadly applicable models ([Peña et al., 2010](#)).
8 [Greene et al. \(2009\)](#) developed a set of multiple regression models to simulate
9 relationships between river loads and concentrations of N and P compared with the extent
10 of hypoxic bottom water. A Bayesian approach was used in combination with a model of
11 hypoxia to project the O₂ demand and extent of hypoxia ([Liu et al., 2010](#)). Estuarine
12 models have been important to policy decision making and formulation of nutrient
13 reduction goals ([Scavia et al., 2006](#); [Scavia et al., 2004](#)). There is an increased interest in
14 developing coupled models that connect physical-chemical-biological nutrient loading
15 and fate models ([Fennel et al., 2011](#)) and that connect chemical eutrophication models to
16 fisheries response models ([Cercio et al., 2010](#)).

17 The responses of estuaries to N loading is partly determined by environmental
18 characteristics. Nutrient-phytoplankton-zooplankton (NPZ) models examine biological
19 responses including the effects of nutrient limitation and zooplankton predation on
20 phytoplankton dynamics and fish production. The NPZ model described by [Swaney et al.](#)
21 [\(2008\)](#) can assess complex responses of estuaries to different climate variables, land use,
22 atmospheric loading, and other stressors ([Appendix 10.3.8](#)).

23 New studies have focused on increasing understanding of spatial variation in DIN export
24 from the watershed to coastal zones. Seasonal patterns of DIN export influence impacts
25 of coastal eutrophication, including HABs and the development of seasonal hypoxic
26 zones. [McCrackin et al. \(2014\)](#) predicted seasonal DIN export to coastal regions, using
27 the NEWS2 model calibrated to measured DIN yield in 77 rivers distributed globally.
28 The DIN transport efficiency was positively correlated with runoff and negatively
29 correlated with temperature. [McCrackin et al. \(2014\)](#) concluded that because of landscape
30 N attenuation, a better representation of land-to-river N transfers, in particular, might
31 improve models of nutrient cycling.

32 [Eldridge and Morse \(2008\)](#) developed a combined water-column and sediment model to
33 investigate sediment and water-column metabolism and their impacts on development of
34 hypoxia on the Louisiana shelf. They found that sediment O₂ demand was the primary
35 sink for O₂ at the beginning and end of a hypoxic event. Once hypoxia has developed,
36 however, sediments became isolated from O₂ rich upper waters.

1 Key drivers of hypoxia in coastal waters include nutrient loading, mainly from
2 anthropogenic sources, C supply, and processes that contribute to thermal stratification.
3 Complex hypoxia models are difficult to validate, however, and this limits the confidence
4 that can be placed on simulation results. [Eldridge and Roelke \(2011\)](#) recommended the
5 use of multiple models and identification of similarities in qualitative model behavior.
6 They provided a brief overview of recent hypoxia models, and identified the need for a
7 meta-analysis of simulations produced by these models in search of qualitative
8 similarities. They concluded that more complex models of hypoxia need to be developed
9 that include three-dimensional hydrology. [Sturdivant et al. \(2013\)](#) developed a model of
10 hypoxia impact on macrobenthic production in the lower Rappahannock River, a
11 tributary of the Chesapeake Bay that experiences seasonal hypoxia. Simulation results
12 suggested that macrobenthic biomass was strongly linked with dissolved O₂
13 concentration. Biomass fluctuations reflected the duration and severity of hypoxia.
14 Results suggested that hypoxia had a negative effect on biomass, with longer duration
15 and greater severity resulting in increased loss of biomass.

16 [Glibert et al. \(2010a\)](#) reviewed modeling approaches to improve understanding of HABs
17 and their relationship with nutrient inputs. They recommended that predictive capabilities
18 will likely improve if a suite of modeling approaches is used. This might include
19 site-specific loading models of nutrient sources and models that couple nutrient discharge
20 to biological responses.

21 [Dale et al. \(2011\)](#) investigated biogeochemical processes that affect N cycling in the
22 sediment of Eckernförde Bay in the southwestern portion of the Baltic Sea, where severe
23 bottom water hypoxia (and sometimes anoxia) commonly occurs during late summer.
24 Sediments acted as net sinks for NO₃⁻, of which three-fourths was characterized as
25 derived from reduction of NO₃⁻ to NH₄⁺. The other 25% was characterized as derived
26 from denitrification of NO₃⁻ to NO₂⁻. The NH₄⁺ flux was high (1.74 mmol/m²/day), in
27 response to degradation of organic N at the sediment interface, and was directed out of
28 the sediment.

7.2.9. National Scale Sensitivity

29 Characteristics of coastal systems sensitive to eutrophication are described in
30 [Appendix 10.1.4](#). In the 2008 ISA and the National Estuarine Eutrophication Assessment
31 (NEEA), a comprehensive survey of eutrophic conditions in the Nation's estuaries
32 conducted by the National Oceanic and Atmospheric Administration (NOAA), the most
33 eutrophic estuaries in the U.S. occurred in the mid-Atlantic region, and the estuaries with
34 the lowest degree of eutrophication were in the North Atlantic [[Figure 10-2](#);[Bricker et](#)

1 [al., 2007](#)]. Areas of eutrophication-related hypoxia are found on the U.S. East and West
2 coasts and the Gulf of Mexico ([Figure 10-5](#)). During the summer of 2017 the extent of
3 hypoxia in the Gulf of Mexico was the largest ever recorded in the U.S. ([U.S. EPA,](#)
4 [2017e](#)). The most recent NCCA report, based on 2010 data and released by U.S. EPA in
5 2016, analyzed survey data from 1,104 sites, representing 35,400 square miles of U.S.
6 coastal waters ([U.S. EPA, 2016g](#)). In this most recent NCCA report, water quality was
7 rated good in 36% of coastal and Great Lakes nearshore waters, fair in 48%, and poor in
8 14%, based on measures of the eutrophication parameters that make up the water quality
9 index (P, N, water clarity, chlorophyll *a*, and DO concentrations) ([Figure 7-9](#)).

10 In the U.S., Chesapeake Bay is perhaps the best-documented case study of the effects of
11 human activities on estuarine eutrophication. Other impacted estuaries identified in the
12 2008 ISA included Long Island Sound, the Pamlico Estuary in North Carolina, and along
13 the continental shelf adjacent to the Mississippi and the Atchafalaya River discharges to
14 the Gulf of Mexico ([U.S. EPA, 2008a](#)). In many parts of the U.S., especially the
15 Southeast, Midwest and Mid-Atlantic deposition of reduced N has increased relative to
16 oxidized N in last few decades ([Appendix 2](#) and [Appendix 10.1.2](#)). Since the 2008 ISA,
17 additional evidence has shown that reduced forms of atmospheric N play an increasingly
18 important role in estuarine and coastal eutrophication ([Appendix 10.3.3](#)). The form of N
19 delivered to some coastal areas of the U.S. is shifting from primarily NO₃⁻ to an increase
20 in reduced forms of N.

21 Nutrient-enhanced coastal acidification was not discussed in the 2008 ISA yet the
22 contribution of increased respiration caused by N enrichment to acidification of coastal
23 areas has resulted in recent research and monitoring efforts in the U.S.
24 ([Appendix 7.2.7.2](#)). Ocean acidification has been documented from the Gulf of Maine,
25 California, Oregon, Washington, and the northern Gulf of Mexico ([Laurent et al., 2017](#);
26 [Gledhill et al., 2015](#); [Gruber et al., 2012](#); [Hauri et al., 2009](#); [Feely et al., 2008](#); [Salisbury](#)
27 [et al., 2008](#)).

28 Unlike freshwaters where chemical recovery linked to decreased atmospheric deposition
29 of N and S is observed in some systems ([Appendix 7.1.5.1](#)), N inputs from atmospheric
30 and other sources contribute to the continued water quality degradation in U.S. coastal
31 waters. There are only a few cases of documented recovery of biological indicators in
32 U.S. estuaries such as SAV in Tampa Bay ([Appendix 16](#)) and Chesapeake Bay
33 ([Figure 10-6](#)).

7.2.10. Water Quality Criteria for Estuaries

1 As discussed for fresh water in [Appendix 7.1.6](#), the U.S. EPA develops WQC using the
2 latest scientific knowledge to determine when water is unsafe for people and wildlife.
3 State and tribal governments may adopt these criteria or use them as guidance in
4 developing their own. Numeric nutrient criteria are critical tools for protecting and
5 restoring a water body's designated uses related to N and P nutrient pollution. These
6 criteria enable effective monitoring of a water body for attaining its designated uses,
7 facilitate formulation of the National Pollutant Discharge Elimination System (NPDES)
8 discharge permits, and simplify development of TMDLs for restoring impaired waters.

9 Generally, it has been considered more complicated to determine appropriate nutrient
10 criteria for estuaries than for many freshwater systems because estuaries are influenced
11 by so many variable factors such as tidal fluctuations, salinity gradients, and other widely
12 varying physical and chemical conditions which impact water quality. The designation of
13 water bodies within which similar ambient conditions are expected to occur is much more
14 difficult in estuaries, as the ambient values often fluctuate widely under natural
15 conditions within the same estuary. Nevertheless, several states have made progress in
16 the development of numeric nutrient criteria for estuaries. One of the first states to
17 implement its own criteria for estuaries, Florida designated 62 different estuary segments
18 and adopted a TN target value for each segment based on extensive monitoring and
19 modeling studies.

20 The U.S. EPA is continuing to work with the states to develop numeric nutrient criteria to
21 better define levels of N that affect U.S. marine and estuarine waters. WQC for TN are
22 now available statewide in American Samoa, Florida, Hawaii, and the Northern Marianas
23 Islands ([Figure 7-10](#)). Guam has statewide criteria for NO_3^- as N, and Puerto Rico has
24 statewide criteria for DIN. Delaware has criteria for DIN as N in some estuaries.
25 Massachusetts has not developed N criteria for estuaries but there is a TMDL in place
26 that limits N loading to select estuaries on Cape Cod, Martha's Vineyard, Nantucket, and
27 the Buzzards Bay/South Coastal area. California has made progress toward numeric
28 nutrient criteria. Currently, the state has numeric criteria for water clarity in all estuaries
29 statewide, but specific N criteria currently exist only for one location based on a TMDL
30 for nutrient compounds (including N) for the Malibu Creek watershed, which includes
31 the estuarine waters of Malibu Lagoon. By 2020, the following additional states are
32 expected to have at least partial numeric N criteria for estuarine waters: Connecticut,
33 Georgia, New York, South Carolina, and the U.S. Virgin Islands ([Figure 7-10](#)).

34 Currently, four states (Florida, Hawaii, North Carolina, Oregon), American Samoa and
35 Washington D.C. have numeric criteria for chlorophyll *a*, a nutrient enrichment indicator
36 in estuaries, and Virginia has chlorophyll *a* criteria for some estuaries. A summary table

7.2.11. Estuary and Near-Coastal Biogeochemistry Summary

1 In the 2008 ISA, the evidence was sufficient to infer a causal relationship between
2 reactive N deposition and biogeochemical cycling of N and C in estuarine and
3 near-coastal marine systems. Nitrogen pollution is the major cause of harm to the
4 majority of estuaries in the U.S. ([Bricker et al., 2008](#); [NRC, 2000](#)) and can lead to
5 eutrophication, the process of increasing nutrient over-enrichment leading to water
6 quality deterioration. Eutrophic systems are characterized by an increase in the rate of
7 supply of organic matter (primary production and organic carbon accumulation) in excess
8 of what an ecosystem is normally adapted to processing ([Diaz et al., 2013](#); [Nixon, 1995](#)).
9 Evidence reviewed in the 2008 ISA, along with new studies indicate elevated N inputs to
10 coastal areas can alter key processes that influence C and N cycling in near-coastal
11 environments. **The body of evidence is sufficient to infer a causal relationship**
12 **between N deposition and the alteration of biogeochemistry in estuarine and**
13 **near-coastal marine systems** which is consistent with the conclusions of the 2008 ISA.

14 As N fluxes to coastal areas have increased in recent decades in many parts of the U.S.,
15 the varying rates of different N cycling processes within estuaries themselves can also
16 affect the magnitude of eutrophication experienced as a result of external N enrichment.
17 Nitrogen additions not only cause the total pool of N to be larger, but may also perturb N
18 cycling in such a way that the system may exacerbate eutrophication to a greater extent
19 than expected based on N additions alone. Research conducted since the 2008 ISA has
20 shown that many of these N cycling processes are more important in the estuarine
21 environment than previously understood. The removal of N through denitrification is a
22 valuable ecosystem service in terms of constraining the extent and magnitude of
23 eutrophication. Additional research has established DNRA as a more important N
24 reduction pathway in some estuaries. Ammonium produced via DNRA can lead to
25 enhanced productivity and respiration, which may exacerbate hypoxia. Recent studies
26 indicate that DNRA rates are higher in warmer months and can also take up a larger
27 percentage of total N reduction activity when temperatures are higher. The roles of
28 sedimentary microbial processes of denitrification and anammox have been further
29 characterized. New research has shown that the community of N fixing microorganisms
30 is more diverse in estuarine and coastal waters than previously thought, and that N
31 fixation occurs more widely than previously assumed. Influence of benthic macrofauna
32 on N cycling has received increased research attention in part due to the potential for
33 these organisms to mitigate external N enrichment.

34 New studies and evidence reviewed in the 2008 ISA continue to show that at many U.S.
35 coastal areas, atmospheric deposition constitutes an important proportion of N inputs to
36 estuaries; ranging from <10 to approximately 70% of the N inputs ([Table 7-9](#)). As stated

1 in the 2008 ISA, estuaries tend to be N limited ([Elser et al., 2007](#); [Howarth and Marino,](#)
2 [2006](#); [NRC, 2000](#); [Nixon, 1995](#); [Vitousek and Howarth, 1991](#); [Howarth, 1988](#); [D'Elia et](#)
3 [al., 1986](#)), and many currently receive high N loads from human activities
4 (e.g., atmospheric deposition, agricultural runoff, wastewater, and other sources), which
5 can cause eutrophication ([Howarth et al., 1996a](#); [Vitousek and Howarth, 1991](#)). It is well
6 known that the development and continuation of hypoxia in estuary and marine systems
7 can be accelerated by increased nutrient loading. Monitoring efforts across the U.S.
8 ([Appendix 7.2.7](#)) continue to show that N enrichment is a widespread problem. Numeric
9 Nutrient Criteria have been established to varying degrees by coastal states in an effort to
10 manage N inputs ([Appendix 7.2.9](#)). Water quality deterioration from N inputs to estuaries
11 including development of hypoxic zones, can be linked to biological changes. Biological
12 indicators of estuarine condition (e.g., chlorophyll *a*, HABs, macroalgae, SAV) are
13 described in [Appendix 10](#).

14 Since the 2008 ISA, a number of papers have identified links between nutrient
15 enrichment and coastal acidification, and several mechanisms have been identified. One
16 of the initial studies found that CO₂ production during decomposition of organic matter
17 delivered to coastal zones from rivers experiencing eutrophication has enhanced the
18 acidification of coastal subsurface waters in the Gulf of Mexico and the East China Sea
19 ([Cai et al., 2011c](#)) and additional studies provide evidence of acidification in estuaries
20 due to this mechanism ([Laurent et al., 2017](#); [Wallace et al., 2014](#); [Cai et al., 2011c](#); [Orr et](#)
21 [al., 2005](#)). In addition to microbial degradation of organic matter, respiration of living
22 algae and seagrasses during the night can also drive acidification. ([Howarth et al., 2014](#)).
23 The CO₂ produced in eutrophic estuarine waters combines with water molecules,
24 producing carbonic acid, which makes the water more acidic ([Sunda and Cai, 2012](#); [Cai](#)
25 [et al., 2011c](#); [Howarth et al., 2011](#)). Nutrient-enhanced coastal acidification tends to
26 occur in locations where there is either thermal or saline stratification. Acidification also
27 can be enhanced indirectly through the creation of anoxic waters and oxidation of HS⁻
28 ([Cai et al., 2017b](#)). Modeling of coastal acidification via N enrichment and atmospheric
29 CO₂ dissolution suggests that the combined effects of these two pathways are synergistic.
30 **The body of evidence is sufficient to infer a likely causal relationship between N**
31 **deposition and increased nutrient-enhanced coastal acidification.**

APPENDIX 8. BIOLOGICAL EFFECTS OF FRESHWATER ACIDIFICATION

1 This appendix characterizes the biological effects of acidifying deposition of nitrogen (N)
2 and sulfur (S) in freshwater systems. Indicators of surface water chemistry are linked to
3 biological endpoints ([Appendix 8.1](#)) in freshwater systems experiencing either chronic or
4 episodic acidification ([Appendix 8.2](#)). Affected biota include plankton, invertebrates,
5 fish, and other organisms ([Appendix 8.3](#)). Next, documentation of biological recovery in
6 previously acidified systems ([Appendix 8.4](#)) is reviewed. [Appendix 8.5](#) includes levels of
7 deposition at which effects are manifested and empirical and modeled CLs for acidifying
8 deposition. A summary section with causal determinations based on a synthesis of new
9 information and previous evidence of biological effects of aquatic acidification is
10 presented in [Appendix 8.6](#). Overall, the updated research synthesized in this ISA reflects
11 incremental improvements in scientific knowledge of aquatic biological effects and
12 indicators of acidification as compared with knowledge summarized in the 2008 ISA.
13 The causal relationships between acidifying deposition and biological effects on aquatic
14 ecosystems are now, and were in 2008, well supported.

8.1. Introduction

15 In the *2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological*
16 *Criteria* (2008 ISA), the body of evidence was sufficient to infer a causal relationship
17 between acidifying deposition and changes in freshwater biota. Changes in
18 biogeochemical processes and water chemistry caused by deposition of N and S to
19 surface waters and their watersheds ([Appendix 7](#)) have been well characterized for
20 several decades and have ramifications for biological functioning of freshwater
21 ecosystems. The 2008 ISA and studies since have shown that acidification from acid
22 deposition can result in the loss of acid-sensitive organisms, population declines, and
23 decreased species richness. This evidence is consistent and coherent across multiple
24 species. More species are lost with greater acidification, providing evidence of biological
25 gradients in effects. Both earlier and more recent studies indicate that aquatic biota in
26 sensitive aquatic ecosystems have been affected by acidification at virtually all trophic
27 levels. **New information is consistent with the conclusions of the 2008 ISA that the**
28 **body of evidence is sufficient to infer a causal relationship between acidifying**
29 **deposition and changes in biota, including physiological impairment and alteration**
30 **of species richness, community composition, and biodiversity in freshwater**
31 **ecosystems.**

1 As reported in the 2008 ISA, effects of acidifying deposition on biotic integrity of
2 freshwater ecosystems can be linked to changes in several key chemical effects
3 indicators, including pH, dissolved inorganic aluminum (Al) concentration, calcium (Ca),
4 and acid neutralizing capacity (ANC). Biological effects are primarily attributable to low
5 pH and high inorganic Al concentration. The ANC, a measure of the overall buffering
6 capacity against acidification, is commonly used because it integrates overall acid status,
7 it is not affected by dissolved carbon dioxide (CO₂), and surface water acidification
8 models do a better job projecting ANC than pH and inorganic Al concentrations.
9 However, ANC does not cause harm to biota. The usefulness of ANC lies in the
10 association between it and the surface water constituents that directly cause or ameliorate
11 acidity-related stress, in particular inorganic Al, —(Ca), and H⁺ (measured as pH).

12 Chemical factors such as pH, Ca, ANC, ionic metals and dissolved organic carbon (DOC)
13 are affected by acid deposition and can profoundly affect the structure and function of
14 biological communities in lakes and streams. Inorganic Al is minimally soluble at soil or
15 surface water pH above about 6.0, but solubility increases markedly as pH values drop
16 below about 5.5. Low concentrations of base cations like Ca enable low pH and high
17 concentrations of inorganic Al to occur ([Baker et al., 1990b](#)). However, DOC can bind to
18 inorganic Al ions and reduce their bioavailability and their toxic impact on aquatic biota.
19 The base cation surplus (BCS) is an alternate index that is similar to ANC and that also
20 adjusts for the organic acid status of surface waters ([Lawrence et al., 2007](#)). BCS is based
21 on a measurement of ANC (calculated from the charge balance of ionic concentrations in
22 water) and also accounts for the influence of natural organic acidity by including the
23 strongly acidic organic acid anions in the calculation.

24 Acid-sensitive freshwater systems can either be chronically acidified or subject to
25 occasional episodes of decreased pH, decreased ANC, and increased inorganic Al
26 concentration ([Appendix 7](#)). Changes to flow and surface water chemistry, characteristic
27 of these events, reflect the influence of acidic inputs from precipitation, gases, and
28 particles, as well as local geology and soil conditions. As stated in the 2008 ISA, surface
29 water chemistry is a good indicator of the effects of acidification on the biotic integrity of
30 freshwater ecosystems because it integrates the sum of soil and water processes that
31 occur within a watershed. Surface water chemistry reflects and integrates N saturation,
32 forest decline, soil acidification, nutrient cycling, and land use ([U.S. EPA, 2003](#)).

33 Acidification studies reviewed in the 2008 ISA included laboratory experiments,
34 bioassays, mesocosm exposures, field observations, and whole ecosystem acidification or
35 deacidification studies. [Baker et al. \(1990a\)](#) conducted a rigorous review of the effects of
36 acidification on aquatic biota for the 1990 National Acid Precipitation Assessment
37 Program (NAPAP) State of Science/Technology report series. In the [Baker et al. \(1990a\)](#)

1 report, hundreds of laboratory studies, in situ bioassays, field surveys, whole-system field
2 experiments, and mesocosm studies on the effects of acidification on aquatic biota were
3 evaluated. The findings in that report, along with literature published after 1990 up to
4 December 2007, were assessed in the 2008 ISA. Measures of health, vigor, reproductive
5 success, and biodiversity of aquatic biota were identified in the 2008 ISA as being
6 affected by acidified waters caused by acidifying deposition. Effects had been most
7 clearly documented for fish, aquatic invertebrates, and algae.

8 Since publication of the 2008 ISA, the overarching understanding of aquatic acidification
9 has not changed appreciably. More recent research has confirmed and strengthened this
10 understanding and provided more quantitative information, especially across the regional
11 landscape. This appendix highlights post-2007 research findings through the spring of
12 2017.

8.2. Chronic versus Episodic Acidification

13 Traditionally acidification involves both chronic and episodic processes. As defined in
14 the 2008 ISA, chronic acidification refers to annual average conditions, which are often
15 represented as summer and fall chemistry for lakes and as spring baseflow chemistry for
16 streams. Episodic acidification refers to conditions during rainstorms or snowmelt when
17 proportionately more drainage water is routed through upper soil horizons, which tend to
18 provide less neutralization of atmospheric acidity as compared with deeper soil horizons.
19 Surface water chemistry exhibits lower pH and ANC during episodic than during
20 baseflow conditions. Chronically acidic lakes and streams maintain ANC <0 µeq/L, on
21 average, throughout the year ([Driscoll et al., 2001b](#)). They are no longer prevalent in
22 regions of the U.S. affected by acidic deposition (cf., [Fakhraei et al., 2016](#); [Fakhraei et al.,](#)
23 [2014](#)). The ANC during acidic episodic events may fall below 0 µeq/L for only a few
24 hours to weeks in a given year. It is known that the biota in many streams/lakes are
25 impacted when the ANC is consistently below 50 ueq/L. For this reason, the U.S. EPA
26 National Lakes Assessment used an ANC threshold of >50 ueq/L as indicative of
27 nonacidified water bodies ([U.S. EPA, 2009b](#)). In addition, dynamic models, such as
28 MAGIC and PnET-BGC, estimate that some lakes and streams in the Adirondack and
29 southern Appalachian Mountains had preindustrial ANC below 50 µeq/L, but few or
30 none had preindustrial ANC below 20 µeq/L.

31 A large portion of the available aquatic acidification data reported in the 2008 ISA
32 focused on lakes and streams in the Northeast and the southern-Appalachian Mountains
33 ([U.S. EPA, 2008a](#)) because these systems have been among the most impacted by
34 acidifying deposition in the past and have the best available surface water monitoring

1 information. Since completion of the literature review for the 2008 ISA, additional
2 research has been conducted on changes in chronic surface water chemistry in the U.S. in
3 response to changing levels of acidic deposition ([Appendix 7](#)). Many of these studies
4 have further documented chemical recovery as S and N deposition continue to decline in
5 most areas in the U.S. Biological recovery has been observed in some systems, but
6 available data generally indicate that it typically lags behind chemical recovery
7 ([Appendix 8.4](#)).

8 Many streams that exhibit chemical conditions during base flow that are suitable for
9 aquatic life are subject to occasional episodic acidification that may exceed the acid
10 tolerance of many aquatic species. Episodic events vary in timing, duration, and intensity.
11 Episodic acidification is most common in the early spring and late fall, and least common
12 in summer, when high flows tend to be infrequent ([Driscoll et al., 2001b](#)). This
13 seasonality of episodic events reflects to some extent the influence of deposition
14 accumulating in the landscape that is flushed to drainage water during precipitation or
15 snowmelt events. Other natural processes can also be involved, including altered
16 hydrologic flowpaths, biological uptake, and the neutral salt effect, whereby deposition of
17 a neutral salt (e.g., NaCl) can lead to ion exchange of H⁺ for Na⁺ in soil, followed by
18 drainage water acidification. Episodic processes are mostly natural, but SO₄²⁻ and NO₃⁻
19 influxes due to atmospheric deposition play important roles in the episodic acidification
20 of some surface waters. Dilution of base cation concentrations in runoff during
21 episodes—a quantitatively important component of the episodic response—may be
22 affected in part by past base cation depletion of watershed soils, due to acidification,
23 which limits the release of Ca and Mg in response to rapid runoff during storms and/or
24 snowmelt ([Wigington et al., 1996a](#); [Wigington et al., 1996b](#)).

25 As reported in the 2008 ISA, episodes are generally accompanied by changes in two or
26 more of the following chemical parameters: ANC, pH, concentrations of base cations,
27 SO₄²⁻, NO₃⁻, aluminum ions, organic acid anions, and DOC ([Sullivan, 2000](#)). During
28 short-term episodes (hours or days), both flow and water chemistry can change markedly.
29 Biological effects of episodes sometimes include fish mortalities, changes in species
30 composition, and declines in aquatic species richness across multiple taxa, ecosystems,
31 and regions. The U.S. EPA's Episodic Response Project (ERP) in the 1980s confirmed
32 the chemical and biological effects of episodic pH depressions in lakes and streams in
33 parts of the U.S. ([Wigington et al., 1993](#)). In the ERP report, streams having acidic
34 episodes showed long-term effects on fish populations compared with streams in which
35 ANC remained above 0 µeq/L. Results reported in the 2008 ISA from in situ bioassay
36 studies conducted across the eastern U.S. showed that acidic episodes (with associated
37 low pH and elevated inorganic Al concentrations and high stream-water discharge)
38 caused rapid fish mortality under some conditions ([Driscoll et al., 2001b](#); [Bulger et al.,](#)

1 [1999; Baker et al., 1996](#)). [Baker et al. \(1990a\)](#) concluded that episodes are most likely to
2 affect biota if the episode occurs in waters with pre-episode pH above 5.5 and minimum
3 pH during the episode of less than 5.0. In a later study, acid episodes reduced the size of
4 fish populations and eliminated acid-sensitive species if median high-flow pH was less
5 than 5.2 and inorganic Al concentration exceeded 100 µg/L (3.7 µM), despite the
6 relatively short duration of the episodes studied ([Baker et al., 1996](#)). Research from
7 several regions in the U.S. indicated that acidifying deposition likely has increased the
8 magnitude, frequency, and biological effects of episodic acidification events.

8.3. Aquatic Organisms Impacted by Acidifying Deposition

9 [Appendix 8.3.1](#) through [Appendix 8.3.8](#) describe effects of acidification on
10 phytoplankton, zooplankton, benthic invertebrates, fish, birds, and other biota. Changes
11 in biota are linked to chemical indicators ([Appendix 7](#)) in surface water. In the 2008 ISA,
12 biological effects were divided into two major categories: (1) effects on health, vigor, and
13 reproductive success of taxonomic groups and (2) effects on biodiversity. The first
14 category included changes at the species level of biological organization such as
15 cumulative sublethal physiological effects (individual condition factor) and recruitment
16 success. Effects on biodiversity include changes in community structure, species
17 composition, and taxonomic richness. Studies reviewed in the 2008 ISA showed that the
18 earlier aquatic lifestyles were particularly sensitive to acidification.

19 In [Appendix 8.3.1](#) through [Appendix 8.3.8](#), findings from the 2008 ISA are summarized
20 for each major taxonomic group, followed by a review of new literature including studies
21 that report physiological alterations, changes in the abundance or presence of taxa,
22 community shifts, and other biological responses associated with acidifying conditions.
23 Effects on organisms at lower trophic levels, such as plankton and invertebrates, are
24 discussed first followed by observations for fish and other vertebrates. Ecological
25 thresholds of chemical indicator(s) associated with the observed responses are included,
26 when available, from the reviewed studies. [Appendix 8.4](#) considers the evidence for
27 biological recovery of different taxa.

8.3.1. Plankton

28 Plankton, floating or drifting organisms in the water column, play an important role in
29 freshwater ecosystems. Phytoplankton, or suspended algae, are primary producers at the
30 base of the aquatic food web. These photosynthetic organisms, encompassing diatoms,
31 cyanobacteria, dinoflagellates, and other groups of algae, vary in tolerance of acidic

1 conditions. Zooplankton comprise many groups of freshwater organisms including
2 protozoans, rotifers, cladocerans, and copepods. Zooplankton feed on phytoplankton or
3 other zooplankton. Abundance and community composition of plankton respond to
4 changes in surface water chemistry associated with acidifying deposition to water bodies.

8.3.1.1. Phytoplankton

5 Studies reviewed in the 2008 ISA reported reduced species richness of phytoplankton
6 with decreases in pH and increases in inorganic Al concentrations associated with
7 acid-affected surface waters ([U.S. EPA, 2008a](#)). There was also a shift in the composition
8 of dominant taxa, but species composition shifts could not be accurately predicted. This
9 kind of effect was most prevalent in the pH 5 to 6 range ([Baker et al., 1990a](#)). It appeared
10 that the phytoplankton community restructured as the water became acidified. However,
11 the response of phytoplankton communities often vary, with some lakes showing
12 increasing biomass, others decreasing, and others having no change in phytoplankton
13 biomass ([Baker et al., 1990a](#)). [Leavitt et al. \(1999\)](#) suggested that the complex
14 interactions between pH, DOC, and light can explain the high variability in
15 phytoplankton-biomass-acidification relationships.

16 More recent studies of the responses of phytoplankton to changes in surface water acidity
17 have been limited. Effects on primary productivity are uncertain. In regards to
18 phytoplankton species composition, changes were not apparent in the lake diatom
19 communities or the diatom-inferred lake pH of sequential core segments in four
20 alpine/subalpine lakes in the Cascade Mountains of Washington and Oregon that have not
21 experienced substantial water acidification ([Eilers et al., 2016](#)). The study lakes were
22 very low in specific conductance ($\leq 3.6 \mu\text{S}/\text{cm}$) and ANC ($\leq 11 \mu\text{eq}/\text{L}$). Sediment cores
23 were collected from each lake and analyzed for nutrients and diatom microfossils in dated
24 (^{210}Pb and ^{14}C) core segments. Water chemistry was simulated using a modified
25 version of the CE-QUAL-W2 model to account for the assumed large influence of in-lake
26 chemical processes. Model projections of future chemistry suggested that the three study
27 lakes in Oregon will not change their acid-base chemistry in the future under N and S
28 deposition increases to 3 times ambient, largely due to long lake water residence times,
29 which allow in-lake processes to neutralize acid inputs. Foehn Lake in Washington was
30 much more acid-sensitive, increasing in acidity in response to projected increases in N
31 and S deposition at levels of 50% above ambient. Shallow depth, large amount of
32 exposed bedrock, and sparse sediment accumulation enhance its acid sensitivity. This
33 lake was formed less than a century ago, probably in response to climate warming and
34 melting of an adjacent snowfield.

1 [Lacoul et al. \(2011\)](#), reviewed information on the effects of acidification on plankton and
2 other organisms in Atlantic Canada and observed that the greatest changes in
3 phytoplankton species richness occurred over a pH range of 4.7 to 5.6, just beyond the
4 interval (pH 5.5 to 6.5) where bicarbonate becomes rapidly depleted in the water. Under
5 acidifying conditions, phytoplankton communities shifted from dominance by
6 chrysophytes, other flagellates, and diatoms to dominance by larger dinoflagellates.
7 However, biomass and productivity were not much affected. Algal biomass in five
8 Pennsylvania streams decreased with the severity of episodic acidification ([Macdougall et
9 al., 2008](#)). Although no significant trends were observed for taxon richness or diversity,
10 the degree of acidification during episodes appeared to affect the quantity of algae in the
11 streams. [Bloch and Weyhenmeyer \(2012\)](#) evaluated physical and chemical time-series
12 data for 13 nutrient-poor Swedish lakes across a latitudinal gradient. Phytoplankton
13 biomass and species richness showed only weak relations with water chemistry. The only
14 significant association observed across seven of the surveyed lakes was the number of
15 chlorophyte taxa and changes in water temperature and color.

16 As stated in the 2008 ISA, diatoms, which comprise an important component of the
17 phytoplankton, are excellent biological indicators of environmental change in aquatic
18 ecosystems, being sensitive to changes in acidity, nutrient status, salinity, and climate
19 ([Stoermer and Smol, 1999](#); [Sullivan and Charles, 1994](#)). Since the 2008 ISA, studies have
20 further linked phytoplankton community shifts to acidification using paleolimnological
21 analysis of fossil diatoms or long-term sampling of phytoplankton from the water
22 column. Most of these studies have documented phytoplankton recovery in historically
23 acidified lakes ([Appendix 8.4.1](#)). Stratigraphy of sediment chrysophyte remains in
24 Brooktrout Lake in the Adirondack Mountains, NY revealed shifts in *Mallomonas* spp.
25 and *Synura* spp., with some species declining and others increasing. After the 1950s,
26 *Fragilariforma acidobiontica*, a diatom that is often abundant at pH <5.0, was present in
27 lake sediments. These observations in Brooktrout Lake correspond to historical
28 acidification, which was most severe during the 1970s and 1980s ([Sutherland et al.,
29 2015](#)). Phytoplankton have also been used as indicators of acidification and recovery in
30 Canada and Europe. In a recent analysis of diatom fossils from 10 lakes located about
31 80–250 km east and northeast of the oil sands development near Fort McMurray and Fort
32 Mackay, northwestern Saskatchewan, [Laird et al. \(2013\)](#) observed increases in scaled
33 chrysophytes and diatom flux rates in post-1980 sediments potentially related to
34 atmospheric deposition in the oil sands region. A slight decrease (0.25 pH unit) in
35 diatom-inferred pH occurred in one study site closest to the oil sands development, but
36 there was no evidence of widespread acidification. Over time, phytoplankton
37 assemblages in Swedish lakes recovering from acidification have become more similar to
38 those in reference lakes ([Johnson and Angeler, 2010](#)).

8.3.1.2. Zooplankton

1 In studies reviewed in the 2008 ISA, decreases in ANC and pH and increases in inorganic
2 Al concentration were shown to contribute to the loss of zooplankton species or
3 decreased abundance in lakes ([Keller and Gunn, 1995](#); [Schindler et al., 1985](#)). A decrease
4 in pH from 6 to 5 reduced species richness in lake zooplankton communities ([Holt et al.,
5 2003](#); [Holt and Yan, 2003](#); [Locke and Sprules, 1994](#)). [Sullivan et al. \(2006a\)](#) found that
6 zooplankton communities varied with ANC in Adirondack lakes, with lower taxonomic
7 richness (number of species of crustaceans, rotifers, and total zooplankton) in lakes
8 having lower ANC. In general, lake-water ANC explained nearly half of the variation in
9 total zooplankton and crustacean taxonomic richness, but less for rotifer richness.
10 Particularly low zooplankton community richness occurred when ANC levels were below
11 0 µeq/L (15 species in highly acidic lakes compared to 35 at the highest values of ANC in
12 the study [near 200 µeq/L]). Observations from in situ enclosure acidification studies at
13 Emerald Lake in the Sierra Nevada showed shifts in zooplankton community with
14 decreased pH ([Barmuta et al., 1990](#)). *Daphnia rosea* and *Diaptomus signicauda* were
15 eliminated below pH 5.0 while other species such as *Bosmina longirostris* and *Keratella
16 taurocephala* became more abundant. Possible mechanisms for zooplankton sensitivity to
17 low pH and ANC include ion regulation failure, reduced oxygen uptake, inability to
18 reproduce, and Al toxicity ([U.S. EPA, 2008a](#)).

19 A number of studies have been conducted since the 2008 ISA to determine the response
20 of zooplankton to lake acidification. Highlighted here are several studies conducted in the
21 U.S. and Canada. Many of these studies indicate that multiple factors could influence
22 zooplankton community changes. *Bosmina* is among the most common North American
23 temperate lake pelagic invertebrate genera. It is a genus of cladoceran filter feeders that
24 can change body size and appendage length over multiple generations in response to
25 changing environmental conditions. This makes it a good candidate ecological indicator.
26 [Labaj et al. \(2016\)](#) evaluated *Bosmina* size responses in lakes near Sudbury, Ontario,
27 Canada, that had been acidified and then chemically recovered in response to changes in
28 nearby metal smelter emissions. Even with the recent return to presmelter lake pH, the
29 *Bosmina* size structure has not yet recovered to preacidification conditions. [Labaj et al.
30 \(2016\)](#) suggested that the observed effects of acidification and deacidification on the size
31 of *Bosmina* may have been mediated by food web dominance of small copepod predators.
32 [Vinebrooke et al. \(2009\)](#) reported variations in zooplankton communities during a
33 whole-lake experimental acidification of Lake 302S in the Experimental Lakes area in
34 Ontario, Canada. There was a negative effect on zooplankton species richness as pH
35 decreased from 6.8 to 4.5. However, no correlation was found between functional
36 properties (productivity or net total biomass) and species richness with this pH change,
37 indicating that other factors such as multiple stressor interactions, species occurrences,

1 and altered trophic interactions might also influence zooplankton community change. In
2 northwestern boreal shield lakes downwind of N emissions from the Athabasca oil sands
3 extraction in Saskatchewan, Canada, zooplankton community structure was influenced by
4 local environmental factors, including acidity, predation, and lake productivity. The role
5 of regional atmospheric deposition on zooplankton community composition could not be
6 distinguished from natural variability due to a lack of baseline data prior to oil extraction
7 operations ([Anas et al., 2014](#)). Thus, the role of acidic deposition in driving changes in
8 zooplankton community composition in that region was not clear.

9 Acidification often reduces Ca availability in lake water, which may impact invertebrates
10 that require Ca for growth such as *Daphnia* spp. and crayfish ([Appendix 8.4.3](#)). [Jeziorski](#)
11 [et al. \(2012b\)](#) examined the growth and survival of daphnid species across a Ca gradient
12 (from 50 to 150 µeq/L) in central Ontario soft-water lakes. Considerable variability in
13 growth and survival was observed within the *Daphnia pulex* species complex, and the
14 variation across all cladoceran genera was best explained by pH and lake depth. This
15 research adds support to the previous observation that among the cladocerans, daphnids
16 are especially sensitive to decreases in Ca which leads to declines in their growth and
17 survival as lake water acidifies with inputs of acidifying deposition.

8.3.2. Periphyton

18 Periphyton mats are biofilms of algae, cyanobacteria, fungi, microinvertebrates, organic
19 detritus, inorganic particles, and heterotrophic microbes imbedded within a matrix and
20 attached to submerged substrates in aquatic systems (e.g., stream or lake bottoms or
21 submerged vegetation). Periphyton is an important food source for invertebrates,
22 tadpoles, and some fish. As reported in the 2008 ISA, acidification impacts periphyton
23 species differently, with some excluded from impacted water bodies while others become
24 dominant. Such changes decrease species richness and alter community structure ([U.S.](#)
25 [EPA, 2008a](#)). For example, many of the brown algae and cyanobacterial periphyton
26 species cannot tolerate acidic conditions, causing their abundance to decline along with
27 pH, while green algae, particularly the filamentous Zygnemataceae, increase in relative
28 abundance at lower pH ([Baker et al., 1990a](#)). There is evidence that the biomass of
29 attached periphyton increases at lower pH. No new studies of acidifying effects on
30 periphyton were identified for this review.

8.3.3. Benthic Invertebrates

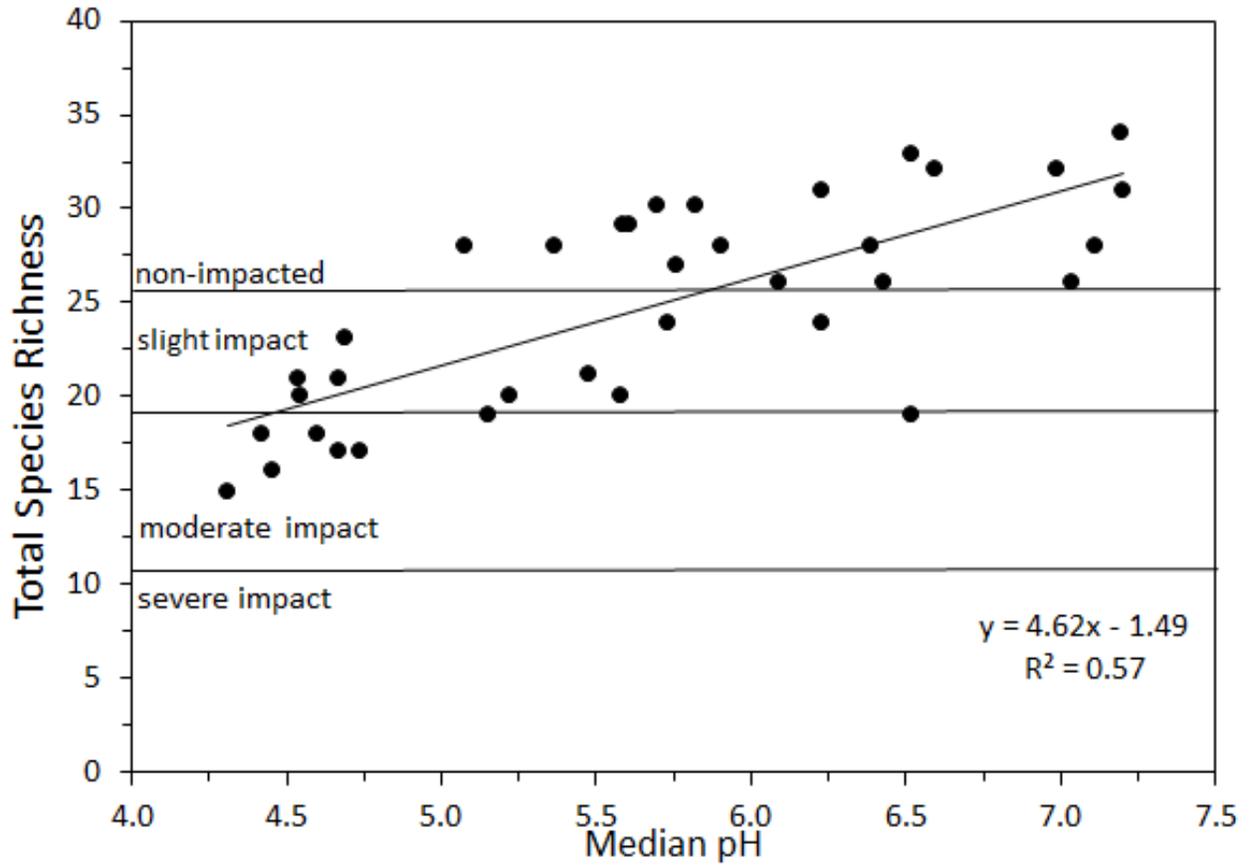

1 Benthic invertebrates live in freshwater sediments and include groups such as bivalves,
2 worms, gastropods and insect larvae. As reviewed in the 2008 ISA, acidification as
3 measured by decreases in ANC and pH and increases in inorganic Al concentration has
4 been shown to contribute to the loss or decline in abundance of benthic invertebrate
5 species in streams. The Ephemeroptera (mayflies)-Plecoptera (stoneflies)-Tricoptera
6 (caddisflies) (EPT) Index is a common measure of stream macroinvertebrate community
7 integrity. The EPT metric is calculated as the total number of families present in those
8 three insect orders. Mayflies tend to be the most sensitive of the three, and stoneflies tend
9 to be the least sensitive ([Peterson and Van Eeckhaute, 1992](#)). The mayfly order alone is
10 often selected for study because it includes a number of genera and species having
11 varying degrees of sensitivity to acidification, including some that are highly sensitive
12 ([Sullivan et al., 2003](#)). Typically, pH values below 5 result in the virtual elimination of all
13 mayflies along with some other aquatic organisms from some streams ([U.S. EPA, 2008a](#);
14 [Baker and Christensen, 1991](#)). These benthic invertebrates are impacted by acidification
15 because H⁺ and inorganic Al can be directly toxic, causing disruption of their ion
16 regulation and reproductive success. U.S. EPA first published freshwater criteria for Al in
17 1988 and is in the process of updating the Aquatic Life Criteria. The current 1988 acute
18 and chronic criteria are 750 and 87 µg/L, respectively, not to be exceeded once every 3 years
19 on average ([U.S. EPA, 1988](#)).

20 Work since the 2008 ISA by [Baldigo et al. \(2009\)](#) assessed effects of acidification on
21 benthic macroinvertebrate community dynamics in the southwestern Adirondack
22 Mountains. Water chemistry and benthic macroinvertebrates were surveyed in 36 streams
23 with different levels of acidity to characterize community response and identify
24 thresholds for biological effects ([Figure 8-1](#)). In the study streams, macroinvertebrate
25 assemblages were severely impacted at pH <5.1, moderately impacted at pH from 5.1 to
26 5.7, slightly impacted at pH from 5.7 to 6.4 and usually unaffected above pH 6.4.
27 Inorganic Al concentrations reached potentially toxic levels in two-thirds of the study
28 streams. The authors applied the Acid Biological Assessment Profile [acidBAP] index,
29 which is based on percentage mayfly richness and percentage acid-tolerant
30 macroinvertebrate taxa ([Burns et al., 2008b](#)). The acidBAP was strongly correlated with
31 pH, ANC, BCS, and the concentration of inorganic Al, indicating the loss of mayflies in
32 the stream as the surface waters pH declines from pH 7.0 to 4.2. A loss of about
33 12 species occurred in streams that had a pH between 7 and 4.2. Regression across all
34 36 streams showed a loss of 4.6 species per unit pH decrease ([Figure 8-1](#)). Inorganic Al
35 toxicity was likely the main cause of the loss of macroinvertebrates. The Al concentration
36 is strongly correlated with surface water pH (as pH decreases solubility of inorganic Al
37 increases) and acid-base balanced as measured by BCS.

1 Several pH thresholds for aquatic invertebrate response have been published since the
2 2008 ISA ([Table 8-1](#)). [Lacoul et al. \(2011\)](#) reviewed available information on the effects
3 of water acidification on aquatic organisms in Atlantic Canada. The median pH for
4 sensitive invertebrate species occurrence was between 5.2 and 6.1, below which species
5 tended to be absent. For example, several species of mayfly and most gastropods are
6 intolerant of acidity and only occur at pH ≥ 5.5 and ≥ 6 , respectively.

7 The make-up of the stream invertebrate community is governed in part by the condition
8 of riparian vegetation and associated humic acid levels in surface water. [O'Toole et al.](#)
9 [\(2017\)](#) investigated riparian vegetation condition under high and low humic acid
10 influence as affected by riparian vegetation. Both perennial and intermittent streams in
11 western Australia were evaluated. Streams having well-developed riparian vegetation
12 showed proportionately more algal grazers and detritivores. Intermittent streams with
13 high humic content had lower numbers of cladocerans and chironomids and higher
14 numbers of grazing gastropods as compared with intermittent streams that had relatively
15 low humic content.

16 Several European studies published since the 2008 ISA have evaluated the use of benthic
17 invertebrates as biological metrics to classify the ecological status of water bodies. These
18 studies have developed or applied indices to predict dose-response relationships between
19 macroinvertebrate communities and water chemistry. One study by [Schartau et al. \(2008\)](#)
20 applied existing macroinvertebrate metrics developed for river acidification to lakes and
21 also developed and tested new species-based indicators of lake acidification based on
22 668 samples of littoral macroinvertebrates taken from 427 lakes across Sweden, the U.K.,
23 and Norway. Although there was high variation in the data, a response threshold between
24 pH 5.8 and 6.5 was identified for littoral macroinvertebrate communities, suggesting they
25 could be used to assess ecological quality of lakes.

Source: Modified from [Baldigo et al. \(2009\)](#).

Figure 8-1 Total macroinvertebrate species (community) richness as a function of median pH in 36 streams sampled in the western Adirondack Mountains of New York, 2003–2005; the four standard (New York State) impact categories for species richness are defined.

Table 8-1 Thresholds of biological response to changes in water acidity for benthic invertebrates published since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria.

Life Forms	Region	Potential Thresholds	Reference
Sensitive invertebrates present	Atlantic Canada	pH 5.2 to 6.1	Lacoul et al. (2011)
Littoral macroinvertebrates	Northern Europe	pH 5.8 to 6.5	Schartau et al. (2008)
Stream macroinvertebrates	Southwestern Adirondacks Mountains	pH 5.1 to 5.7	Baldigo et al. (2009)
Stream macroinvertebrates	Sweden	pH 5.7 to 6.0	Andrén and Wiklund (2013)

1 Using macroinvertebrate monitoring data (1,462 samples) from Northern Europe [Moe et](#)
2 [al. \(2010\)](#) tested new and existing acidification metrics with the aim of selecting a
3 common metric to assess pH effects on biota in this region. Most investigated metrics
4 responded to pH, with most of the variance explained by a few variables, including the
5 number of Ephemeroptera families and the proportion of sensitive Ephemeroptera. Most
6 biological metrics were higher (less impacted) in humic than in clear waters, suggesting
7 smaller acidification effects in humic waters. [Murphy et al. \(2013\)](#) described an approach
8 for developing diagnostic indices for assessing acidity in British streams that could be
9 useful in the U.S. Variation in macroinvertebrate assemblages in 76 test sites was
10 quantified with a 197-site calibration set. The Acid Water Indicator Community Index
11 expressed at the species level was related to base-flow pH and to storm-flow pH and
12 ANC, accounting for 38 to 56% of the variation in acid condition.

13 Interactions among Al, pH, and organic matter, and their collective influence on toxicity
14 to aquatic biota, are discussed in [Appendix 8.3.6](#). In general, decrease in pH brings larger
15 amounts of Al into solution whereas when dissolved organic matter is also present, it
16 binds with Al, converting it into organo-Al complexes, decreasing its toxicity. In six
17 humic (mean total organic carbon [TOC] 10–18 mg/L) streams in central Sweden,
18 [Andrén and Wiklund \(2013\)](#) evaluated acute and sublethal toxicity of macroinvertebrate
19 salmonid prey items exposed to episodes of acidity during spring snowmelt. The
20 threshold for mortality was pH <5.7 and inorganic Al >20 µg/L (0.7 µM) for mayflies
21 (*Baetis rhodani*) and pH <6.0 and inorganic Al >15 µg/L (0.6 µM) for the freshwater
22 amphipod *Gammarus pulex*. [Traister et al. \(2013\)](#) investigated shifts in macroinvertebrate
23 communities and food webs in nine small forested streams in the Czech Republic across a

1 pH gradient from 4.0 to 7.7. Acidification was related to reduced taxon richness and
2 reduced Ephemeroptera family richness and lower population densities.

8.3.4. Bacteria, Macrophytes, and Bryophytes

3 At the time of the 2008 ISA, most observations of biological effects of acidification were
4 for phytoplankton ([Appendix 8.3.1.1](#)), benthic invertebrates ([Appendix 8.3.3](#)), and fish
5 ([Appendix 8.3.6](#)), and relatively little information was available regarding the response of
6 other biological taxa to surface water acidification. This has not changed appreciably. A
7 few studies have been conducted on bacteria, macrophytes (aquatic plants), and
8 bryophytes, as described below.

9 [Percent et al. \(2008\)](#) assessed bacterioplankton community diversity and structure in
10 18 Adirondack lakes across a range of acid-base chemistry using sequencing and
11 amplified ribosomal DNA restriction analysis of constructed rRNA gene libraries. Based
12 on principal components analysis, pH was positively correlated with bacterioplankton
13 community richness and diversity. The richness of several bacterial classes, including
14 Alphaproteobacteria, was directly correlated with pH. However, other environmental
15 factors, such as lake depth, hydraulic retention time, dissolved inorganic C, and nonlabile
16 (organically bound) monomeric Al, were also important in explaining bacterioplankton
17 community richness and diversity, suggesting that acidity is only one factor that controls
18 community composition.

19 Macrophyte studies provide additional information on the biological responses to acidic
20 conditions in lakes. For example, a pH threshold for the absence of sensitive macrophytes
21 was determined to be 5.5 in Atlantic Canada lakes by [Lacoul et al. \(2011\)](#). In an analysis
22 of factors affecting the distribution of aquatic macrophytes in lakes in the Pyrenees
23 Mountains of southern Europe, [Pulido et al. \(2015\)](#) constructed statistical models to
24 predict optimum ranges and ecological niches of 11 aquatic macrophyte species.
25 Macrophytes were most suited to lakes with low water concentrations of NO_3^- and SO_4^{2-}
26 in vegetated watersheds at low elevation. It was possible to delineate individual species
27 ranges along gradients of specific conductance and water pH.

28 Bryophytes, most notably mosses and liverworts, are nonvascular plants that often
29 constitute an important component of the biodiversity and productivity of low-order
30 streams. [Tessler et al. \(2014\)](#) assessed bryophyte assemblages in southeastern New York
31 streams and found that some species like *Hygrohypnum egyptium* and *Codriophorus*
32 *aduncooides* were generalists and able to tolerate pH in the range from approximately 4 to
33 7, whereas others were more strongly limited by pH. For example, *H. ochraceum*
34 occurred only at circumneutral pH near 6.5, while *Andreaea rothii* was restricted to pH

1 <5. Stream pH and amount of bedrock substrate were identified in this study as the
2 primary determinates of byrophyte assemblage composition.

8.3.5. Amphibians

3 Amphibians such as frogs, newts, toads, and salamanders have aquatic lifestages and may
4 be in contact with acidified waters in areas affected by acidifying deposition. Although
5 some species of amphibian are on the decline, in the 2008 ISA, there was no evidence to
6 suggest that acidic deposition was an important factor that impacts the health and
7 abundance of amphibian communities ([U.S. EPA, 2008a](#)). Nevertheless, there are both
8 relatively acid-sensitive and acid-tolerant amphibians. Examples of acid-sensitive
9 amphibians in [Baker et al. \(1990a\)](#) include the spotted salamander (*Ambystoma*
10 *maculatum*) and Jefferson salamander (*Ambystoma jeffersonianum*). Jefferson
11 salamanders were absent from ponds with very low pH (<4.5; [Freda and Dunson, 1986](#)).
12 Based on transplant studies into ponds or to the laboratory, embryos of this species did
13 not hatch in water with pH less than about 4.5. Acid-tolerant embryos such as the Pine
14 Barrens treefrog (*Hyla andersonii*) may hatch at a pH of 3.7 ([Freda and Dunson, 1986](#)).
15 Toxicity is not solely a matter of pH, but is also influenced by Ca²⁺, inorganic Al, and
16 DOC concentrations, lifestage, and water temperature ([Baker et al., 1990a](#)). Large-scale
17 amphibian extinctions due to acidifying deposition had not been detected in any
18 geographic region at the time of the 2008 ISA ([Baker et al., 1990a](#)) and have not been
19 documented in more recent years.

20 Studies published since the 2008 ISA further indicate that amphibian species are
21 relatively tolerant of acidifying conditions. In a review of toxicity data for amphibian
22 species found in Atlantic Canada, [Lacoul et al. \(2011\)](#) concluded that some amphibians
23 can survive at pH as low as 3.5 to 4.0. [Chambers et al. \(2013\)](#) explored the relationship
24 between pH and hormonal response in salamanders. In their field studies with Jefferson
25 salamander larvae from eight natural breeding populations and a mesocosm experiment
26 with varying pH, they observed an increase in baseline corticosterone concentration with
27 lower pH (in the range of 5 to 5.8). Elevation of baseline corticosterone level is a
28 physiological alteration associated with stress response. In contrast, no significant
29 relationship was observed between corticosterone and pH in adult Allegheny Mountain
30 dusky salamanders (*Desmognathus ochrophaeus*) living in nine streams in the Central
31 Appalachian ecoregion with differing pH ([Woodley et al., 2014](#)). Three-week laboratory
32 exposures with the same species showed that low pH (3.5) decreased locomotory activity
33 but had no effect on plasma corticosterone levels. A change of average pH from pH 7 to
34 pH 6 resulted in a shift in the skin microbial community composition on larval American
35 bullfrogs (*Rana catesbeiana*) ([Krynak et al., 2015](#)). Following metamorphosis, shifts in

1 pH did not alter skin microbial community structure significantly in juvenile frogs.
2 However, antimicrobial peptide production was affected by interactions between pH and
3 degree of shading, suggesting that environmental variability may influence amphibian
4 susceptibility to fungal pathogens.

8.3.6. Fish

5 Physiological and population-level responses associated with exposure of fish to acidified
6 waters have been well characterized for many decades. As summarized in the NAPAP
7 report by [Baker et al. \(1990a\)](#) and studies reviewed in the 2008 ISA, fish populations in
8 acidified streams and lakes of Europe and North America have declined, and some have
9 been eliminated due to atmospheric deposition of acids and the resulting decrease in pH
10 and ANC and increase in inorganic Al concentrations in surface waters. By 1990, it was
11 well established that freshwater acidification could cause significant adverse biological
12 effects on fish, although the effects were not uniform across species. Summary
13 information from the 2008 ISA for pH, ANC, and Al and effects on fish are presented in
14 [Appendix 8.3.6.1](#) to [Appendix 8.3.6.5](#) along with results of new studies. In general,
15 understanding of the effects of acidification on fish has not changed since the 2008 ISA.
16 Effects of acidification on fish and other organisms must be viewed in the context of
17 other stressors and management actions, in particular climate change and the effects of
18 fish stocking.

19 Responses among fish species and lifestages within species to changes in pH and Al in
20 surface waters are variable. In general, early lifestages such as larvae and smolts are more
21 sensitive to acidic conditions than the young-of-the-year, yearlings, and adults ([Baker et](#)
22 [al., 1990a](#); [Johnson et al., 1987](#); [Baker and Schofield, 1985](#)). Some of the most commonly
23 studied species have been brown trout (*Salmo trutta*), brook trout (*Salvelinus fontinalis*),
24 and Atlantic salmon (*Salmo salar*). Among these three species, [Gjedrem and Rosseland](#)
25 [\(2012\)](#) recently showed substantial additive genetic variation in tolerance to acidic water,
26 with heritabilities (h^2) ranging from 0.09 to 0.27 for dead-eyed eggs (a development
27 period that is highly sensitive to low pH [4.7 to 5.2]).

28 Several new studies of Atlantic salmon provide additional information documenting the
29 sensitivity of this species to acidification during different lifestages. Evidence suggests
30 that acidification has been an important stressor that has limited the distribution and
31 abundance of Atlantic salmon in the northeastern U.S. Atlantic salmon are anadromous
32 and they are susceptible to physiological effects of acidification as they develop and
33 move to different habitats. The salmon start their life cycle in freshwater then migrate to
34 the ocean, returning to freshwater to spawn. In rivers, eggs hatch into fry, which develop

1 into parr. Before migrating to the ocean, parr start developing into smolt, which are more
2 sensitive to acidification than the parr lifestage ([Kroglund et al., 2008](#); [Monette and](#)
3 [McCormick, 2008](#)). Recent research has shown that exposure to concentrations of
4 inorganic Al that have no apparent effects in freshwater may subsequently affect smolt
5 survival in seawater. Thus, the timing of acidification episodes in relation to fish lifestage
6 and migration from freshwater to seawater may impact fish survival due to the delayed
7 response to inorganic Al exposure ([Kroglund et al., 2008](#); [Kroglund et al., 2007](#)).

8.3.6.1. Physiological Responses to Acidification

8 The modes of action of biological impacts on fish from surface water acidification were
9 reasonably well known at the time of the 2008 ISA. Physiological disturbances to fish
10 exposed to acidic waters reported in the 2008 ISA included iono- and osmoregulatory
11 failure, acid-base regulatory failure, and respiratory and circulatory failure. These
12 impacts can often be directly attributed to effects on gill function or structure. Al has
13 been shown to accumulate on the gill surface when fish are exposed to water having high
14 inorganic Al concentration. The primary mechanism for the toxic effects of low pH and
15 elevated inorganic Al on fish involves disruption of normal ion regulation at the gill
16 surface, resulting in increased rates of ion loss and inhibition of ion uptake ([Bergman et](#)
17 [al., 1988](#); [Wood and McDonald, 1987](#); [Leivestad, 1982](#); [McWilliams and Potts, 1978](#)).
18 The disruption of salt and water balance causes red blood cells to rupture and blood
19 viscosity to increase ([Driscoll et al., 2003b](#)). Additional effects might include disruption
20 of Ca metabolism ([Reader et al., 1988](#); [Gunn and Noakes, 1987](#); [Peterson and Martin-](#)
21 [Robichaud, 1986](#)) and loss of Ca from important binding sites in the gill epithelium,
22 which reduces the ability of the gill to control membrane permeability ([Exley and](#)
23 [Phillips, 1988](#); [Havas, 1986](#); [Mcdonald, 1983](#)).

24 Newly available literature since the last review supports previous findings of effects of
25 acidification on fish physiology. Several in situ studies on brook trout in the southeastern
26 U.S. and New England provide additional information on sensitivity of different fish
27 lifestages to episodic acidification. Changes in native brook trout physiology were
28 determined during two acid runoff episodes in the Great Smoky Mountains National Park
29 by [Neff et al. \(2008\)](#). Results of an in situ bioassay of whole-body sodium concentrations
30 before and after acidification showed that stream acidification negatively impacted native
31 trout physiology. Loss of whole-body sodium when stream pH dropped below 5.1
32 indicated that trout lost the ability to ionoregulate. Stream water ANC and pH decreased
33 episodically during the stormflow events studied. An ANC contribution analysis
34 indicated that acidic deposition may have been the major cause of episodic stream
35 acidification; increased concentrations of organic acid anions and base cation dilution

1 during episodes also appeared to be important. Subsequently, [Neff et al. \(2009\)](#)
2 investigated the effects of hydrologic episodes on loss of blood plasma Na^+ in native
3 southern brook trout, a response associated with physiological stress from acid exposure.
4 In situ bioassays were conducted at three sites during a 2-year period. Whole-body Na^+
5 concentrations decreased by 10 to 20% following acidic episodes during which 24-hour
6 mean pH values of 4.88, 5.09, and 4.87 and total dissolved Al concentration of 210, 202,
7 and 202 $\mu\text{g/L}$ (7.8, 7.5, and 7.5 μM) were observed.

8 In a combination lab and field study designed to establish whether the smolt or parr
9 lifestage is more sensitive to short-term acid/Al pulses, [Monette and McCormick \(2008\)](#)
10 observed that compared with control fish, smolts exposed to elevated acid/Al levels
11 showed greater losses of blood plasma Cl^- (9–14 mM) after 2 and 6 days and increases in
12 plasma cortisol (4.3-fold) and glucose (2.9-fold) levels after 6 days of exposure, while
13 parr were not affected. Gill Na^+/K^+ -ATPase (NKA) activity was not affected in either
14 lifestage. Smolts were shown to be more sensitive than parr to short-term acid/Al
15 exposure although gill accumulation of Al was observed in both lifestages.

16 [McCormick et al. \(2009\)](#) determined the effects of pH and Al on survival, development
17 of smolts, ion regulation, and stress levels of Atlantic salmon in southern Vermont. Two
18 6-day field studies during the peak of smolt development (late April and early May) were
19 conducted in five streams having different acid-base chemistry. The researchers found
20 increased mortality, loss of blood plasma chloride (Cl^-), altered NKA activity in the gills,
21 and higher gill Al in fish that were caged in streams that experienced low pH (5.4–5.6)
22 and high inorganic Al concentration (50–80 $\mu\text{g/L}$ [1.9–3 μM]). Fish confined at sites that
23 were less impacted by acidification showed more moderate decrease in blood plasma Cl^-
24 and more moderate increase in plasma cortisol, glucose, and gill Al.

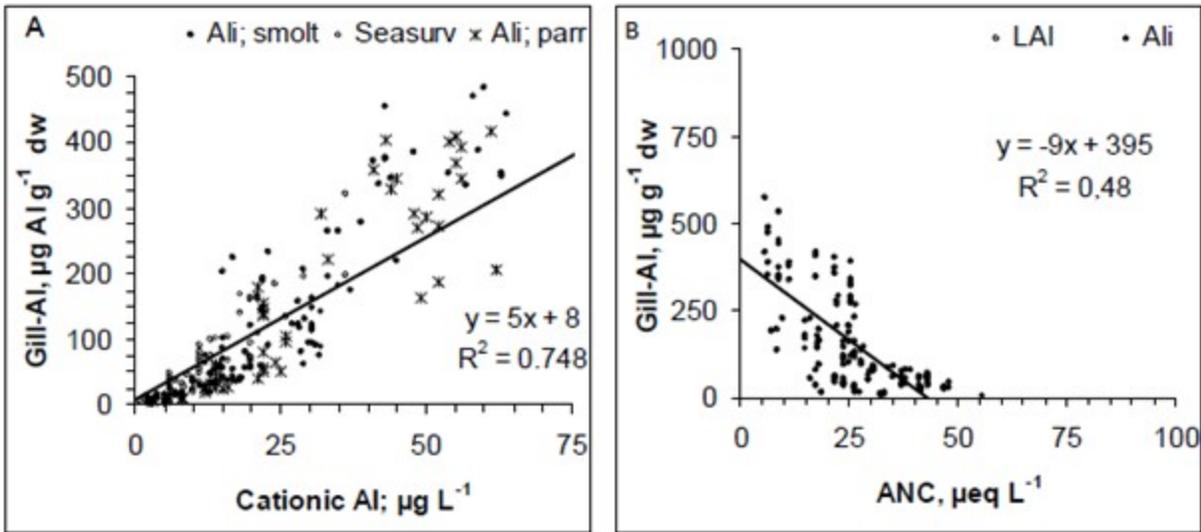

25 Individual Atlantic salmon physiological responses were strongly inter-correlated, with a
26 single principal component axis (PC1) that comprised cortisol, glucose, Cl^- , and NKA
27 accounting for 90% of the total variation in the physiological response variables data set
28 ([McCormick et al., 2009](#)). The authors suggested that physiological impairment was the
29 most appropriate interpretation of PC1. In a stepwise linear regression model using water
30 chemistry variables only, PC1 scores were best explained by low pH ($r^2 = 0.53$). Gill Al
31 also was a strong predictor of physiological impairment.

32 Recent studies on salmon examined Al toxicity following transfer to seawater to simulate
33 the physiological changes associated with migration to the marine environment. In an
34 exposure to high acidity and inorganic Al followed by 24-hour seawater exposure, blood
35 plasma Cl^- levels were higher in exposed fish than in controls, suggesting reduced
36 seawater tolerance ([Monette et al., 2008](#)). Loss of seawater tolerance was accompanied
37 by lower levels of gill NKA activity. Exposure to acidity and inorganic Al also caused

1 decreased plasma insulin-like growth factor (IGF-I) and levels of 3,3',5'-triiodo-L-
2 thyronine (T-3). Results of this research suggest that smolt development and seawater
3 tolerance can be affected by exposure to high acidity and inorganic Al despite an absence
4 of detectable impacts on blood plasma ion regulation in freshwater. In 2- and 5-day
5 Al/acid exposures of Atlantic salmon followed by a seawater challenge test, [Monette et](#)
6 [al. \(2010\)](#) showed that seawater tolerance of smolt is reduced by prior acute exposure to
7 acidic conditions and low levels of Al, and that the mechanisms of blood ion regulation
8 depend on the extent and duration of Al exposure. In both seawater and freshwater,
9 exposure to pH 5.3 and moderate Al levels led to accumulation of gill Al, alterations in
10 gill morphology, reduced gill NKA activity, and impaired ion regulation. In contrast, gill
11 Al accumulation was decreased, with only slight effects on gill morphology in smolts
12 exposed to acidic conditions and the lowest level of Al concentration.

13 Sockeye salmon (*Oncorhynchus nerka*) fry were raised in freshwater for 126 days under
14 sublethal conditions of low to moderate pH (4.8–6.8) by [Kennedy and Picard \(2012\)](#).
15 Effects on growth, stress, and seawater tolerance were determined after smoltification. At
16 the lower pH treatment (5.0), fish gained significantly less mass (average 46% of control
17 [pH 6.8] values), exhibited lower condition factor, and showed lower liver somatic index
18 values than control fish. The concentrations of liver glycogen (49% of control values) and
19 whole-body lipids (65% of control values) were also significantly lower. Acid exposure
20 caused increased stress, as measured by increased concentrations of blood plasma
21 cortisol. Fish exposed to pH 5.0 in freshwater for 30 days, and then challenged with
22 seawater, exhibited 14% higher mortality, on average, compared to control fish. They
23 also showed osmoregulatory stress (increased blood plasma Na⁺ and Cl⁻ concentrations)
24 and lower critical swimming speed (22% reductions compared to control fish). Results
25 suggested that sockeye salmon are acid sensitive and do not acclimate to low pH under
26 chronic exposure conditions. This sensitivity could decrease the probability of fish
27 surviving after moving to the marine environment.

28 In a synthesis of results of bioassay studies on Atlantic salmon in Norway, gill Al
29 concentration was significantly correlated with water inorganic Al and ANC [[Figure 8-2](#);
30 [\(Kroglund et al., 2008\)](#)]. They also analyzed results of seawater challenge tests showing
31 that the fish had impaired hyporegulatory capacity due to inorganic Al exposure in
32 freshwater.

Al = aluminum; Al_i = inorganic monomeric aluminum; ANC = acid neutralizing capacity; dw = dry weight; g = gram; L = liter; Lal = labile aluminum; µg = microgram; seasurv = seawater survival.

Notes: Linear relationships are entered into the graphs whenever significant.

Source: [Kroglund et al. \(2008\)](#).

Figure 8-2 Relationship between (a) inorganic monomeric aluminum and gill aluminum for parr and smolt, and (b) acid neutralizing capacity and gill aluminum.

1 To assess the ability of Atlantic salmon smolts to recover from acid/Al exposure, [Nilsen](#)
 2 [et al. \(2013\)](#) subjected salmon for 2- and 7-day periods to low pH (5.7) and inorganic Al
 3 (40 µg/L [1.5 µM]). Fish were subsequently transferred to good quality water (control
 4 exposure; pH 6.8; inorganic Al <14 µg/L [0.52 µM]). Accumulations of Al on fish gills
 5 measured after 2 and 7 days of acid/Al exposure were 35.3 ± 14.1 and 26.6 ± 11.8 µg/g
 6 (dry weight), respectively. High gill Al decreased 2 days after moving exposed fish to
 7 control water, but gill Al was still higher than under sustained control conditions
 8 (5–10 µg/L [0.18–0.37 µM] inorganic Al) over the following 2-week period. Decreases
 9 in blood plasma Na⁺ levels were observed in both test groups and remained significantly
 10 lower than in control fish for the 2-week period after transferring fish to control water.
 11 Blood plasma Cl⁻ levels in smolts exposed for 7 days were significantly lower than in
 12 control smolts and then remained low in both treatments following transfer to control
 13 water. Treated smolts maintained high blood plasma glucose levels, indicative of
 14 increased stress, after being transferred to control water and for more than a week
 15 following exposure.

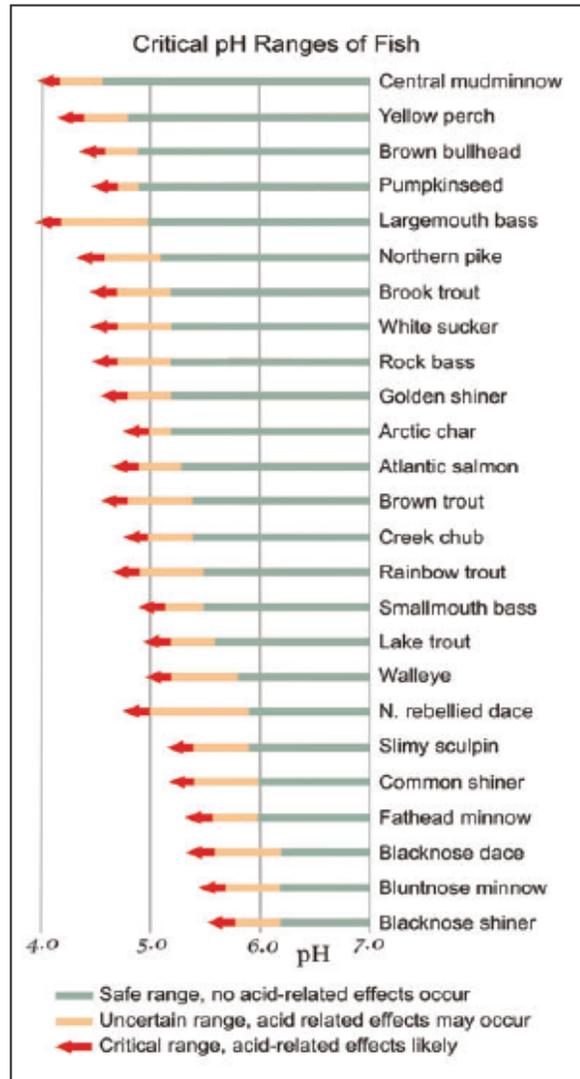

1 Responses of Atlantic salmon smolts to episodic pH fluctuations were assessed during
2 in situ experiments in rivers and streams in eastern Maine ([Liebich et al., 2011](#)). Altered
3 plasma chloride and plasma glucose were strongly correlated with pH, consistent with the
4 laboratory findings of [Monette and McCormick \(2008\)](#) and others. High DOC
5 concentrations in streams could reduce the inorganic Al impact by enhancing
6 complexation with organic ligands.

7 Recently, gill Al and NKA activity were assessed in smolts migrating downstream in
8 New England ([Kelly et al., 2015](#)). Smolt immigrating from the Connecticut River, where
9 most tributaries were well buffered, had low levels of gill Al and high levels of NKA
10 activity. In the Merrimack River watershed, where most tributaries were characterized by
11 low pH and high inorganic Al concentrations, salmon smolt immigrating downstream
12 showed higher gill Al and lower gill NKA activity. Stocked salmon return rates were
13 lower in the Merrimack River watershed, and the authors suggested that episodic
14 acidification could be affecting salmon smolts in poorly buffered streams in New
15 England.

8.3.6.2. Fish and pH Thresholds

16 The detrimental effects on fish associated with pH are also closely tied to ANC, which is
17 strongly correlated with water pH and Al [[Appendix 8.3.6.4](#); ([Driscoll et al., 2001b](#))]. In
18 the 2008 ISA, pH effects on fish were well characterized. A pH range of 5.0 to 5.5 was
19 found to cause the absence of several fish species ([Haines and Baker, 1986](#)). Among
20 lakes with fish, there was an unambiguous relationship between the number of fish
21 species and lake pH, ranging from about one species per lake for lakes having pH less
22 than 4.5 to about six species per lake for lakes having pH higher than 6.5 ([Driscoll et al.,](#)
23 [2001b](#); [Baker et al., 1990b](#)). The observations from field studies of pH effects on fish
24 have been corroborated by bioassay data ([Figure 8-3](#)). Some species and lifestages
25 experienced significant mortality in bioassays at relatively high pH (e.g., pH 6.0–6.5 for
26 eggs and fry of striped bass and fathead minnow; [McCormick et al., 1989](#); [Buckler et al.,](#)
27 [1987](#)), whereas others were able to persist at quite low pH without adverse effects. Many
28 minnows and dace (Cyprinidae) are highly sensitive to acidity, but some common game
29 species such as brook trout, largemouth bass, and smallmouth bass are less sensitive
30 (threshold effects at pH <5.0 to near 5.5). In many Appalachian Mountain streams that
31 have been acidified by acidic deposition, brook trout is the last fish species to disappear;
32 it is generally lost at pH near 5.0 ([MacAvoy and Bulger, 1995](#)), which usually
33 corresponds in these streams with ANC near 0 µeq/L ([Sullivan et al., 2003](#)). While brook
34 trout and other fish species may be absent at pH <5.0, detrimental effects on population

1 size and density may occur at higher pH values ([Baker et al., 1990a](#); [Baker and Schofield,](#)
2 [1985](#)).

Notes: [Baker and Christensen \(1991\)](#) generally defined bioassay thresholds as statistically significant increases in mortality or by survival rates less than 50% of survival rates in control waters. For field surveys, values reported represent pH levels consistently associated with population absence or loss.

Source: [Fenn et al. \(2011b\)](#) based on [Baker and Christensen \(1991\)](#).

Figure 8-3 Critical aquatic pH ranges for fish species.

1 Studies in the Adirondack Mountains reviewed in the 2008 ISA demonstrated the effect
2 of acidification on fish species richness. Of the 53 fish species recorded in Adirondack
3 lakes, about half (26 species) were absent from lakes with pH below 6.0. Those
4 26 species included important recreational species plus ecologically important minnows
5 that serve as forage for sport fish ([Baker et al., 1990b](#)). There is often a positive
6 relationship between pH and number of fish species, at least for pH values between about
7 5.0 and 6.5, or ANC values between about 0 and 50 to 100 $\mu\text{eq/L}$ ([Cosby et al., 2006](#);
8 [Sullivan et al., 2006a](#); [Driscoll et al., 2003b](#); [Bulger et al., 1999](#)).

9 Since the 2008 review, additional pH thresholds have been published for fish species
10 ([Table 8-2](#)). A pH threshold of <5.9 was identified as potentially harmful to Atlantic
11 salmon smolts in eastern Maine ([Liebich et al., 2011](#)). [Kirby et al. \(2008\)](#) showed that
12 when streams in central Pennsylvania had pH below 5 because of their underlying
13 geology, brook trout were only present in 9 of 28 streams, whereas all streams that had
14 $\text{pH} \geq 6$ had brook trout. Overall, the available data suggested that the threshold for brook
15 trout mortality is at about $\text{pH} = 5.0$.

16 Despite recent reductions in acidic deposition in northern Europe, mobilized Al remains a
17 threat to brown trout that are native to many European fresh waters and stocked in many
18 U.S. waters. [Andrén and Rydin \(2012\)](#) identified a threshold for healthy brown trout
19 populations by exposing yearling trout to a pH and inorganic Al gradient in humic
20 streams in Scandinavia. Results suggested a threshold of less than 20 $\mu\text{g/L}$ (0.74 μM)
21 inorganic Al and pH higher than 5.0. Toxic effects beyond these thresholds included Al
22 accumulation on the gills, increased hemoglobin and plasma glucose, decreased plasma
23 chloride, and increased mortality.

24 Brown trout embryo and first-year juvenile survival in 12 streams in northern Sweden
25 were investigated by [Serrano et al. \(2008\)](#) during snowmelt using in situ bioassays. The
26 study streams had high DOC, which causes a pH decrease, but also protects fish against
27 Al toxicity. High juvenile brown trout mortality was documented during the spring flood,
28 in association with low pH. No significant effect of inorganic Al concentration on
29 juvenile or embryo mortality was observed, likely due to Al complexation by organic
30 acid anions. An empirical model developed to predict juvenile brown trout mortality in
31 high-DOC streams suggested a critical chemical threshold of pH in the range of 4.8–5.4.
32 High embryo and yolk sac fry survival was recorded, even at stream sites with pH as low
33 as 4.0. As expected, the observed pH threshold in DOC-rich water was lower than
34 previously observed thresholds for low-DOC freshwaters. First-year juveniles are likely
35 to be most sensitive to adverse effects of low pH in northern boreal stream ecosystems,
36 especially during snowmelt-driven episodic pH depressions.

Table 8-2 pH thresholds in fish published since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria.

Fish Species and Effects	Region	Potential Thresholds	Reference
Atlantic salmon smolts reduction of plasma ions	Eastern Maine	pH 5.9	Liebich et al. (2011)
Brook trout loss of whole-body Na	Great Smoky Mountains NP	pH 5.1	Neff et al. (2008)
Brook trout loss of whole-body Na of 10 to 20%	Great Smoky Mountains NP	pH 4.9 to 5.1	Neff et al. (2009)
Juvenile brown trout mortality in high DOC streams	Sweden	pH 4.8 to 5.4	Serrano et al. (2008)
Brown trout embryo and yolk sac fry survival during episodes in DOC-rich lakes	Sweden	pH 4.0	Serrano et al. (2008)
Toxicity to brown trout in humic streams	Northern Europe	pH 5.0; inorganic aluminum 20 µg/L	Andrén and Rydin (2012)
Response of Atlantic salmon to alarm cues after episodic exposure ^a	Canada	6.2	Leduc et al. (2009)
Interference of chemical alarm cues to assess predation risk in juvenile Atlantic salmon ^a	Canada	pH <6.6	Elvidge and Brown (2014)

DOC = dissolved organic carbon; Na = sodium; NP = national park.

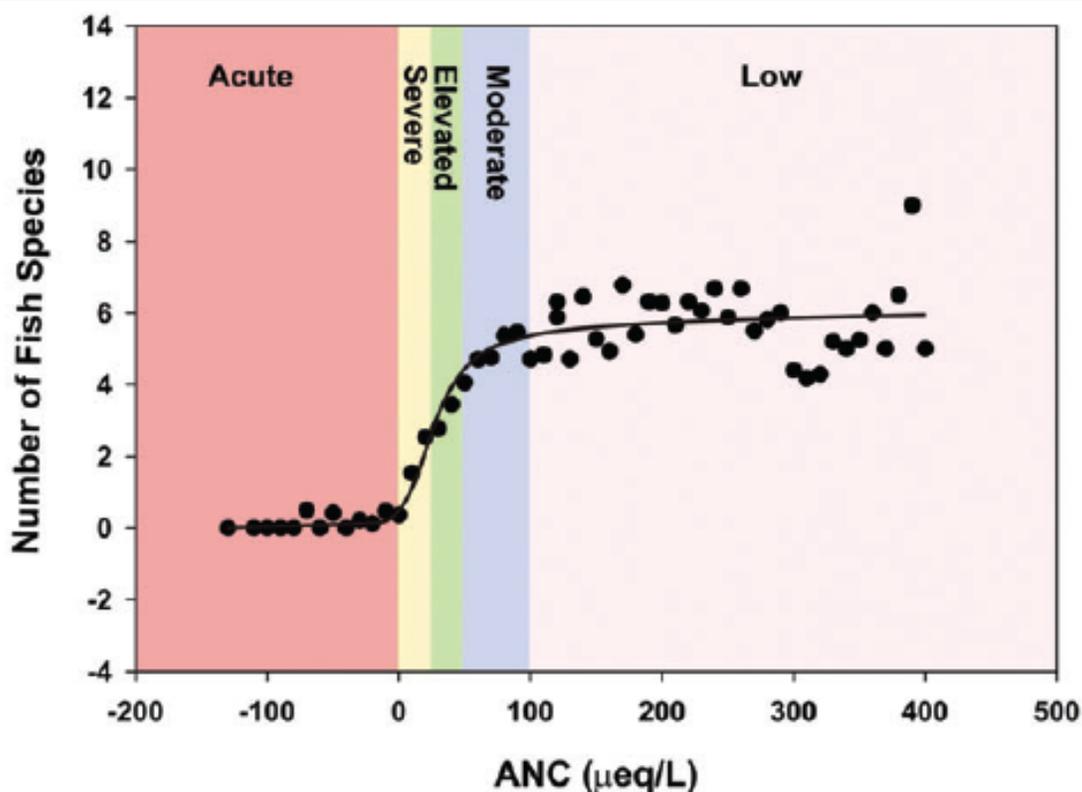

^aBehavioral responses of fish are discussed in [Appendix 8.3.6.5](#). Table B-23 and Table B-24 in the 2008 ISA summarize pH thresholds from the NAPAP report ([Baker et al., 1990a](#)).

8.3.6.3. Fish and Acid Neutralizing Capacity Thresholds

1 ANC has been found in various studies reviewed in the 2008 ISA to be a good single
2 indicator of the biological response and health of aquatic communities in acid-sensitive
3 systems ([U.S. EPA, 2008a](#); [Sullivan et al., 2006a](#)). For fish and other aquatic biota, ANC
4 is closely tied to pH ([Appendix 8.3.6.2](#)) and the bioavailability of Al [[Appendix 8.3.6.4](#);
5 ([Driscoll et al., 2001b](#))]. There is often a positive relationship between pH or ANC and
6 number of fish species, at least for pH values between about 5.0 and 6.5, or ANC values
7 between about 0 and 50 to 100 µeq/L ([Cosby et al., 2006](#); [Sullivan et al., 2006a](#); [Bulger et
8 al., 1999](#)). In Shenandoah National Park streams in Virginia, fish species richness was
9 lower by one species, on average, for every 21 µeq/L decrease in ANC ([Sullivan et al.,
10 2003](#); [Bulger et al., 1999](#)). Interpretation of species richness can be difficult, however,

1 because more species tend to occur in larger lakes and streams as compared with smaller
2 ones, irrespective of acidity (Sullivan et al., 2003). This might be due to increased aquatic
3 habitat complexity and diversity in larger watersheds (Sullivan et al., 2003).

4 As summarized in the 2008 ISA, lakes and streams having an annual average
5 ANC < 0 $\mu\text{eq/L}$ generally do not support fish (Figure 8-4). The analysis shown in this
6 figure suggests that there could be a loss of fish species with decreases in ANC below a
7 threshold of approximately 50 to 100 $\mu\text{eq/L}$ (Sullivan et al., 2006a).

ANC = acid neutralizing capacity; L = liter; μeq = microequivalent.

Notes: The data are presented as the mean (filled circles) of species richness within 10 $\mu\text{eq/L}$ ANC categories, based on data collected by the Adirondacks Lakes Survey Corporation.

Source: Modified from Sullivan et al. (2006a).

Figure 8-4 Number of fish species per lake verses acidity status, expressed as acid neutralizing capacity, for Adirondack lakes.

8 Various ecological effect criteria, including effects on fish communities, have been used
9 to classify ranges of ANC values (Table 8-3). The use of these criteria lies in the

1 association between ANC and the surface water constituents that directly affect
2 acidity-related stress. These include, in particular, pH, Ca²⁺, and inorganic Al
3 concentration. [Bulger et al. \(2000\)](#) developed ANC thresholds for brook trout response to
4 acidification in forested headwater catchments in western Virginia. Across the eastern
5 U.S., brook trout are often selected as a biological indicator of aquatic acidification
6 because they are native to many eastern surface waters and because residents place
7 substantial recreational and aesthetic value on this species. Note that because brook trout
8 are comparatively acid tolerant, adverse effects on many other fish species would be
9 expected at higher ANC than the threshold values that impact brook trout. Annual
10 average ANC greater than about 50 µeq/L is generally considered suitable for brook trout
11 in southeastern U.S. streams. Such streams have sufficient buffering capacity to prevent
12 acidification from eliminating this species, and there is reduced likelihood of lethal
13 storm-induced acidic episodes. In streams having ANC > 50 µeq/L, reproducing brook
14 trout populations are expected if the habitat is otherwise suitable ([Bulger et al., 2000](#)), but
15 some streams may periodically experience episodic chemistry that affects species more
16 sensitive than brook trout. Streams having annual average ANC from 20 to 50 µeq/L may
17 experience episodic acidification during storms to pH and ANC levels that can be lethal
18 to brook trout, as well as other fish ([Bulger et al., 2000](#)). Streams that are designated as
19 episodically acidic (chronic ANC from 0 to 20 µeq/L) are considered marginal for brook
20 trout because acidic episodes are likely ([Hyer et al., 1995](#)), although the frequency and
21 magnitude of episodes can vary widely. Streams that are chronically acidic (average
22 ANC less than 0 µeq/L) are not expected to support healthy brook trout populations
23 ([Bulger et al., 2000](#)).

24 [Hesthagen et al. \(2008\)](#) used a regional water chemistry database to determine critical
25 values of pH, ANC, and inorganic Al for survival of brown trout in 790 Norwegian lakes.
26 The threshold value (ANC_{limit}) to avoid fish damage was compared with that found in a
27 similar study conducted in 1986. In 1995, the threshold ANC value to avoid toxic effects
28 to fish and retain unaffected fish populations was 67 µeq/L, compared with 20 µeq/L in
29 1986. The higher ANC_{limit} found for 1995 was attributed to lower pH and higher
30 inorganic Al concentration at a given ANC value in 1995 than in 1986. This, in turn, was
31 attributed to increases in total organic carbon in these lakes. Thus, the value of ANC as
32 an indicator of biological effects may differ between acidification and recovery periods.

Table 8-3 Expected ecological effects and concern levels in freshwater ecosystems at various levels of acid neutralizing capacity.

Category Label	ANC Level $\mu\text{eq/L}$	Expected Ecological Effects
